Table of Contents

About this Collection – A Short Introduction to the Open MIND Project
Thomas Metzinger

General Introduction: What Does it Mean to Have an Open Mind?
Thomas Metzinger & Jennifer M. Windt

Target Papers, Commentaries, and Replies

- 1 Beyond Componential Constitution in the Brain: Starburst Amacrine Cells and Enabling Constraints**
Michael L. Anderson

Carving the Brain at its Joints - A Commentary on Michael L. Anderson
Axel Kohler

Functional Attributions and Functional Architecture - A Reply to Axel Kohler
Michael L. Anderson

- 2 What a Theory of Knowledge-How Should Explain – A Framework for Practical Knowledge beyond Intellectualism and Anti-Intellectualism**
Andreas Bartels & Mark May

The Semantic Reading of Propositionality and Its Relation to Cognitive-Representational Explanations - A Commentary on Andreas Bartels & Mark May
Ramiro Glauer

Preparing the Ground for an Empirical Theory of Knowing-How - A Reply to Ramiro Glauer
Andreas Bartels & Mark May

- 3 Introspective Insecurity**
Tim Bayne

“I just knew that!”: Intuitions as Scaffolded or Freestanding Judgements - A Commentary on Tim Bayne
Maximilian H. Engel

Introspection and Intuition - A Reply to Maximilian H. Engel
Tim Bayne

- 4 Meaning, Context, and Background**
Christian Beyer

Grasping Meaning - A Commentary on Christian Beyer
Anita Pacholik-Żuromska

Self-identification, Intersubjectivity, and the Background of Intentionality - A Reply to Anita Pacholik-Żuromska
Christian Beyer

- 5 The Puzzle of Perceptual Precision**
Ned Block

Phenomenal Precision and Some Possible Pitfalls - A Commentary on Ned Block
Sascha Benjamin Fink

Solely Generic Phenomenology – A Reply to Sascha Benjamin Fink
Ned Block

- 6 Rules: The Basis of Morality... ?**
Paul M. Churchland

Applied Metascience of Neuroethics - A Commentary on Paul M. Churchland
Hannes Boelsen

A Skeptical Note on Bibliometrics - A Reply to Hannes Boelsen
Paul M. Churchland

- 7 Embodied Prediction**
Andy Clark

Extending the Explanandum for Predictive Processing - A Commentary on Andy Clark
Michael Madary

Predicting Peace: The End of the Representation Wars - A Reply to Michael Madary
Andy Clark

8 Levels

Carl F. Craver

Mechanistic Emergence: Different Properties, Different Levels, Same Thing! A Commentary on Carl F. Craver
Denis C. Martin

Mechanisms and Emergence - A Reply to Denis C. Martin
Carl F. Craver

9 Mental States as Emergent Properties: From Walking to Consciousness

Holk Cruse & Malte Schilling

The “Bottom-Up” Approach to Mental Life - A Commentary on Holk Cruse & Malte Schilling
Aaron Gutknecht

The Bottom-Up Approach: Benefits and Limits - A Reply to Aaron Gutknecht
Holk Cruse & Malte Schilling

10 Why and How Does Consciousness Seem the Way it Seems?

Daniel C. Dennett

Qualia Explained Away - A Commentary on Daniel C. Dennett
David H. Baßler

How our Belief in Qualia Evolved, and Why We Care so much - A Reply to David H. Baßler
Daniel C. Dennett

11 The Heterogeneity of Experiential Imagination

Jérôme Dokic & Margherita Arcangeli

Imagination and Experience - A Commentary on Jérôme Dokic & Margherita Arcangeli
Anne-Sophie Brügger

The Importance of Being Neutral: More on the Phenomenology and Metaphysics of Imagination - A Reply to Anne-Sophie Brügger
Jérôme Dokic & Margherita Arcangeli

12 On the Eve of Artificial Minds

Chris Eliasmith

Future Games - A Commentary on Chris Eliasmith
Daniela Hill

Mind Games - A Reply to Daniela Hill
Chris Eliasmith

13 Can We Be Epigenetically Proactive?

Kathinka Evers

Should We Be Epigenetically Proactive? A Commentary on Kathinka Evers
Stephan Schleim

Understanding Epigenetic Proaction - A Reply to Stephan Schleim
Kathinka Evers

14 The Paradigmatic Body: Embodied Simulation, Intersubjectivity, the Bodily Self, and Language
Vittorio Gallese & Valentina Cuccio

Multisensory Spatial Mechanisms of the Bodily Self and Social Cognition - A Commentary on Vittorio Gallese & Valentina Cuccio
Christian Pfeiffer

Embodied Simulation: A Paradigm for the Constitution of Self and Others - A Reply to Christian Pfeiffer
Vittorio Gallese & Valentina Cuccio

15 All the Self We Need

Philip Gerrans

Memory for Prediction Error Minimization: From Depersonalization to the Delusion of Non-Existence - A Commentary on Philip Gerrans
Ying-Tung Lin

Metamisery and Bodily Inexistence - A Reply to Ying-Tung Lin
Philip Gerrans

16 Visual Adaptation to a Remapped Spectrum: Lessons for Enactive Theories of Color Perception and Constancy, the Effect of Color on Aesthetic Judgments, and the Memory Color Effect
Rick Grush, Liberty Jaswal, Justin Knoepfler & Amanda Brovold

What Can Sensorimotor Enactivism Learn from Studies on Phenomenal Adaptation in Atypical Perceptual Conditions? A Commentary on Rick Grush and Colleagues
Aleksandra Mroczko-Wąsowicz

Phenomenology, Methodology, and Advancing the Debate - A Reply to Aleksandra Mroczko-Wąsowicz
Rick Grush

17 An Information-Based Approach to Consciousness: Mental State Decoding
John-Dylan Haynes

What's up with Prefrontal Cortex? A Commentary on John-Dylan Haynes
Caspar M. Schwiedrzik

Can Synchronization Explain Representational Content? A Reply to Caspar M. Schwiedrzik
John-Dylan Haynes

18 Beyond Illusions: On the Limitations of Perceiving Relational Properties
Heiko Hecht

The Illusion of the Given and Its Role in Vision Research - A Commentary on Heiko Hecht
Axel Kohler

Manifest Illusions - A Reply to Axel Kohler
Heiko Hecht

19 The Neural Organ Explains the Mind
Jakob Hohwy

From Explanatory Ambition to Explanatory Power - A Commentary on Jakob Hohwy
Dominic L. Harkness

The Diversity of Bayesian Explanation - A Reply to Dominic L. Harkness
Jakob Hohwy

20 Millikan's Teleosemantics and Communicative Agency
Pierre Jacob

Communicative Agency and *ad hominem* Arguments in Social Epistemology - A Commentary on Pierre Jacob
Marius F. Jung

Assessing a Speaker's Reliability Falls Short of Providing an Argument - A Reply to Marius F. Jung
Pierre Jacob

21 Wild Systems Theory as a 21st Century Coherence Framework for Cognitive Science
J. Scott Jordan & Brian Day

Thickening Descriptions with Views from Pragmatism and Anthropology - A Commentary on J. Scott Jordan & Brian Day
Saskia K. Nagel

After Naturalism: Wild Systems Theory and the Turn To Holism - A Reply to Saskia K. Nagel
J. Scott Jordan & Brian Day

22 The Crack of Dawn: Perceptual Functions and Neural Mechanisms that Mark the Transition from Unconscious Processing to Conscious Vision
Victor Lamme

Consciousness as Inference in Time -

1 What is this?

This is an edited collection of 39 original papers and as many commentaries and replies. The target papers and replies were written by senior members of the MIND Group, while all commentaries were written by junior group members. All papers and commentaries have undergone a rigorous process of anonymous peer review, during which the junior members of the MIND Group acted as reviewers. The final versions of all the target articles, commentaries and replies have undergone additional editorial review.

Besides offering a cross-section of ongoing, cutting-edge research in philosophy and cognitive science, this collection is also intended to be a free electronic resource for teaching. It therefore also contains a selection of online supporting materials, pointers to video and audio files and to additional free material supplied by the 92 authors represented in this volume. We will add more multimedia material, a searchable literature database, and tools to work with the online version in the future. All contributions to this collection are strictly open access. They can be downloaded, printed, and reproduced by anyone.

2 What is the MIND Group?

The MIND Group is an independent, international body of early-stage researchers, which I founded in 2003. It is formed of young philosophers and scientists with a strong interest in questions concerning the mind, consciousness, and

cognition. They come from various disciplines such as philosophy, psychology, cognitive science, and neuroscience.

Over the past decade, the MIND Group has cooperated with a number of institutions, such as the Frankfurt Institute for Advanced Studies, the *Meditationszentrum Beatenberg*, the *Wissenschaftskolleg zu Berlin*, and the *ICI Kulturlabor Berlin*. I first founded the group at the *Johannes Gutenberg-Universität* in Mainz in 2003, but soon had to relocate it to Frankfurt am Main, where we meet twice a year. Meetings typically involve two or three public lectures at the *Johann Wolfgang Goethe-Universität*, delivered by highly prominent guests, most of whom are now authors of the target papers in this collection and senior members of the group. In addition, our invited speakers offer extended, closed workshops, where advanced students have the opportunity to give short mock-lectures in English.

This format was inspired by a question which kept confronting me in my teaching: namely why are there so many excellent, smart young philosophers in Germany, who nevertheless are—and often remain—almost completely invisible on the international stage? More than half a century after World War II, only three or four German universities rank among the top 100. The established philosophical community is still largely disconnected from many of the latest and most exciting developments in modern philosophy of mind. One result of my thinking about this

problem was that this lack of integration into the global research context was caused, in part, by the language barrier. The biggest psychological obstacles for many young German philosophers seem to be, quite simply, to prepare a talk in English; find the courage to travel to an international conference in another country; and actually present their work there. One of the things we practice at MIND Group meetings is to prepare them for this.

The MIND Group sees itself as part of a larger process of exploring and developing new formats for promoting junior researchers in philosophy of mind and cognitive science. One of the basic ideas behind the formation of the group was to create a platform for people with one systematic focus in philosophy (typically analytic philosophy of mind or ethics) and another in empirical research (typically cognitive science or neuroscience). One of our aims has been to build an evolving network of researchers. By incorporating most recent empirical findings as well as sophisticated conceptual work, we seek to integrate these different approaches in order to foster the development of more advanced theories of the mind. One major purpose of the group is to help bridge the gap between the sciences and the humanities. This not only includes going beyond old-school analytic philosophy or pure armchair phenomenology by cultivating a new, type of interdisciplinarity, which is “dyed-in-the-wool” in a positive sense. It also involves experimenting with new *formats* for doing research, for example, by participating in silent meditation retreats and trying to combine a systematic, formal practice of investigating the structure of our own minds from the first-person perspective with proper scientific meetings, during which we discuss third-person criteria for ascribing mental states to a given type of system.

In addition to bridging geographical and disciplinary gaps, the MIND Group also aims to bridge conventional gaps produced by institutionalized hierarchies in academia. If you will, this is simply the academic variant of the generation gap: Few things are more intimidating to young researchers than being confronted, at a conference, with criticism from a researcher who has long been one of their intellectual heroes, known

only from textbooks, university classes, and research articles. For this reason, the MIND Group meetings have provided a protected space for promoting supportive and collegial interactions between senior and junior group members. In particular, the meetings of the MIND Group have helped establish and cement collaborations both among junior members and between junior and senior members. In some cases this has led to research visits, joint research projects, or long-term mentoring relationships. One motivation for founding the group, after all, was to smooth the path from university studies to being a professional academic for advanced students and young researchers.

3 Why did we do this?

We wanted to make a contribution by offering a freely available resource to others. When we first started thinking about what to do for the 20th meeting of the MIND Group, we knew we wanted it to be something special, some way of sharing with the interested academic public some of the expertise and collegial atmosphere we had built up over more than 10 years of working together. Initially we considered inviting everyone to a big four-day conference at an attractive location. But then we decided that we would do something more substantial and innovative - rather than creating a transient event and an enormous CO₂ footprint. We wanted to create a resource of lasting value that will subsist for years to come, and most importantly something that really is accessible for everybody—not only for people in affluent parts of the world, like ourselves. There seemed no better way to do this than by providing a large, open-access collected edition showcasing the work of our senior and junior members.

It quickly became clear that because of the scope of the project, and also because we had specific ideas about how it should be realized, this was going to be an experiment in autonomous open-access publishing. The MIND Group is an independent body, and apart from evening lectures by our invited speakers, its meetings are not open to the public. One goal of the Open MIND project was to first publish our scientific work without the support of a publisher, who would

eventually sell our own intellectual property back to us and our peers and simultaneously make it inaccessible to students in Brazil, India or China by locking it behind a paywall. We wanted to see if we could successfully establish a professional form of quality control via a systematic, journal-independent peer review process—and also if we could make it happen faster than existing and established institutions of academic publishing. We gave authors a deadline of 1st March 2014, and planned to publish the entire collection (including commentaries and replies) on January 15th 2015. We knew that these two pillars—speed and quality control—would be crucial to the success of the project. Academics are sometimes reluctant to publish their work in edited collections that often only appear years after the manuscripts have been submitted. We suspected that we would only succeed in obtaining state-of-the-art research papers if we could guarantee that the research discussed within them would not be out-of-date by the time the collection went online.

This publication format is also novel in another sense. Because a selected subset of junior group members acted as reviewers and commentators, the whole publication project is *itself* an attempt to develop a new format for promoting junior researchers, for developing their academic skills, and for creating a new type of interaction between senior and junior group members. Many of the reviewers and commentators in this edited volume have never actively participated in any scientific review process before, and, for many their commentary is their first ever publication. Throughout the project, all junior members were able to play different roles: they acted as reviewers, trying to improve and constructively criticize the target articles submitted by senior group members and commentaries submitted by their peers. Sometimes, reviewers were asked to go back and revise their reviews—and sometimes their reviews also led to the rejection of target papers altogether. They also acted as authors; and because their commentaries also went through a review process, they got to experience the review process from the other side as well.

This collection, therefore, is the result of a three-layered interaction between junior and senior members: personal (through meetings), ed-

itorial (through implementing a common publication project), and philosophical and scientific (through writing commentaries and replies). Throughout this process, we were often surprised and impressed by the results—and we hope that you will be, too.

4 Who did this?

Many people have made this contribution possible and many hours of unpaid work have gone into it. [Here](#) are the most important supporters.

4.1 The editors

As founder and director of the MIND group, I consider myself to be neither a junior nor a senior member. Therefore, I have not contributed a target paper or a commentary. If anything, my contribution lies in the choice and selection of authors and in the work, together with my collaborator Jennifer Windt, of bringing this project to completion.

4.2 Financial funding

All in all it has cost about € 241.000, to realize this project. First and foremost, the [Barbara Wengeler-Stiftung](#) needs to be mentioned: not only has it supported the current project with € 80,000, but over the years it has enabled the MIND Group to stay independent, and to realize a long series of fruitful meetings, during times when it was difficult to get support elsewhere. It has also supported some members by providing PhD and travel grants and by offering the annual € 10,000 *Barbara Wengeler-Prize*, awarded at our meetings in Frankfurt. The [Gutenberg Research College](#) and the [Volkswagen-Stiftung](#) have generously supported the project by providing two editorial staff positions for David Baßler, Daniela Hill, and Dr. Ying-Tung Lin, and by awarding a five-year Research Fellowship, beginning in April 2014, to me, Thomas Metzinger. This work was also partly supported by the European FP7 collaborative project [VERE](#) (contract no. 257695).

1 Instead of an introduction

In our discussions leading up to the Open MIND collection's going online, we thought long and hard about how exactly to showcase the vast material in this collection and the ideas and motivations behind the project in our editors' introduction. We first thought about using the introduction to briefly summarize the take-home message of every single target article, commentary, and reply, as is customary in introductions to edited collections. This struck us, however, as being both unwieldy and redundant: it would have entailed summarizing and commenting on a total of 117 texts. More importantly, due to the online format of the collection (including in-text search functions) and the inclusion of abstracts and keywords in the papers themselves, the authors have already provided concise introductions to their own texts. Retracing their steps in an editorial introduction would not have added anything to the value and usability of the collection.

We then considered using the introduction to create our own personal best-of-Open-MIND list, discussing what we take to be the most valuable insights in every single article, or perhaps even focusing on the contributions that we personally take to be the most theoretically important. Though our own list of personal favor-

ites seemed to write itself naturally during the editing process, this strategy quickly struck us as being at odds with our motivation for creating the collection in the first place. Using the editors' introduction to create a personal best-of list would have been highly selective and biased by our own personal research interests and styles in a way that we felt would have contradicted our own ideal of open mindedness. In fact, for this reason, we decided to omit any references to the contributions to Open MIND in this introduction.

These considerations naturally gave rise to a more difficult and more profound question: What exactly do we mean by "open mindedness," not just in general, but in the context of interdisciplinary research on the mind? The strategy of using the contributions to the Open MIND collection as a foil for this more general academic variant of open mindedness was tempting. But again, we quickly realized that this approach would strike many readers (as well as, perhaps, some of our own authors) as highly idiosyncratic, arbitrary, or self-important.¹

¹ This is not, of course, to deny that we take "Open MINDedness" (as broadly practiced in the context of this collection) to be an example of "open mindedness" as a more general epistemic stance. And we are certainly proud enough of what we like to think of as our little star-collection to allow ourselves at least a few words on why we think this

So we decided to use our editors' introduction to briefly address a difficult, somewhat deeper, and in some ways more classical problem: that of what *genuine* open mindedness really is and how it can contribute to the Mind Sciences. The material in the collection speaks for itself. Here, and in contrast to the vast collection that is Open MIND, we want to be concise. We want to point to the broader context of a particular way of thinking about the mind. And we want to propose an account of what open mindedness could mean in the context of the contemporary, interdisciplinary Mind Sciences. This variant of open mindedness is characterized by epistemic humility, intellectual honesty, and a new culture of charity. It also has a pragmatic dimension: open mindedness of this kind is research generating and fosters an environment of sincere and constructive interdisciplinary collaboration. And it is profoundly inspired by the classical ideals of philosophy as a pursuit of genuine insight and rational inquiry, the importance of a critical and in a certain sense non-judgmental attitude, and the deep relationship between wisdom and skepticism as an epistemic practice. Finally, and again very classically, open mindedness has an ethical dimension

is the case. To begin with, many of the papers published here explore new ways of thinking, in the broadest sense, about the mind and new and innovative ways of driving research forward. In addition and perhaps most importantly, our choice of the title Open MIND reflects the idea that by introducing a two-way interaction between senior target authors and junior commentators through the review process, the commentaries and replies, we wanted to give our commentators the opportunity to enter into a discussion with more senior and prominent representatives of the field. Relatedly, the availability of the online version of the Open MIND collection to students and researchers from anywhere in the world, free of charge exemplifies theoretical and practical dimensions of what we consider to be academic open mindedness. And finally, on many levels, Open MIND was an exercise in editorial open mindedness. The authors and commentators asked to contribute to this collection were explicitly encouraged to discuss any topic they themselves thought relevant. The only restriction was that the target articles fall within the scope of the Mind Sciences. We also tried to foster a particular type of intellectual atmosphere by encouraging authors, commentators, and reviewers to be consistently constructive and charitable. Our hope was that this approach would bring out the best in our contributors in the different stages of the project. In many cases, we explicitly encouraged our authors to write in a way that would be accessible to readers from different academic backgrounds and to take different disciplinary perspectives into account. Generally, the publication of academic articles always involves a process of give and take between authors, editors, and reviewers. And we strongly felt that it would be a good indicator of the success of our collection if, at the end of the day, our authors were themselves happy and proud of their contributions. This entailed carefully calibrating our own roles as editors and in many cases leaving the final decision to our authors.

sion as well: it implies sensitivity to normative issues, including issues of an anthropological, sociocultural, and political kind. By bringing these different strands of ideas together and creating a bigger (and admittedly still sketchy) picture of what "open mindedness" might mean in the interdisciplinary Mind Sciences, we hope to start a conversation about how an open-minded attitude and a charitable culture of collaboration can be cultivated in the future. This is very much intended as an invitation to further think about and develop this topic. We hope our readers will join us in this endeavor.

2 Open mindedness as an epistemic stance

Open mindedness is not a theoretical position, but an epistemic practice. Clearly, there are many different kinds of open mindedness, and the precise way of characterizing the relevant kind will depend on the subject matter in question, or, more simply, on what it is that one is open minded about. As a first pass at a definition, we might say that open mindedness, in its most general sense, is characterized by epistemic humility and adherence to a general ideal of intellectual honesty. This is true for open mindedness in general, but also for the specific variants we are interested in here, namely open mindedness in academic research, including interdisciplinary scientific discourse on the mind.

Whatever else it may be, open mindedness is also an *attitude* that is now shared by a growing number of researchers in philosophy of mind, cognitive science, neuroscience, and artificial intelligence (AI). We are all interested in the deep structure of the human mind and of conscious experience, but we also recognize how far away we still are from a unified theoretical model that could satisfy philosophers and scientists alike, a model that is conceptually convincing, able to integrate all existing data and make use of different methods at the same time. We do not want to fool ourselves. Although great progress has been made during the last five decades, it is not at all clear which combination of methods and which type of theoretical approach will generate the final breakthrough

or even facilitate epistemic progress. We, meaning researchers of different stripes and from different disciplines comprising the Mind Sciences, including the authors contributing to this collection, are all in the same boat: we share a common epistemic goal, and we find ourselves working in a period of major historical transition. Progress in the empirical sciences of the human mind is certainly impressive and continuously gaining momentum, generating large amounts of new and sometimes surprising data. At the same time, exciting new approaches in formal modeling and philosophical meta-theory are increasingly opening up new perspectives. Yet it is not at all clear that we are already asking the right kinds of questions or exactly which combination of conceptual and empirical tools will do the trick. Seeing this fact clearly has already begun to change our attitude. Researchers from different disciplines are listening and talking to each other in new ways. Developing new forms of inter- (and intra-)disciplinary collaboration is an integral part of this process. “Having an open mind” also refers to a kind of scientific practice that involves honestly listening to representatives of exactly those approaches and academic disciplines that you may not have expected to make a contribution.

At the same time, open mindedness, understood as a fruitful and research-generating epistemic practice, should be clearly distinguished from arbitrariness, indecisiveness, lack of specificity, and, especially in the context of philosophy, lack of conceptual precision. Open mindedness is not just any kind of openness, and it is different from simply being non-committal or hedging. The challenge is to develop an understanding of open mindedness that is guided by theoretical considerations and empirical research findings alike. Ideally, this account should suggest specific strategies for cultivating forms of sincere interdisciplinary collaboration, sharpening the underlying conceptual issues, and developing precise predictions for future research. Open mindedness of this epistemically fruitful type will often be more about asking better questions than about committing to specific answers. It will involve an attitude of willingness to question or even reject one's own

prior commitments. It will be inherently critical (cf. [Lambie 2014](#)). And it will, perhaps, have more to do with striving for genuine understanding than with the search for truth and knowledge ([Taylor 2014](#)). One core idea of the great philosopher of science [Karl Popper](#), which is now reappearing in the latest mathematical theories of brain functioning, was that we are always in contact with reality at exactly the moment at which we falsify a hypothesis: the moment of failure is exactly the moment at which we touch the world.² Similarly, the best scientific theories will be those that most easily lend themselves to falsification. For this reason, open mindedness involves, among other things, endorsing very specific theoretical positions purely for the sake of epistemic progress, rather than for the sake of being right, advancing one's career, publishing in high-impact journals, and so on. Open mindedness is not so much about the specific content of a belief, be it personal or theoretical, but about the way in which it is held.

Searching for the right kinds of questions without considering the specific answers they are likely to generate or their immediate practical implications is a good first-order approximation to the specific type of attitude we are trying to describe. Another is to consider it as an interdisciplinary variant of the principle of charity. Our point is not just that philosophers should be empirically informed or that neuroscientists should listen carefully to constructive attempts at conceptual or methodological clarification. We need to develop a new culture of scientific investigation, and this will require new and sustainable forms of interdisciplinary collaboration. In philosophy, the “principle of charity” has long been recognized and pursued in the form of reading others' statements according to the best, strongest possible interpretation

² Here is what he said about the fundamental principle of any ideological form of rationalism turned *weltanschauung*: “Uncritical or comprehensive rationalism can be described as the attitude of the person who says ‘I am not prepared to accept anything that cannot be defended by means of argument or experience’. [...] Now it is easy to see that this principle of an uncritical rationalism is inconsistent; for since it cannot, in its turn, be supported by argument or by experience, it implies that it should itself be discarded” (cited from [Popper 2013](#), p. 435; originally in [Popper & Kieseewetter 1945/2003](#); see [Metzinger 2013c](#) for a popular discussion).

—that is, to never attribute irrationality, falsehoods, or fallacies to another if alternative and more charitable readings exist. But we also all know how hard this can be. Still, the point is to not gratuitously maximize disagreement with the aim of showcasing the novelty or importance of one's own arguments. Agreement should be optimized and as each other's interpreters, we should always, whenever possible, prefer the most coherent reading in order to maximize the truth or rationality of what another philosopher says. We now need an interdisciplinary variant of this principle, and not only in bridging the gap between the humanities and the so-called hard sciences of the mind, but also in organizing novel and more efficient forms of cooperation. This point applies not only to the relationship between disciplines, but also to that between different generations of researchers. An optimization problem has to be solved: What is the best way of pooling intellectual resources and of efficiently structuring research? Therefore, a second step toward approximating an undogmatic attitude of open mindedness is to characterize it as an openness to the possibility that, for mind and consciousness, there may be no such thing as a single leading or dominating discipline, no *Leitwissenschaft*, as we say in German. Rather, not only does the connectivity between already-existing research programs have to be strengthened, the overall pattern of scientific practice also requires a new internal structure. What is needed is a new and as we will argue genuinely philosophical way of thinking.

A genuine receptiveness to unexpected ideas and different disciplinary perspectives also presupposes a certain set of abilities and different types of epistemic virtues. Some of these may lie in the field of what is commonly, if somewhat vaguely, called “first-person methods”, for instance in the systematic cultivation of contemplative practice (i.e., the philosophically motivated development of *non-cognitive* and *non-intellectual* epistemic abilities). Another is tolerance of ambiguity: to not only tolerate transient cognitive, conceptual and theoretical inconsistencies between disciplines or generations, but to view certain kinds of ambiguity

as actually desirable, as a source of progress. Again, the challenge will be to distinguish productive types of ambiguity from those that are overly cautious or vague, hampering real progress. The same is true, of course, within academic disciplines themselves. Academic disciplines are not natural kinds. Contrary to what some might think, there may be no single authoritative or right way of doing philosophy, and there may be no clean way to distinguish philosophy from the empirical sciences. Open mindedness of the constructive kind will not waste time worrying too much about disciplinary demarcation criteria or labels, but will be open to different methods and approaches both between and within individual disciplines. Put differently, it may turn out to be less important whether a given question or position is philosophical (in the sense of being of a purely conceptual nature) or empirical than whether it genuinely helps advance the overall debate. Open mindedness clearly also has an inherently pragmatic dimension. When this kind of tolerance of ambiguity, for instance towards disciplinary borders, but also towards different (and ideally complementary) research methods is paired with conceptual clarity and precision, it becomes a driving force for research. This balancing act is what academic open mindedness is all about.

3 Open mindedness and the phenomenology of (un)certainty

Having an open mind involves, among other things, a specific way of being noncommittal with respect to the truth of a theoretical claim or proposition. As pointed out earlier, this is not the same as hedging: one can investigate and even defend the truth of a proposition or the adequacy of a given theoretical-conceptual or empirical model while at the same time acknowledging that it might be false. This continued openness to the falsifiability of scientific hypotheses, often associated with attempts to bring about specific ways of establishing and testing their falsity, is commonly regarded as a marker of good scientific practice. It is also the core of intellectual honesty. As [Russell](#) tells us,

“intellectual integrity [is] the habit of deciding vexed questions in accordance with the evidence, or of leaving them undecided where the evidence is inconclusive” (2009, p. 579). The moment at which we give up this openness is the moment at which we lapse into dogmatism. The real danger, says Russell, is never the content of a doctrine, be it religious or political, but always “the way in which the doctrine is held” (Russell 2009, p. 582). Of course, this intrinsic connection between wisdom and not-knowing has long been recognized (Ryan 2014). In the *Gorgias*, Socrates explicitly claims that he is happy to be refuted if he is wrong. In fact, he claims he would rather be refuted than to refute someone else because it is better to be delivered from harm oneself than to deliver someone else from harm. And in the *Apology* (21d), after being accused of blasphemy and of corrupting the youths of Athens, Socrates famously states, before the tribunal of 501 Athenians, “I neither know nor think that I know”. Both in Western and in Eastern philosophy, the acknowledgment of not-knowing has long been regarded as an antidote to epistemic harm.

This is not the place to enter into a discussion of open mindedness in the context of the philosophy of science or to trace the history of philosophical theorizing about the concept of “wisdom”. We do, however, want to draw attention an important point: open mindedness as an epistemic practice involves a specific kind of mental attitude and is closely related to certain kinds of phenomenal states. Cultivating the relevant kinds of conscious states and epistemic attitudes makes a real difference, or so we suspect, by facilitating the development of a research climate that is conducive to constructive and genuinely fruitful discourse and new forms of collaboration. This is an empirical prediction, and it could turn out to be false. For now, our claim is that the kind of open mindedness we describe here is needed if we are even to begin investigating the truth of this prediction. If, at the end of the day, this strategy should fail — that is, if there turn out to be good empirical reasons for rejecting the claim that there actually are specific phenomenological profiles and mental attitudes that decisively facilitate pro-

gress in interdisciplinary research on the mind—this would be a valuable insight. But this insight about the value of open mindedness in scientific discourse itself depends on an initial willingness to cultivate exactly the kind of epistemic practice in question.

If this is right, there is another reason to be interested in open mindedness in the present context. This is that open mindedness, as an epistemic practice and mental attitude, is itself a potential target for interdisciplinary consciousness research. Philosophy of mind in particular can contribute by laying the theoretical–conceptual groundwork for the further empirical investigation of open mindedness in academic life and proposing points of contact with psychology and cognitive neuroscience. To make this inner connection more clearly visible, we will now briefly sketch the outlines of such an account.

Where might one begin investigating open mindedness as a mental state? At the outset, it stands to reason that the relevant form of open mindedness has precursors in the history of philosophy and might also be interestingly related to current debates on philosophical methodology. After all, the principles of epistemic humility, intellectual honesty, charitability, and searching for more accurate questions while cultivating a productive form of tolerance of ambiguity are deeply rooted in the history of philosophy. On a systematic and more general level, one would expect philosophy, as the discipline traditionally most concerned with the status of knowledge and truth and the practice of inquiry itself, to be able contribute to an analysis of what open mindedness really is. Based on these considerations, four questions seem particularly relevant: one, what is the relationship between open mindedness, intuitions, and philosophical methodology? Two, what is the relationship between open mindedness and the tradition of philosophical skepticism? Three, what would answers to the first two questions tell us about the relationship between open mindedness and the allegedly most pressing problem for interdisciplinary consciousness research, the subjectivity of phenomenal mental states? Might we even use the analysis of open mindedness to formu-

late principles for the investigation of phenomenal states and the status of first-person data? And four, how is open mindedness as an epistemic stance related to ethical and practical questions? For instance, how can the analysis of open mindedness contribute to normative issues related to neurotechnological interventions in the human brain? And does it lead to any specific suggestions on how to cultivate new forms of interdisciplinarity?

3.1 Intuitions and the phenomenology of certainty

The concept of intuition has a long philosophical history and is also firmly rooted in everyday language and folk psychology.³ Intuition, in everyday language, refers to immediate and direct insight, independent of reflection, to instinctively grasping or sensing a matter of fact. In the history of philosophy, the concept of intuition often has dual epistemic and experiential readings, and this is true for the traditions of rationalism and empiricism alike. In the *Rules for the Direction of the Mind* (Rule 3), Descartes describes intuitions as an immediate, effortless, and indubitable kind of seeing with the mind, which is even more reliable than deduction. In his *Essay Concerning Human Understanding* (IV.II.I), Locke tells us that intuition involves a direct perception of ideas that is, once more, the basis of all forms of knowledge. The close relationship between intuitions and sensory perception, and especially seeing, is already evident in the Latin verb *intueri*, which means to look and observe, but also to examine or consider. The central underlying element is the immediacy and directness of perception, which is imported into the concept of intuition via an implicit analogy between the phenomenology of sensory perception and genuine insight in an epistemic sense.

The epistemic status of intuitions, as well as different ways of defining the concept of intuition, are a matter of controversy in the current debate on philosophical methodology. The debate on intuitions stands at the center of the

confrontation between classical and allegedly intuition-based conceptual analysis conducted in the proverbial philosophical armchair (for critical discussion, see Cappelen 2012) and recent claims from experimental philosophy. Experimental philosophy typically involves collecting laypersons' responses to vignettes inspired by well-known philosophical thought experiments (for discussion, see Knobe & Nichols 2008; Alexander 2012; for a general introduction to intuitions in philosophy, see Pust 2014). These questionnaires are supposed to offer a new, empirically-based method for investigating intuitions and the underlying cognitive mechanisms. According to some experimental philosophers (for discussion and further references, see Alexander & Weinberg 2007), the results of these types of studies cast doubt on the reliability of intuitions as a mark of philosophical expertise. Intuitions, in this view, are simply too variable and context-dependent to count as insights in any deep, epistemologically interesting sense.

Here, we would like to propose a definition of intuitions that is compatible with the historical literature as well as being phenomenologically and empirically plausible. Departing from our brief remarks on the history of intuitions in philosophy, we suggest that intuitions are the “phenomenal signature of knowing”, a seemingly direct and effortless way of perceiving or seeing with one's mind arising independently of a prior process of reflection. The analogy between intuiting and perceiving provides an entry point for a naturalized concept of intuition. But it also suggests a potentially dangerous equivocation between phenomenological and epistemological readings of the concept of intuition. If the phenomenology of intuiting is indeed similar to that of perceiving in virtue of its effortless and seemingly direct experiential quality, then this immediately poses the problem that the phenomenology of intuiting and perceiving can be deceptive: what seems, subjectively, to be a case of veridical perception can always turn out to be a hallucination or an illusion (for an introduction to the problem of perception, see Crane 2014), or a nocturnal dream (see Windt & Metzinger 2007; Metzinger 2013a; Windt 2015). Similarly, what seems to bear the

³ This section draws on arguments first presented in Metzinger & Windt (2014).

marks of genuine insight can always turn out to be an epistemic illusion.⁴

If intuitions are indeed mental states characterized by a specific phenomenology, this suggests that the attempt to simultaneously characterize them both as involving genuine insight and as the basis of knowledge rests on what elsewhere we call the “*E-error*”: a category mistake in which epistemic properties are ascribed to something that does not intrinsically possess them (Metzinger & Windt 2014, p. 287). If our account of intuitions is on the right track, then intuitions are potentially dangerous, because in virtue of their phenomenology and their possessing an occurrent conscious character of “insight”, they predispose us to believe certain propositions merely on the basis of seemingly “understanding” them. The phenomenology of intuitions is such that it immediately and effortlessly creates a bias towards accepting the truth of propositions that, subjectively, we simply *know* or feel to be true, while simultaneously preventing us from seeking further justification, because these truths also seem unconstructed, indubitable, and self-evident. In this view, one of the factors underlying intuitions and intuitive

plausibility is that, because of their phenomenal character, they prevent open-minded inquiry. Intuitions turn us into inner dogmatists. And this is true not only for individual propositions held to be intuitively true, but also for continued adherence to theoretical claims about the status of intuitions as a guide to or even as the basis of knowledge and genuine insight. The phenomenal character of intuitions even predisposes us towards certain meta-theoretical intuitions about the general epistemic status of intuitions, and we can see the marks of this throughout the history of philosophy as well as in contemporary debate (e.g., Bealer 1998; Chudnoff 2013). The analysis of intuition clearly should not itself be driven by intuitions. Instead, this is a prime example of where an open mind is needed.

Our own account starts out from the assumption that intuitions are a specific class of phenomenal states. Human beings can direct their introspective attention toward the content of the relevant states and, at least partly and under certain conditions, report on it. Many higher animals very likely also possess intuitions even if they are not able to directly attend to or verbally report on their intentional contents. Before the evolution of biological nervous systems and before the emergence of phenomenal consciousness, no intuitions existed on our planet. Patients in coma or human beings in unconscious, dreamless sleep have no intuitions in the sense intended here. At the same time, intuitions probably have a long evolutionary history: there must have been a point in time at which the first intuition appeared in the mind of some conscious organism and this specific type of inner state then propagated itself across thousands of generations while its functional profile became ever more differentiated. Plausibly, one could describe the having of intuitions as an *ability*—a mental ability that was adaptive and that was acquired gradually.

If one takes the phenomenal character of intuitions seriously, this ability clearly seems to be an epistemic ability: *prima facie*, to have an intuition means to have the subjective experience of knowing something, directly and immediately, without necessarily being able to ex-

⁴ For a striking case study of two patients who experienced strong feelings of subjective certainty, including religious beliefs, during epileptic seizures, see Picard (2013). These cases are particularly interesting as these beliefs seemed entirely convincing during the seizures, even though they contradicted the patients’ longstanding convictions. It is interesting to see the connection to what earlier, we called the “ability to tolerate ambiguity”: While conceptually, “certainty” involves “knowing that one knows” (or *maximal epistemic precision*), on a purely formal level describing the underlying brain dynamics, epistemic precision is the inverse of variability, or the “confidence” the system places in a source of sensory information about the external world (Picard & Friston 2014). Empirical research suggests that it is the functional role of the anterior insula to signal uncertainty, the fact “that there is something we do not understand” (Picard 2013, p. 2497). The representation of uncertainty and ambiguity, in turn, causes an aversive affective state, often involving feelings of discomfort and anxiety of the type we continuously try to minimize. By contrast, direct electrical stimulation of a small area in the anterior-dorsal insula causes intense feelings of bliss (Picard et al. 2013), and it has been suggested that such blissful states, if occurring in the context of epileptic seizures, are associated with maximized coherence of the phenomenal self-model (PSM; Metzinger 2003). Subjectively, this coherence is expressed by a dramatically heightened sense of self, by an intense phenomenal experience of presence, integratedness, harmony with the world, plus intense positive affect (for five case reports, see Picard & Craig 2009). For human beings, ambiguity is not easy to tolerate, because it presents a constant threat to the coherence of our PSM, and cultivating such tolerance requires developing the functional ability to de-identify from the aversive affective states and the “epistemic anxiety” that automatically accompanies them. Tolerance of ambiguity, it seems, demands courage and a specific form of choiceless awareness.

press this knowledge linguistically or to provide an epistemic justification. Typically, inner experience seems to present knowledge to the subject of experience, even if one does not know *how* and *why* one possesses this knowledge. Intuitions are the phenomenal signature of knowing, a seemingly direct form of “seeing” the truth. As soon as we ascribe epistemic status to intuitions on the basis of their phenomenology alone, however, we commit the E-error. “Epistemicity”, the phenomenal quality of “insight” and “comprehension”, or the feeling of being a knowing self, as such is only a phenomenal quality, just as redness, greenness, and sweetness are. One well-known philosophical problem is that the phenomenological and epistemological readings can always come apart, because what phenomenologically appears as a kind of perception could really be a hallucination or an illusion. Subjectively indistinguishable mental states do not necessarily have the same epistemic status. Trivially, the difference between veridical perception and hallucination (in the philosophical sense; see [Macpherson 2013](#); [Crane 2014](#)) is not available on the level of subjective experience itself, and therefore the confusion between phenomenal character and epistemic content is naturally grounded in the transparent phenomenology, the seeming directness and immediacy of the relevant kinds of phenomenal states. The same is true for the phenomenology of intuition. Conflating epistemic status and phenomenal character becomes particularly dangerous if it is imported into theoretical debates, and if the phenomenal quality in question is that of “epistemicity”, of direct and non-inferential knowing itself. The important lesson is that *as* phenomenal states, such states are neither necessarily veridical nor necessarily non-veridical. Experience as such is not knowledge. *As* subjective experiences, these states possess no intentional properties and cannot be semantically evaluated by concepts like “truth” or “reference”. Phenomenal transparency is not epistemic transparency.

Many, but not all, of our philosophically relevant intuitions are characterized by an additional element of *certainty*, of *just knowing* that one knows. Here, the phenomenal signature of

knowing does not only refer to the content of what is seemingly known in a direct, and non-inferential manner, but to our higher-order, subjectively-experienced knowledge itself. This means that the phenomenal character of “epistemicity” that accompanies and tags the respective mental content as an instance of knowing has itself become transparent. Its representational character is not introspectively available anymore: the fact that epistemicity is itself the content of a non-conceptual mental representation, that it is internally constructed and always contains the possibility of misrepresentation, is veiled by an experience of immediacy. Transparency is a special form of darkness. Something constructed is experienced as a *datum*, as something given. Therefore, in stable intuition states we not only experience the first-order content as directly given, but the epistemicity of the state itself. Let us call such states *intuitions of certainty*. Referring to [G. E. Moore](#)⁵ one might say that the phenomenal signature of knowing has itself become diaphanous or transparent: according to my own subjective experience, I simply *know* that I know, and the possibility of error and falsehood is not given on the level of conscious experience itself. From the fact that a conscious perception instantiates the phenomenal quality of “greenness” it does not follow that the underlying process or even the perceptual object are green. The same is true for the “phenomenal signature of knowing” that characterizes intuitions.

Intuitiveness is a property of theoretical claims or arguments, relative to a class of representational systems exhibiting a specific functional architecture. Conscious human beings are one example of such a class. The brains of human beings are naturally evolved information-processing systems, and when engaging in explicit, high-level cognition they use specific representational formats and employ characteristic

5 In *The Refutation of Idealism*, [G. E. Moore](#) wrote: “The term ‘blue’ is easy enough to distinguish, but the other element which I have called ‘consciousness’—that which a sensation of blue has in common with a sensation of green—is extremely difficult to fix. [...] And in general, that which makes the sensation of blue a mental fact seems to escape us; it seems, if I may use a metaphor, to be transparent—we look through it and see nothing but the blue; we may be convinced that there is something, but what it is no philosopher, I think, has yet clearly recognized” (1903, p. 446).

styles of processing. Whenever we try to comprehend a certain theory, an argument or a specific philosophical claim, our brains construct an internal model of this theory, argument, or claim (Johnson-Laird 1983, 2008; Knauff 2009). This mostly automatic process of constructing mental models of theories possesses a phenomenology of its own: some theories just “feel right” because they elicit subtle visceral and emotional responses, some claims “come easily”, they are experienced as sound and healthy, and some arguments (including the implicit assumptions upon which they rely) seem “just plain natural”. Some forms of skepticism appear “healthy” to us, while others do not—there seems to be a deep connection between sanity and reason.

There may be two overarching reasons for this well-known fact. First, theories that are intuitively plausible exhibit a high degree of “goodness of fit” in regard to our network of explicit prior convictions. More generally, they optimally satisfy the constraints provided by our conscious and unconscious models of reality as a whole. These microfunctional constraints implicitly represent both the totality of the knowledge we have acquired during our lifetime and certain assumptions about the deep causal structure of the world that proved functionally adequate for our biological ancestors. Theories that immediately feel good because they are characterized by a high degree of intuitiveness maximize a specific kind of internal harmony. What we introspectively detect is a high degree of consistency, but in a non-linguistic, subsymbolic medium. Therefore we could also replace the term “intuitiveness” with a notion like “intuitive soundness” or “introspectively detected consistency or goodness of fit” (relative to a preexisting model of reality). In principle it should be possible to spell out this point on a mathematical level, by describing the underlying neural computations and their properties in a connectionist framework, or by utilizing the conceptual tools provided by dynamical systems theory or predictive coding.

A second perspective might be to look at intuitions not from a representationalist, but from biophysical perspective. We are embodied

beings, and there are different levels of embodiment (Metzinger 2014). Computational, but also thermodynamical imperatives guide the self-organization of representational states in our brains. One major causal factor underlying the conscious experience of “intuitive soundness” might simply be the amount of energy it takes to activate and sustain a mental model of a given theory, plus the amount of energy it would take to permanently *integrate* this theory into our pre-existing model of reality. Our mental space of intuitive plausibility can in principle be described as an energy landscape: claims that “come easily” do so because they allow us to reach a stable state quickly and easily, theories that “feel good” are theories that can be appropriated without a high demand of energy. Theories that *don’t* feel good have the opposite characteristics: they “don’t add up”, they “just don’t compute”, because they endanger our internal harmony and functional coherence, and it would take a lot of energy to permanently integrate them into our overall mental model of reality. They are costly. In a biophysical system like the human brain there may well be a direct connection between thermodynamic efficiency and reduction of complexity on the level of information processing. If biological self-organization involves continuously minimizing the prediction errors generated by the flow of “hypotheses” originating in the brain’s current model of reality, then the process that creates what today we call our deepest “theoretical intuitions” may also be described as such an attempt to reduce variational free energy. While on a more abstract level this process can be said to minimize representational complexity while simultaneously maximizing the evidence for the overall model, it is also a physical process that is not guided by abstract rationality constraints, but simply one that optimizes metabolic and statistical efficiency at the same time (Sengupta et al. 2013; Friston 2010; Hohwy 2013).

We need an open mind, because many of the best future theories about the human mind and conscious experience may just “not compute” for beings like us. However, what does or does not compute is, in part, a contingent fact determined by the functional architecture of our

brain, shaped by millions of years of biological evolution on this planet, as well as—to a much lesser degree—by our individual cognitive history and a given cultural/linguistic context. The phenomenology of intuitive soundness—the fact that some arguments seem “just natural”—is a biological phenomenon that is additionally supported by a short cultural history of cognitive niche construction. In this framework, the space of intuitive plausibility reflects exactly those aspects of our evolutionary history and of our more recent cognitive niche that have become transparent—that we have long ceased to experience as evolved and culturally driven, but regard as unconstructed, immediate, and even indubitable. Importantly, the inner landscape of our space of intuitive plausibility is not simply contingent on our evolutionary history and on certain physical and functional properties of our brains—it was optimized for *functional adequacy* only. This process of optimization serves to maximize reproductive success and to sustain an organism’s coherence and physical existence, but this does not mean that the *content* of intuitions is epistemically justified in any way. This is especially true because the evolved functional adequacy of intuitions applies to everyday action in practical contexts and ancestral environments—not to abstract reflection in theoretical contexts or cognitive environments. This is why searching for a comprehensive theory of the conscious mind presents such a major challenge to our intellectual honesty: it demands that we investigate a claim even if it contradicts our deepest intuitions, even if it cries out for a more moderate, weaker version because it just “doesn’t compute” and somehow seems “just too radical”, costly, painful or even self-damaging. In this view, any philosophical methodology that just tries to make our “deepest intuitions” explicit in a conceptually coherent manner appears to be a rather trivial enterprise. If our claims here are correct, then intuition-mongering may even border on intellectual dishonesty. At best, it just charts our intuition space; at worst, it confuses failures of imagination with insights into conceptual necessity (“philosopher’s syndrome”, according to [Dennett 1991](#), p. 401).

3.2 Suspending judgment, inner quietude, and the phenomenology of uncertainty

If intuitions can be described as creating a transparent inner bias and perhaps even as involving an inner form of dogmatism, then we might, it would seem, make progress in understanding open mindedness as a mental state by looking to cases characterized by the phenomenal signature of *not* knowing and of uncertainty. The philosophical tradition of skepticism seems to be a promising place to look. Skepticism comes in many different strengths and flavors (see [Landesman 2002](#) for a comprehensive introduction), but what is distinctive about philosophical skepticism is perhaps best captured by the meaning of the original Greek term, where skeptic (related to the Greek verb *sképtomai*) refers, quite simply, “to one who inquires into the truth of things or wishes to gain knowledge about some subject matter” ([Landesman & Meeks 2003](#), p. 1). Skeptical inquiry, in the philosophical sense, is not so much concerned with the truth of particular beliefs or theoretical claims as with the possibility of knowledge and certainty in a more fundamental sense. It also does not always aim at denying the truth of our most basic beliefs by construing outlandish skeptical hypotheses such as the Cartesian evil genius. Generally, skeptical arguments cast doubt on commonly (and often implicitly and unreflectively) accepted means for attaining knowledge—and in so doing frequently give rise to new and fruitful discussions on how our epistemic practices might be improved. Throughout the history of philosophy, skepticism, at its best, has often been deeply constructive and has enabled genuine progress.

The philosophical tradition that has perhaps been most concerned with cultivating a skeptical attitude and with uncertainty and not-knowing as a mental state, at least in Western philosophy, is Pyrrhonian skepticism, which was one of the two major schools of skepticism in antiquity. Here, we want to tentatively suggest that it could be instructive to trace many of the aspects that we claim characterize open mindedness all the way back to the Pyrrhonian skeptics. This claim might strike some as sur-

prising, because Pyrrhonian skepticism is often seen as a particularly radical and excessive kind of skepticism (Hume's *Enquiry Concerning Human Understanding* is a classical example of this). It is fair to say that in contemporary philosophy, Pyrrhonian skeptics are an endangered species (for an introduction, see Fogelin 1994; Sinnott-Armstrong 2004; especially Stroud 2004; Fogelin 2004), with the tradition often being regarded as a bit of a historical oddity. This is fueled by what little is known of its founding father, Pyrrho of Elis (c. 360 to c. 270 BCE). Most of this is anecdotal, as Pyrrho wrote nothing himself (Bett 2014). Diogenes, for instance, tells us that Pyrrho:

led a life consistent with this doctrine, going out of his way for nothing, taking no precaution, but facing all risks as they came, whether carts, precipices, dogs, or what not, and, generally, leaving nothing to the arbitrage of his sense; but he was kept out of harm's way by his friends, who [...] used to follow close after him. (1943, 9.62)

Pyrrho did not return the favor, reportedly passing by an acquaintance who had fallen into a slough without offering him any help (*ibid.*, 9.63). Clearly, this is a far cry from the constructive and research-generating type of open mindedness we hope to promote here.

A more thoughtful and differentiated account can be found in Sextus Empiricus's (1987) treatment of skepticism, where he refers solely to Pyrrhonian skepticism.⁶ According to Sextus:

Skepticism is an ability, or mental attitude, which opposes appearances to judgments in any way whatsoever, with the result that, owing to the equipollence of the objects and reasons thus opposed, we are brought firstly to a state of mental suspense and next to a state of 'unperturbedness' or quietude. (1987, Chapter 4)

⁶ Sextus distinguishes three types of philosophers by their adherence to different types of systems: dogmatists, or those who claim to have discovered the truth; academics, who deny that the truth can be apprehended; and skeptics, who continue to inquire.

Clearly, there is at least a superficial similarity between Sextus's claim that skepticism is an ability and our description of open mindedness as an epistemic practice. Here, we briefly review the most important characteristics of Pyrrhonian skepticism and argue that there indeed exist a number of insightful parallels to open mindedness as an epistemic practice.

A first point is that from the perspective of Pyrrhonian skepticism, dogmatism is the end of reasoning and the opposite of philosophical reflection. At the same time, the anti-dogmatism of the Pyrrhonian skeptics did not prevent them from giving "assent to the feelings which are the necessary results of sense-impressions" (1987, 7.13). The Pyrrhonian skeptics merely withheld assent to "the non-evident objects of scientific inquiry" (*ibid.*, 7.13). As an early form of what we call academic open mindedness, Pyrrhonian skepticism was directed, first and foremost, "against the dogmas of 'Professors'—not the beliefs of common people pursuing the honest (or, for that matter, not so honest) business of daily life. The Pyrrhonian skeptic leaves common beliefs, unpretentiously held, alone." (Fogelin 2004, p. 163)

This suggests that if we want to contrast the cultivation of an anti-dogmatic mindset with intuitions, this point should be applied not to intuitions and feelings of certainty in general, but to philosophical intuitions in particular. Philosophical intuitions, in virtue of their distinctive phenomenal character, involve a specific and often highly-specialized form of inner dogmatism: they quickly and effortlessly create an inner bias towards a given theoretical position, while at the same time making it seem so indubitable and certain as to prevent further critical inquiry. Even though the terminology is, of course, different, the Pyrrhonian attitude of anti-dogmatism presents itself as an antidote to exactly the type of uncritical, judgmental attitude that is the hallmark of intuitions.

Second, the Pyrrhonian skeptic, in his quest for "quietude in respect of matters of opinion and moderate feeling in respect of things unavoidable" (Sextus 1987, 12.25), makes use of stereotyped tropes or modes of argument. The tropes are all very similar in structure, in-

volving a series of contrasts between opposing statements, with the aim of leading to irresolvable disagreement and inducing a suspension of judgment. True to the characterization of the Pyrrhonian skeptic as one who inquires, “the modes [...] were not designed to inhibit reasoning. Rather, they were designed to assist the Pyrrhonian in continuing to inquire by shielding her from the disquieting state of dogmatism” (Klein 2014). As Sextus (1987, 7.13) tells us, the Pyrrhonian, when entering into a debate with the dogmatist, does not assert his arguments in the manner of claiming their truth; instead, he asserts them only provisionally and purely for the sake of argument, enabling him to practice epoché, or to bracket his assumptions about the truth of the relevant propositions. The tropes, then, are not just a strategy for convincing one’s opponent, but a specific way of cultivating this more general kind of epistemic attitude:

Like piano exercises for the fingers that would result in semi-automatic responses to the printed notes on a sheet of music, the modes were mental exercises that would result in semi-automatic responses to claims being made by the dogmatists—those who assented to the non-evident. (Klein 2014)

We certainly do not mean to suggest that we should all become Pyrrhonian skeptics by formulating modernized versions of the tropes. We only want to point out that the naturalistic strategy of preparing and then handing over questions to scientific research can be viewed as fulfilling a similar function, namely as cultivating the epistemic virtues and abilities associated with open mindedness. This in itself, of course, is nothing new. A similar idea can be found, for example, in Russell’s claim that,

as soon as definite knowledge concerning any subject becomes possible, this subject ceases to be called philosophy, and becomes a separate science. [...] those questions which are already capable of definite answers are placed in the sciences, while

those only to which, at present, no definite answer can be given, remain to form the residue which is called philosophy. (Russell 1912/1999, p. 112)

Following Russell, philosophy itself is a specific variant of cultivating what, earlier, we called a tolerance of ambiguity, and its value is “to be sought largely in its very uncertainty” (1912, 113). The Pyrrhonian tropes are just one example from the history of philosophy of how a particular style of argumentation can be used not just to generate particular insights but also to promote a particular style of thinking. Analogously, one of the reasons why interdisciplinary collaboration and data-driven arguments in philosophy are valuable may be that they are a way of practicing and cultivating open mindedness. Interdisciplinary research projects don’t just produce new data, but leave their marks on the minds of the researchers involved as well.

Third, the suspension of judgment, which is the outcome and in some sense the aim of the modes, is described by Sextus as a state of mental rest and as an “untroubled and tranquil condition of the soul” (1987, 4. 10). It also, however, has a normative dimension, involving the claim that if there is irresolvable disagreement between two opposing positions, one should refrain from adopting either of them.

In the ambiguity between these two readings, there is a nice point of contact between open mindedness as a mental state and something that today one might call the ethics of belief (Clifford 1877/1999; Chignell 2010) and of belief formation. There is clearly a social (Goldman 2010) and perhaps even an interdisciplinary dimension of epistemology, both in a theoretical and in practical sense. As is the case for the dialectical confrontation between the Pyrrhonian and the dogmatist, progress (in the sense of suspension of judgment) will often result from confronting one’s own convictions with those held by others, as well as from confronting them with real-world counterexamples.⁷ By contrast, accumulating evidence suggests that

⁷ This reliance on actual cases of disagreement, rather than on hypothetical scenarios and thought experiments, is also one of the differences between Pyrrhonian and Cartesian skepticism.

merely simulating this process by charting one's own intuitive responses to carefully calibrated thought experiments is not nearly as effective, and is actually often quite misleading (Gendler & Hawthorne 2010; Alexander 2012; Dennett 2013). Doing, as the Pyrrhonian skeptics realized, is better than merely imagining.

Indeed, empirical evidence suggests that our natural confidence in naïve realism is so strong that it remains largely unscathed by theoretical evidence to the contrary. In one study, when participants read a text about cognitive limitations and biases, this did not affect their confidence in their own social judgments. Confidence levels were only significantly reduced when theoretical challenges to naïve realism were presented alongside specific examples, such as visual illusions. As the authors put it, “acknowledging susceptibility to bias [...] may not always translate to actually tempering one's confidence or expressing an openness to change. Instead, experiencing unconscious cognition and bias was required to reduce confidence and closed-mindedness” (Hart et al. 2015, 6). This acknowledgment of the value of the practical and experiential dimensions of suspending judgment is implicit in the Pyrrhonian tropes.

Fourth, ataraxia, or quietude, according to Sextus, automatically and effortlessly follows on the heels of the suspense of judgment. This unintentional character of quietude is important, because it means not only that quietude cannot be actively brought about, but also that it is found in a place quite different from that in which one was looking:

the Skeptics were in hopes of gaining quietude by means of a decision regarding the disparity of the objects of sense and of thought, and being unable to effect this they suspended judgment; and they found that quietude, as if by chance, followed upon their suspense, even as a shadow follows its substance. (Sextus Empiricus 1987, 12.29)

This mental quietude may well be the phenomenal signature of not-knowing and of uncertainty, coupled with a highly developed toler-

ance of ambiguity; and it may be intimately related to the ability to formulate a question or identify a problem while refraining from giving a solution.

What we can see now, especially by contrasting this point with what we said about intuitions earlier, is how mental quietude might be turned into a target for consciousness research in its own right, perhaps even forming a new branch of the psychology or cognitive neuroscience of interdisciplinarity. In particular, the mental state cultivated by the Pyrrhonian skeptics is diametrically opposed to that involved in intuitions. Both are phenomenal states only, and as such have no intrinsic epistemic warrant. However, where intuitions block further inquiry, mental quietude and the phenomenology of uncertainty promote it. The skeptic aims, in a sense, at a state in which inquiry has become permanent.

But there is also an important difference. Whereas intuitions and intuitive plausibility come to us naturally and effortlessly, open mindedness, the suspension of judgment and the tolerance of ambiguity are the result of careful cultivation, long-term practice, and sustained effort. From a purely evolutionary perspective, uncertainty and a non-judgmental attitude are costly and perhaps even dangerous, because they do not motivate action in the same immediate, quick, and unreflected way as intuitions.⁸

⁸ In fact, if doubt has an evolutionary function, it might be to prohibit activity and induce rest in situations in which the benefits of physical activity are outweighed by its risks, for instance in illness. Doubt and certainty of the theoretical sort may have more distinctly bodily precursors; they may be different ways of regulating how we relate to our own bodies and gauge our own level of physical ability. Carel (2013) describes bodily certainty as involving a tacit confidence “that our bodies will continue to function in a similar fashion to the way they have functioned in the past: we expect our stomachs to digest the lunch we have just eaten, our brains to continue to process information, our eyes to continue to see, and so on” (*ibid.* p. 4). By contrast, bodily doubt involves a breakdown of our beliefs about our own bodily capacities, but also a disruption on the level of subjective experience. “Bodily doubt is a physical sensation of doubt and hesitation arising in one's body. It is not solely cognitive, although it can be expressed in propositions. [...] Bodily doubt not only changes the content of experience, it also pierces the normal sense of bodily control, continuity, and transparency in a way that reveals their contingency. It shows our tacit faith in our own bodies to be a complex structure that becomes visible when it is disturbed. It changes the normal experience of continuity, transparency, and trust that characterize this structure” (*ibid.* p. 11). Bodily doubt is often associated with physical illness and depression, and in some cases, it seems this form of experiencing our own physical vulnerability may have a protective function. But according to Carel, the analysis of bodily doubt

If on encountering a bear in the wilderness you take too much time to contemplate the nature of the threat (or to question your intuitive assessment that the bear is indeed a threat), you might be eaten before you come to a conclusion. Clearly, introducing the Pyrrhonian spirit to such practical, everyday situations is absurd and perhaps even unhealthy. However, in the context of philosophical and scientific inquiry, cultivating vulnerability of the epistemic type (cf. Chinnery 2014) might be a strength and might help prepare the ground for genuine collaboration and fruitful discourse. But we can now also understand why, even in science, open mindedness is so frustratingly difficult to sustain: mental quietude is not a state of passivity or mental inertia. It is a mental ability that requires constant alertness and a lifetime of practice.

3.3 Acknowledging the problem of subjectivity

If open mindedness indeed draws from the same ideals as are rooted in Pyrrhonian skepticism, how can we put these insights to work in investigating phenomenal states and tackling the problem of subjectivity? In contemporary philosophy of mind, the problem of subjectivity is often taken to be the main conceptual and methodological obstacle for a true science of the mind. Can the first-person perspective be naturalized? What, exactly, is the place of subjectivity in the scientific world-view? And is there really something like “first-person data” that can—and perhaps must—enter the process of constructing a truly comprehensive theory of the conscious mind? Questions of this kind are

also illuminates the extent to which we are normally guided by a tacit and unshakeable kind of bodily certainty that typically cannot be rejected or rationally justified and that forms part of our brute animal nature. If this is right, then it might also explain why even the more abstract and theoretical variants of certainty continue to be associated with health and strength on the level of subjective experience—even though this confidence can be epistemically misleading. This also fits in nicely with the claim, elaborated in footnote 4, that ambiguity threatens the perceived coherence of the phenomenal self-model, whereas certainty, on the level of subjective experience, appears to be associated with heightened self-awareness. We might now say that doubt and the tolerance of ambiguity are an acquired taste: while in their early stages, they are often associated with discomfort or even anxiety, their cultivation may also be the key to genuine peace of mind.

good examples of high-level theoretical issues that require the epistemic virtues associated with an open mind. Even the editors of this collection have a tendency to disagree on this question—and we hope that this disagreement is of a constructive sort.

One of us (TM) thinks that a greater practical openness to so-called “first-person methods” on the part of researchers in philosophy and cognitive science alike might lead to great heuristic fecundity and would, perhaps dramatically, improve the quality and efficiency of research. Many such methods can be seen as the cultivation of a set of abilities that increase mental autonomy (M-autonomy; Metzinger 2013b, 2013d) and establish the inner preconditions for critical, rational thought: by stabilizing the first-person perspective, they create a more robust “epistemic agent model” (EAM; Metzinger 2013a, Box 1; Metzinger 2013d), or the experience of being a knowing self. At the same time he holds that there simply are no “first-person data” in any strict or conceptually more rigorous sense. Seriously assuming the existence of such data rests on an extended usage of a concept that is only well-defined in another (namely, scientific) context. First, the whole concept of a “first-person perspective” is just a visuo-grammatical metaphor, without a theory to back it up—and currently we simply don’t know what that could be, namely what “a” first-person perspective would look like (for a first conceptual differentiation, see Metzinger 2003, 2004; Blanke & Metzinger 2009). Second, “data” are extracted from the physical world by *technical* measuring devices, in a *public procedure* that is well-defined and well-understood, replicable, and improvable; and which is necessarily *intersubjective*. But in introspecting our own minds we never have any truly direct or immediate access to a mysterious class of “subjective facts”—all we have are neural correlates and publicly observable reports (which need not be verbal). Speaking of “first-person data” rests on an extended usage of a concept that is only well-defined in another context of application, rhetorically exploiting a fallacy of equivocation. “Data” are typically (though not always) gathered with the help of technical measuring

devices (and not individual brains) and by groups of people who mutually control and criticize each other's methods of data-gathering (namely, by large scientific communities). In particular, data are gathered in the context of rational theories aiming at ever better predictions, theories that—as opposed to phenomenological reports—are open to falsification.

To be sure, autophenomenological *reports*, theory-contaminated as they may be, are themselves highly valuable and can certainly be treated as data. But the experience “itself” cannot. However, even if one presupposes this rather straightforward view, having an open mind certainly also means acknowledging the additional fact that, for various reasons, this cannot be the *whole* story. It would be intellectually dishonest to deny without argument that what is sometimes called “first-person methods” could have enormous potential in our quest for a rigorous, empirically based theory of the human mind. The question rather is: What *exactly* is it about these methods that generates the extra epistemic value, if there really is one? It seems clear that not all epistemic virtues are *intellectual* virtues, and it is striking to note how such methods have played a central role in all cultures and in almost all ancient philosophical traditions of humankind. This is not only true for Asian systems of philosophy. At the very beginning of Western philosophy, Cicero (1971), in the *Tusculanae disputationes* (II 5), defined philosophy itself as *cultura animi*, as a way of caring for and cultivating the soul.

The other (JW) thinks that first-person data exist, and that for a true science of the mind, of consciousness and of subjectivity, it is important to acknowledge their existence. First-person data are not, however, to be found in the direct observation of conscious experience—thus far JW and TM are in perfect agreement—but in describing and more properly in reporting it. A first step towards seeing why this is the case is to clearly distinguish first-person reports from general opinions, convictions, or even intuitions about experience. First-person reports, in this view, are the product of (verbal or non-verbal) behaviors conducted with the sincere intent of conveying or recording certain rel-

evant information about a specific experience. They are not mere opinions about what it is typically like for oneself to have a certain kind of experience. They also should not be confused with attempts to generalize from one's own case to what it is typically like for other people to undergo a given type of experience, or with the practice, occasionally found in academic philosophy of mind, of relying on intuitive judgments or thought experiments to reach general conclusions about the necessary or even typical characteristics of given types of experience.

First-person reports, construed as sincere descriptions of specific and individual experiences, form the data-base of scientific consciousness research. They can be gathered with the help of public methods such as standardized interview techniques or questionnaires, and the data obtained from these reports are open to intersubjective validation (e.g., by using independent raters, different methods of statistical analysis and of scoring the content of reports, and so on). At the same time, this strategy works only against a background of trust that first-person reports can, when gathered under sufficiently ideal reporting conditions, be regarded as trustworthy with respect to the specific experiences they purport to describe. Indeed, assuming at least a subgroup of first-person reports to be trustworthy is a necessary condition of possibility for scientific consciousness research, for methodological reasons (see Windt 2013, 2015).⁹

Much of the serious work, in this view, will consist in identifying and improving the appropriate conditions under which maximally accurate experience reports can be obtained. Seen in this manner, the trustworthiness of first-per-

⁹ Clearly, this is not to say that such reports, or the data obtained from their analysis, are trustworthy with respect, for instance, to the neural underpinnings of the respective experiences, and we should not expect them to be. First-person reports, when gathered under ideal reporting conditions, are trustworthy with respect to the phenomenal character of experience only. Moreover, because this type of phenomenological information cannot be gleaned, for instance, from neuroimaging data, first-person data obtained from the analysis of experience reports necessarily complement third-person data. As dream researchers Tore Nielsen & Philippe Stenstrom (2005, p. 1289) put it, “[i]n an era of high-resolution brain imaging, similarly high-resolution reports of dream imagery may be needed”. A true science of consciousness will draw from different methodologies and different ways of measuring experience, and it will strive to integrate different types of data and different levels of description.

son reports becomes, to a considerable degree, a methodological problem for empirical research, not a principled philosophical or conceptual one, and the contribution of philosophy consists, at best, in showing why this is the case (again, see Windt 2013; for critical discussion, see Solomonova et al. 2014). By contrast, principled distrust in first-person reports, or even the attempt to investigate the phenomenology of experience independently of first-person reports, is an obstacle to a true science of consciousness.

While we, the editors, may disagree on the trustworthiness and epistemic status of first-person reports or even on the existence of first-person data in a strict sense, we certainly agree about the need to take our own subjective experience seriously, and we also agree that the epistemic stance we call “open mindedness” may well include a need to cultivate familiarity with our own subjective experience. In this respect, our accounts may well be complementary. Readers familiar with contemplative traditions may also have noted that there is a surprisingly direct and often quite literal correspondence between many classical notions such as “withholding judgment”, “mental quietude”, or “ataraxia”, and the practical instructions given by meditation teachers around the world, from different periods and different non-Western systems of philosophy. These notions are not only theoretical concepts—they draw our attention to the fact that there is more than one type of epistemic practice, and that open mindedness may in part be constituted by the set of abilities that connects them (Metzinger 2013c). On a more theoretical level, to have an open mind again means to acknowledge (and not repress) the fact that there may actually be a deep, unresolved ambiguity here, between the need to take subjective experience seriously and the suspension of judgment. In fact, bracketing one’s own folk-psychological or intuitive judgments about experience is part of what it takes to move towards a truly scientific approach to subjective experience. For this reason, open mindedness involves cultivating not only a particular attitude towards one’s beliefs, but also towards oneself as a believer.

A similar tolerance of ambiguity is at play in the attitude of lending equal credence to reports from different subjects, acknowledging inter- and intrasubjective variation in experience, and, ultimately, trying to integrate these reports into a maximally large data-base, while resisting the pull of generalizing from one’s own case or engaging in armchair phenomenology (where this involves pumping intuitions about experience rather than carefully observing and describing what it is like to have particular experiences). We might even say that this strategy of stepping back from one’s own convictions about experience and formulating questions about the phenomenal character or the subjectivity of experience is in keeping with the Pyrrhonian spirit: both are directed at academic disputes and assume commonplace experience or individual experience reports to be trustworthy, and both strive towards a confrontation of theoretical statements with real-world counterexamples, with the aim of ultimately giving rise to more sophisticated theories.

The issue of subjectivity is an excellent example of a persevering problem that comes in many different guises and reappears on many different levels. Perhaps there really *is* something about the conscious mind that cannot be explained reductively, even in principle. But searching for a maximally parsimonious scientific explanation is a rational research heuristic, not an ideology. It should never be a substitute for religion, and as such it carries it with it no immediate metaphysical commitments. To have an open mind is an *epistemic* stance, which means that epistemic progress is what counts in the end. Many of the authors in this collection, including the editors, are staunch methodological naturalists, because they view philosophy and science as engaged in essentially the same enterprise, pursuing similar ends and using similar methods. If it could be shown, however, more precisely than ever before in the history of philosophy and science, that there are strictly irreducible aspects of the human mind, then most of the authors in this collection, and indeed most researchers in this field, would be satisfied with this result. They would have what they wanted all along: epistemic progress.

4 The wider context

Having an open mind means never losing sight of the bigger picture and being continuously aware that scientific research, including research on the mind, is embedded in a wider context. In what follows, we will very briefly draw attention to three examples of what we mean by the “bigger picture” and the “wider context”: ethical, anthropological, and sociocultural issues; globalization and transcultural philosophy; and what we provisionally call “the sapiential dimension”—getting *philosophy* back into philosophy.¹⁰ Let us begin with the ethical ramifications of the type of work presented in this collection.

New theories lead to new technologies and new potentials for action. Gradually, they also change the image of humankind, a fact that may in turn have major social and cultural consequences. Having an open mind means being sensitive to normative issues and ethical aspects of research in philosophy of mind and cognitive science. It also means acknowledging the fact that the human mind is a culturally embedded phenomenon and that what we come to believe about it will eventually change not only sociocultural practice, but our own minds as well. Such “soft issues” are not empirically tractable, at least not in any direct manner (Metzinger 2000, pp. 6–10; Metzinger 2009). Here, perhaps even more so than elsewhere, the challenge is to formulate the right kinds of questions in a rigorous, precise, and fully intelligible manner. These questions are certainly difficult, but they are also clearly *relevant*.

4.1 Sensitivity to ethical issues

Theoretical innovation leads to technological innovation, necessitating careful and reflected risk

¹⁰ Again, this comes back to the classical idea of wisdom as not only knowing how to live well, but also succeeding at doing so (Ryan 2014). There is also a clear connection between open mindedness as an epistemic practice and its ethical dimension. As Russell (1912/1999, p. 116) puts it, “[t]he mind which has become accustomed to the freedom and impartiality of philosophic contemplation will preserve something of the same freedom and impartiality in the world of action and emotion. [...] The impartiality which, in contemplation, is the unalloyed desire for truth, is the very same quality of mind which, in action, is justice, and in emotion is that universal love which can be given to all, and not only to those who are judged useful or admirable”. The true value of philosophy lies not just in its effects on our thoughts, but on our lives, on our actions; “it makes us citizens of the universe” (*ibid.*, p. 116).

assessment. For example, modern virtual reality technology not only enables the concrete realization of a large number of new experimental paradigms, but has also provided us with many novel and philosophically relevant insights into the multimodal bodily foundations of selfhood and subjectivity (Blanke 2012; Blanke & Metzinger 2009; Metzinger 2014). In combination with constantly improving brain-computer interfaces, virtual reality technology also possesses the potential for military applications, for example via *virtual or robotic re-embodiment*. New ways of causally coupling the human-self-model with avatars and surrogate bodies in virtual reality will have clinical benefits in the medical treatment of patients and, perhaps, in rehabilitation programs for prisoners. But it also opens the door to new forms of consumer manipulation and potentially unexpected psychological side-effects (e.g., Blascovich & Bailenson 2011).

A second example of the social and political dimension of new action potentials, in terms of how they might intervene in the brain, is provided by new developments in pharmaceutical cognitive enhancement (Merkel et al. 2007; Metzinger & Hildt 2011). Cognitive enhancement is a molecular-level technology, which aims to optimize a specific class of information-processing functions: *cognitive* functions, physically realized by the human brain. The human brain, however, is also embodied as well as embedded in a dense network of environmental interactions, many of which are of a distinctly cultural and social nature. And it not only possesses a long evolutionary history, but also changes over an individual’s lifespan. Here, the central philosophical problem is that *normative* elements are already built into the concept itself. In bioethics, the term “enhancement” is “usually used [...] to characterize interventions designed to improve human form or functioning beyond what is necessary to sustain or restore good health” (Juengst 1998, p. 29). As opposed to medical treatments or therapies, enhancements modify physical or mental characteristics in healthy individuals, just like cosmetic surgery. In psychopharmacological enhancement, psychoactive drugs originally devised as therapy

for specified diseases are typically used off-label or illicitly by normal, healthy individuals in order to modify brain functioning. In the future, how exactly can we benefit from scientific progress, for example by influencing and constructively interacting with the ever-developing neuronal architecture of our brains on a molecular level, while not leaving the social context out of consideration?

Who counts as a “healthy individual”? A trivial but important point is that concepts like “normal mental functioning” or, say, “normal age-related cognitive decline” possess a statistical and a normative reading. The semantics of both types of concepts change over time. For example, the statistical and descriptive features of “normal mental functioning” or “normal age-related cognitive decline” change as science progresses, as the predictive success of our theories improves, and as textbook definitions are adapted. Our concepts become richer in content and more differentiated. But if a specific society suddenly has new tools and new potentials for action—say, to alter certain cognitive functions in the elderly—then the statistical distribution of even those objective properties underlying a purely statistical notion of what is “normal” may also change. Cognitive enhancement is a neurotechnology, and technologies change the objective world. However, objective changes are also subjectively perceived and may lead to correlated shifts in value judgments. Concepts such as “healthy individual”, “normal mental functioning”, or “normal age-related cognitive decline” always have a descriptive as well as a normative reading, because they appear in statements about what human beings *should* be like. Is it really necessary to succumb to memory loss or a decreasing attention span after the age of 55? If other options are actually on the table, does this turn passively capitulating to age-related cognitive decline or certain individual limitations in the ability to engage in high-level, abstract thought into a cognitive form of unkemptness and dishevelment?

In this example, the not-so-trivial challenge lies in understanding the dynamic interaction between “normality” (in the descriptive sense) and “normalization” (in the normative

sense). The theoretical and social dynamics linking both concepts and their interpretation is highly complex. It involves scientific theories (in cognitive neuroscience, molecular neurobiology, and psychopharmacology), applied philosophical ethics, changing cultural contexts, globalization, policy-making, as well as industrial lobbies trying to influence the historical change of our very own concepts and their meaning in order to market new products. Normalization is a complex sociocultural process by which certain new norms become accepted in societal practice. For this reason, the scientific process, say, of optimizing textbook definitions, empirical predictions, and therapeutical success has a political dimension as well. It attempts to firmly ground theoretical entities such as “normal mental functioning” or “normal age-related cognitive decline” in empirical data, but it is also driven by individual career interests, influenced by funding agencies, the pharmaceutical industry, media coverage, and so on.

A third important example of how new ethical issues emerge is presented by the question of animal consciousness and animal suffering. What is the ethics of creating suffering in non-human species, for example in the scientific pursuit of uniquely human epistemic goals? Much recent research shows that many animals are very likely not only conscious, but also self-conscious and able to suffer (Brown 2015; Boly et al. 2013; Edelman & Seth 2009; Seth et al. 2005). They represent a frustration of their own individual preferences on the level of their consciously experienced self-model and thus *own* their sensory pain. They are also very likely to be unable to distance themselves from negative emotions such as fear, anxiety, or depression. In the light of new and better descriptive theories of consciousness, classical normative issues such as animal ethics reappear in a new guise and with increasing urgency.

Philosophical questions such as “Who or what exactly should count as an object of ethical consideration?” soon may also become relevant for the applied ethics of synthetic phenomenology, that is, for all research programs in artificial intelligence that risk or even directly intend the creation of phenomenal experience,

of truly subjective, conscious states in non-biological hardware. “Synthetic phenomenology” (SP) was first introduced by J. Scott Jordan in 1998, explicitly paralleling the idea of “synthetic biology”.¹¹ The possibility of machine consciousness now is not only part of the bigger picture and the wider context mentioned above, it also illustrates how theoretical innovation may eventually lead to technological innovation and require a careful assessment of possible risks. For example, the *Principle of Negative Synthetic Phenomenology* (Metzinger 2013b, pp. 2–8) is an ethical norm that demands that, in artificial systems, we should not risk the unexpected emergence of conscious states belonging to the phenomenological category of “suffering” or even aim at the direct creation of states that would increase the overall amount of suffering in the universe. But how exactly are we to unpack the logical details of this normative proposal? How does one approach these new types of questions in a rational and data-driven manner? Machine consciousness, just like VR-technology, pharmaceutical enhancement, and animal suffering is another example of a topic where a lack of imagination might prove dangerous and where an open-minded approach is pertinent.

Perhaps one central aspect of this problem is that in an increasing number of cases we will not only have to ask, “What is a good action?” but also, “What is a good state of consciousness?” Opening, cultivating and further developing one’s own mind clearly is in the spirit of not only Cicero, Plato, and the ancients—systematically increasing our own mental autonomy seems to be a common ideal shared by many of humankind’s philosophical traditions. However, the boundary conditions for this old philosophical project are beginning to change because the tools for manipulating or

even systematically cultivating our own minds are constantly becoming better—and precisely as a result of interdisciplinary, empirical work in the Mind Sciences. If we arrive at a comprehensive theory of consciousness, and if we develop ever more sophisticated tools to alter the contents of subjective experience, we will have to think hard about what a *good* state of consciousness is. This again illustrates the point that as some parts of neurotechnology inevitably lead to consciousness technology, new normative issues arise and classical philosophical questions reappear in new guises (Metzinger 2009).

As editors of this collection, we do not want to take a specific position on any of these important and highly controversial issues. We merely want to point out that having an open mind also means cultivating a specific kind of sensitivity: a sensitivity for the actual and potential suffering of other sentient beings, for newly emerging ethical issues and for the obvious fact that the kind of research we are developing together does not take place in a political, social, or cultural vacuum. For example, open mindedness also requires a self-critical sense of responsibility to global society as a whole. It is also in *this* context that new conceptual bridges have to be built between artificial intelligence, cognitive neuroscience, philosophy of mind, and ethics. Once more, a first and important step may be to carefully consider the questions themselves, rather than to rush into an answer or attempt to quickly implement mere technocratic solutions. Ultimately, all of these questions have a lot to do with the classical philosophical problem of what a good life actually is.

4.2 Globalization and intercultural philosophy

There is not only an ethics of science, there is also an ethics of globalization. It has to do with fairness and, for example, the willingness of the rich to relinquish some of their sovereignty for the benefits of cooperation. Of course, there are technical issues behind philosophical notions such as “global fairness”. But many would agree that we should distribute resources in a way that helps the worst-off, and that the only way

¹¹ See Chrisley 2009, p. 68 and Chrisley & Parthemore 2007, note 2. SP encompasses a variety of different approaches, methodologies, and disciplines, but what they all have in common is that they see SP as the construction or guided dynamical self-organization of phenomenal states in artificial systems. They also share the deep-seated methodological intuition that any scientific explanation of consciousness necessarily involves a systematic *re-construction* of the target phenomenon. See Gamez (2008, pp. 887–910); Holland & Goodman (2003); Holland et al. (2007); Chrisley & Parthemore (2007); Aleksander (2008) for a first overview.

of justifying giving more to those members of humanity who are already well-off is if it demonstrably improves the position of those in the poorest and most dangerous parts of the world as well. The movement of effective altruism uses scientific research to determine the optimal ways of distributing goods to the poorest regions of the world, with the goal of maximizing the benefits and long-term efficiency for instance of donations to charities (for general information, see <http://www.effectivealtruism.org/>). Such debates apply to the globalization of science and philosophy as well. In this context, it is interesting (and sobering) to note how in academic philosophy, the basic idea of making scholarly work available free of charge and free of usage restrictions online is vastly underdeveloped in comparison to other fields of research. It is also sobering to note that academic philosophy, possibly more than other academic disciplines, continues to be dominated by white, Western (and mostly Anglo-Saxon) males. This is not just reflected in philosophy departments themselves, but also in well-known and widely consulted ranking systems, which almost exclusively focus on Anglo-Saxon departments. We could do much better here, in all of these respects. Of course, many of us have long realized this, and as editors of this collection, we are preaching to the choir. What is needed now are viable ways of changing this situation.

Because of the open access format of the Open MIND collection, which was conceived of, in part, as a donation of intellectual property, we want to focus on one single aspect here. One might argue that the current subscription-based publishing system, which comprises nearly all of the top-ranked journals that young researchers in particular strive to have on their CVs, is inherently conservative, stabilizes the academic status quo, and, given the context of academic globalization plus the urgent need to strengthen deeper and not just intellectual forms of intercultural exchange, potentially leads to a “global closed-mindedness”, to a narrowing of intellectual and scholarly life. Typically, publically funded academics will be involved on different levels and in different stages of the publication process, not only as authors, but also as review-

ers, members on editorial boards, editors, and so on. Indeed, these types of participation are awarded and often expected by hiring committees. Yet, despite all of the hours of free labor (from the perspective of the publishing houses), the scientific publications that flow out of this process are often locked behind a paywall, giving authors only limited rights to distribute their own research. More innovative journals give authors the opportunity to publish their papers open access—typically in return for a hefty publication fee that, once more, is most likely to be funded by rich universities in affluent countries. Again, we can, and should, do much better.

Through their work, scientists and philosophers continuously produce knowledge and new intellectual property. However, there exists not only knowledge production, but also knowledge consumption—and the overall process has an economical basis. How should such goods be justly distributed? Who can *participate* in the process of producing and consuming them? The world continues to be divided into “haves” and “have-nots” when it comes to accessing the fruits of the intellectual labor of humankind. The point is not only that taxpayers should have access to the results of all publicly funded work. A more central point is that, given globalization, we now need a much more transcultural type of philosophy. In order to realize this goal, we urgently need to experiment with different formats of open access publishing, testing out what works best. In this way, we could finally create a unified public sphere for research—a “global workspace” for the science and philosophy of all humankind. Clearly, this in itself is not sufficient, but is a very first, necessary step.¹² Still, the historical transition we are witnessing is one where having an open mind also

¹² And new questions continuously arise. Is it, for instance, unethical to publish one’s research in scientific journals or books that are not open access and which therefore systematically exclude a large majority of students and researchers from the less affluent part of the world? If you answer affirmatively to this question, would you also say that it is unethical to consume research published in books or journals that are not open access? And do you think, in terms of civil disobedience, that it is permissible to disregard copyrights (and authors’ rights to royalties) to make such research, either your own or even that of others, openly available? This is just a small selection of the potentially difficult questions facing today’s scholars and researchers. And people are already acting upon their answers (see, for instance, Ludlow 2013).

means publishing open access whenever possible—which in no way excludes *additionally* using, and paying for, traditional dissemination formats as well. But in creating humanity's global workspace, as Steven Harnad (2007) puts it, it has now simply become “unethical for the publishing tail to be allowed to continue to wag the research dog.” What is needed is an honest and objective assessment of the most effective methods of scientific publishing—where effective not only means cost-efficient from the perspective of large publishing houses, but also addresses the dual challenges of optimizing the quality of research and peer-review processes while making scientific results available to all interested researchers and scholars.

“Intercultural philosophy” may sound good—but what does it really mean? Philosophy was born at different places and at different times, for example in India, in China, and in Europe. Philosophical thinking evolved in different cultural contexts that were often quite independent of each other and sometimes remained largely isolated for many centuries. Globalization now forces us to face the need to create novel forms of communication between philosophers as well as new forms of cooperation between different traditions and cultures. Yet this development is also an opportunity. The idea of “intercultural philosophy” is certainly not new, and there are many different ways of spelling it out. Here, we want only to point out that in our view, intercultural philosophy should not be a new academic discipline, but that it is, again, an *attitude*, an increasingly important form of epistemic practice.

At the same time, not *all* philosophical research contexts originally evolved in isolation, and the globalization of wisdom may be older than we think. To give just one familiar example, it is noteworthy that Pyrrhonian skepticism plausibly has a strong (and entirely mutual) intercultural dimension as well. The practice of using standardized arguments involving opposing statements to cultivate positionlessness, suspension of judgment, and epoché can be found in the Indian tradition as well, for instance in the Madhyamaka tradition and in Nagarjuna's writings. Textual evidence suggests that not only might Pyrrho himself have

been inspired by ideas with which he came into contact in India, but also that later, Sextus's version of Pyrrhonian skepticism might have shaped Nagarjuna's Middle Way (Dreyfus & Garfield 2010; Geldsetzer 2010; Kuzminski 2008). Having an open mind, in this sense, involves not only bridging *disciplinary* cultures, but also integrating different research traditions from different cultures and different periods and looking for their common sources.

Obviously, the open-minded “pooling of intellectual resources” that we mentioned above must increasingly also include philosophers not only from Europe or the Anglo-Saxon world. From a traditional Western perspective, epistemic humility also means acknowledging that other philosophical traditions may long ago have had deep insights into theoretical problems that still puzzle us today, even if their knowledge is not presented in a format and terminology that we are used to or can easily understand. It would be intellectually dishonest to assume that the style of thought developed in Anglo-Saxon analytical philosophy is the only way of being intellectually honest. And obviously, if, as we do, one calls for an expansion of the principle of charity into interdisciplinary discourse, then one should also accept that the same principle applies to intercultural collaboration. If there is to be a culture of charity, then it must be a *global* culture of charity—including open access publishing and global fairness in the distribution of academic goods. Today, even more than in the past, this is another reading of what it means to have an open mind.

4.3 The sapiential dimension

Thanks to the internet and major technological advances, modern academic life is unfolding at a greater pace than ever before. It has also become more competitive than it ever was in the past. This development bears the promise of progress; but it also poses a very real risk. As knowledge production becomes a commodity and academia is increasingly reorganized based on economic principles of marketing and business administration, universities are replacing tenure-track lines with adjunct teachers and a constantly growing number of brilliant young academics are now

competing for scarce resources in a globalized academic environment. The acceleration of academic life as well as increased social pressure are beginning to have psychological effects on individual researchers as well. A recent surge in the detection of fraud and scientific misconduct may be a sign of underlying counterproductive incentives that have begun to influence scientists worldwide. According to a report in the journal *Nature*, published retractions in scientific journals have increased by around 1,200% over the past decade, even though the number of published papers grew only 44% in the same period (Van Noorden 2011). A detailed review of all 2,047 biomedical and life-science research articles indexed by PubMed as retracted by the 3rd of May, 2012 revealed that only 21.3% of retractions were attributable to error (Fang et al. 2012). 67.4% of retractions were attributable to misconduct, including fraud or suspected fraud (43.4%), duplicate publication (14.2%), and plagiarism (9.8%). It is also possible, however, that the rising number of retractions has been caused by a growing propensity to retract flawed and fraudulent papers and does not in fact involve a substantial increase in the prevalence of misconduct (Fanelli 2013). These numbers might therefore also suggest an increasing willingness to retract faulty publications. They might also be artefacts of an increased availability of data on such retractions. We do not know what the final interpretation of such data should be. But we do regard them as one potential indicator of overheated competition turned counterproductive.

In philosophy, there is a high and continuously growing pressure for specialization, and this historical development presents a major problem. One classical model of what philosophy is says that philosophers are “specialists for the general”, who are concerned with integrating the knowledge of their time into an overarching conceptual model. As one German idealist philosopher put it, philosophy “is its own time comprehended in thought”.¹³ Today, the realization of this metaphilosophical vision has long become an impossible task for even the

greatest scholar. The sheer number of publications in any given, specialized area of research—such as embodied cognition, self-consciousness, or the evolution of culture and complex societies—has become so large that it is now extremely difficult for any ambitious young philosopher to even get an overview of the field. At the research frontier, great progress has been made in the fine-grained differentiation of research questions, while conceptual precision, argumentational density, and the general speed with which technical debates are conducted is continuously rising. This historical shift has become particularly obvious in philosophy of mind. In the age of cognitive neuroscience and Bayesian modeling, “raising one’s own age to the level of thought”, as Hegel put it, has simply become an impossible task. On the other hand, philosophers of mind are not embedded journalists of the neuroscience industry. A philosopher’s task today clearly goes far beyond offering methodological criticism plus a bit of applied ethics. Philosophers should not confine themselves to laying and clarifying some conceptual foundations or just developing a local, domain-specific “conceptual commentary” on the general way in which the empirical Mind Sciences change our perspective on reality and the human mind’s position within it. In the future, philosophers must more actively introduce their own epistemic goals into the overall process as well. Failure to do so is to exercise a counterproductive sort of epistemic humility—and runs the risk of letting academic philosophy slip into irrelevance.

Having an open mind also means that there are no taboo topics. At the outset, philosophy was the “love of wisdom” and, as everybody knows, knowledge and wisdom are not the same thing. Knowledge is something that can be accumulated in an incremental and systematic way, but wisdom has to do with synthesizing very different kinds of knowledge in ways that are practically relevant, for example with respect to knowing what a good life is and, importantly, also with being *successful* at living a good life (Ryan 2014). This in turn may include actively minimizing the number of unjustified beliefs one has and continuously maximizing the

¹³ Hegel, in his preface to the *Elements of the Philosophy of Right*, ed. Allen W. Wood, trans. H. B. Nisbet, Cambridge, UK: Cambridge University Press, 1991.

dynamic coherence between one's beliefs, one's values, and one's actions. Perhaps wisdom can also be characterized by a sustained striving for accuracy and for the possession of a wide variety of epistemically justified beliefs on a wide variety of relevant subjects—with one such subject being the deep structure of the human mind itself. In this case, knowledge will automatically be self-knowledge, and the question now becomes on what level the *relevant* form of self-knowledge is to be found. Tackling this problem may involve a commitment to a deeper form of rationality that includes not only epistemic humility, but heightened sensitivity towards moral issues and one's limitations in both fields.

It now has become dramatically obvious that something has been lost along the way. Academic life has become distinctly *unphilosophical*. Professionalization, acceleration, and excessive competition have led us into a form of academic life that can now very rarely be described as a good life. First, it seems safe to say that many of the best and leading researchers are not very successful at living a good life—even if they are philosophers who, at least at the beginning of their careers, may have had a great interest in exactly what a “good” life in the philosophical sense might be. Second, overheated competition increasingly draws people into the field who are predominantly interested in competition and professional success *per se*, and not so much in the pursuit of knowledge, let alone wisdom. But intellectual superiority and insight are different things, just as knowledge and wisdom are. There is no intrinsic link between striving for intellectual superiority and being intellectually honest, practicing epistemic humility and cultivating an atmosphere of charitable collaboration. In academic philosophy, the sapiential dimension, in which theoretical insight and practical know-how are deeply interwoven, has now been lost almost completely, and one aspect of what it means to have an open mind—as opposed to just being professional, knowledgeable, and smart—is to be aware of this fact and to be ready to face it.

We, the editors, certainly do not claim to know what exactly philosophy really is or what

it is to lead a good life, nor do we always agree on these questions—but we are convinced that whatever the answer is, it is deeply connected with a particular kind of attitude that reaches back all the way to the skeptical tradition, East and West. Philosophy at its best is not just purely academic or technical: it is also a practice, a way of life; and its theoretical and practical dimensions should never be completely independent of each other. This is what we mean when we say that academic philosophy would greatly profit from a sapiential dimension. And if we are right to say that philosophy is, among other things, an epistemic practice, a particular style of thinking resulting from the cultivation of an open-minded attitude (and one that is skeptical, we might add, in the most constructive sense), then this may also suggest a new reading of what it means to say that philosophy has an important role to play in the Mind Sciences. Asking for an interaction between cognitive neuroscience and philosophy as academic disciplines is one thing—but asking for the introduction of a particular way of thinking and a particular type of collaborative practice—a more genuinely *philosophical* attitude—into scientific research is another. We hope that by now it is clear that we think philosophy can contribute to the Mind Sciences in both respects, as an academic discipline and as an epistemic practice. Still, what we have been discussing here under the heading of open mindedness is first and foremost an example of philosophy as an epistemic practice—and as such it can be quite independent of philosophy as an academic discipline. Indeed, this is why we think that an important goal is to put philosophy, in this practical and classical sense, back into philosophy in the academic sense as well.

We openly admit that we have no ready-made answer to the question of how to re-introduce the sapiential dimension into modern academic philosophy, in a way that is rational and intellectually honest. In fact, we think this might well be the biggest challenge for the future. Obviously, what we call the “sapiential dimension” here has nothing to do with any kind of theology or organized religion. And we suspect that the real value of what we called “first-

person methods” above may lie not in supporting dubious metaphysical arguments, but lies, in part, in their potential for reintroducing the sapiential dimension into academic philosophy. But we also want to point out that this could simply be empirically false. Sometimes it is enough to remain with the question, to simply see it for what it is and to face the facts. Sometimes things take care of themselves. As we said when sketching the problem of subjectivity, to have an open mind means to acknowledge (and not repress) the fact that there may actually be a set of deeper metatheoretical ambiguities here. Having an open mind can also consist in admitting the existence of a problem—and that is all we want to do here.

4.4 Developing new forms of interdisciplinarity

Taking empirical constraints into account has become absolutely central in current philosophy of mind. However, there are different models of what good interdisciplinary practice is and *how* empirical constraints are to be satisfied or integrated. Interdisciplinary philosophy of mind does not simply consist in turning away from old-school armchair philosophy, which sometimes took intuitions as main input for philosophical work. And it would be false to say that “pure” philosophy has no place in the newly unfolding scheme of things—there is clearly relevant and highly valuable work that has only a small empirical component, or perhaps even none at all. One aspect of the Open MIND approach is that young philosophers should increasingly become active as experimenters themselves, for instance by proposing epistemic goals and novel experimental designs to empirical researchers and even by joining their colleagues from different disciplines to work on shared research projects. Another aspect of the approach, as we noted earlier, is that the extended principle of charity applies not only to the relationship between disciplines, but also to that between different generations of researchers.

We are all learning as we go along. Perhaps most centrally and most obviously, to have an open mind means to acknowledge the fact that while there has long been an “interdiscip-

linarity turn” in philosophy of mind, the real task consists in creatively testing out and developing entirely new *types* of interdisciplinary cooperation. For example, it is important to preserve a critical spirit and an openly inquisitive mindset—interdisciplinarity must never be purely decorative, a fashionable necessity, or reduced to a rhetorical element in edifying Sunday speeches. Along the way, we will also need a new understanding of progress, of acceptable forms of inquiry and methods, as well as new measures of success, for instance concerning novel forms of collaboration and publication formats that are still under the radar of institutionalized impact factors.

To give a second example, the newly emerged discipline of neuroethics is an important and innovative form of interdisciplinary philosophy, but it should never indirectly contribute to moral hypocrisy, as a fig leaf ultimately used by others to cover the failure to directly and open-mindedly address the political issues involved. If interdisciplinarity becomes merely strategic (e.g., in dealing with funding agencies) or is really guided by off-topic motives, then it loses its systematic force and becomes counterproductive and stale. Interdisciplinary philosophy of mind is not simply about being empirically informed, or about introducing strong and fine-grained “bottom-up constraints” in the formation of new theories about mind and consciousness. It may actually be about the emergence of a new type of researcher. We like the idea of “dyed-in-the-wool interdisciplinarity”, where “dyed-in-the-wool” is not used in a pejorative sense but indicates that young philosophers have learned how to *think* in a way that transgresses boundaries between disciplines, naturally and effortlessly. The classical approaches were intuition-based, and they made analytical philosophy one of the strongest intellectual currents of the 20th century. But we are now slowly moving from a priori methods and thought experiments to real experiments, and from abstract metaphysical questions about the relationship between mind and body to the investigation of specific aspects of cognition (Knobe 2015). And while it is clear that an open-minded philosophy of mind should not be

strictly or exclusively data-driven, it is equally true that it should be both empirically informed and informative, guided (but not completely constrained) by empirical data and theoretical-conceptual considerations alike.

In the end, there is also a sociological aspect to the current transition in our understanding of what good philosophy amounts to. [Max Planck](#), the German theoretical physicist who created quantum theory and won the Nobel Prize for Physics in 1918, famously said: “A new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it” (1948). As the editors of a collection promoting, among other things, senior–junior interaction, we think this may be a bit too pessimistic—and once more, we leave it to our readers to decide how successful this interaction was here, in this project. Still, for now, a careful suggestion is that possibly, the old should learn a little more from the young.

One of our experiences with the MIND Group was that there was a difference between what one might call “junior mentoring” and “senior mentoring”. Junior researchers need friends in neighboring disciplines whom they can trust and ask about literature, current trends, and technical issues that are hard to understand. Our experience is that interdisciplinary exchange works best in excellent young people who are not yet on the job market, and in non-competitive situations in which at best no holders of academic resources are present, such as senior researchers who have grants, post-doc positions, etc. to give away. Good and established systems of senior–junior mentoring already exist, but we believe that given the current situation, junior–junior mentoring is an important resource to be developed as well. For this reason, in the Open MIND project, we installed a form of junior–junior mentoring during the anonymous peer-review process for commentaries. And while replies can be seen as a form of senior–junior mentoring, there was also, covertly in the form of target article reviews, a phase of junior–senior mentoring, in which some of our junior members not only wrote their first

reviews ever, but now, after the collection’s publication, can also see for themselves how their comments were implemented and whether this maybe even led to an improvement of the target papers. But above all, it is important that young people from the *same* generation have the opportunity to meet each other and form their own, autonomous networks based on shared interests and mutually shared (or acquired) expertise. And this will require a radical restructuring of research funding and of the university system itself, as well as new subsidizing schemes. The function of older, more mature researchers may rather consist in creating and offering such platforms, giving a better overview of the intellectual landscape and offering insight into what is really relevant in a specific phase of a young researcher’s academic life. Today, the sociological aspect of what it means to have an open mind has an unprecedented global dimension. In trying to promote young blood, mostly in Germany, we found that language and cultural barriers actually are often higher than we wanted to admit. If what we have said about the ethics of globalization and intercultural philosophy here is correct, then we might not only need new formats of interdisciplinary and intragenerational collaboration, but also new types of intercultural mentoring as well.

As we said at the outset, instead of an introduction we wanted to begin a new conversation by offering some first starting points and perhaps even first building blocks for a fresh understanding of what, today, it could mean to have an open mind. Once again, we openly admit that we have no ready-made answers. But we are convinced that it is important to ask these questions. Somehow, we have to get philosophy back into philosophy.

Acknowledgements

We would like to thank Michael Madary, Nicole Osborne, Marius Jung, and Daniela Hill for editorial support and their helpful comments on an earlier version of this manuscript. And, as always, we are deeply indebted to Stefan Pitz, Anja Krug-Metzinger, and Janice Kaye Windt for their support.

Beyond Componential Constitution in the Brain

Starburst Amacrine Cells and Enabling Constraints

Michael L. Anderson

Componential mechanism (Craver 2008) is an increasingly influential framework for understanding the norms of good explanation in neuroscience and beyond. Componential mechanism “construes explanation as a matter of decomposing systems into their parts and showing how those parts are organized together in such a way as to exhibit the explanandum phenomenon” (Craver 2008, p. 109). Although this clearly describes some instances of successful explanation, I argue here that as currently formulated the framework is too narrow to capture the full range of good mechanistic explanations in the neurosciences. The centerpiece of this essay is a case study of Starburst Amacrine Cells—a type of motion-sensitive cell in mammalian retina—for which function emerges from structure in a way that appears to violate the conditions specified by componential mechanism as currently conceived. I argue that the case of Starburst Amacrine Cells should move us to replace the notion of mechanistic componential constitution with a more general notion of enabling constraint. Introducing enabling constraints as a conceptual tool will allow us to capture and appropriately characterize a wider class of structure-function relationships in the brain and elsewhere.

Keywords

Componential constitution | Constitution | Constraint | Enabling constraint | Explanation | Functional levels | Levels | Mechanisms | Mechanistic explanation | Neuroscientific explanation | Spatial levels | Starburst amacrine cells | Structure function mapping

1 Introduction

How, in the brain or any other system, does specific function arise from underlying structure? The question is a general one, and also in some sense a vague one, for it asks simultaneously about how structures shape events—generate causes—and also about what kinds of explanations one should aim for in neuroscience. Here I will focus on the second question in the hope of partially illuminating the first. One increasingly influential class of answers to this second question “construes explanation as a matter of decomposing systems into their parts

and showing how those parts are organized together in such a way as to exhibit the explanandum phenomenon” (Craver 2008, p. 109; see also Craver this collection). This is an attractive idea as it is expressed, but what I hope to illustrate here is that the leading formalizations of this general idea (Craver 2008; Craver & Bechtel 2007) place overly restrictive conditions on good mechanistic explanation. In what follows, I lay out the norms of mechanistic explanation, as developed by Craver and Bechtel, and describe some cases that their model nicely cap-

tures. I then introduce the case of Starburst Amacrine Cells (SACs)—a type of motion-sensitive cell in mammalian retina. In SACs, and in the functionally coupled direction-selective ganglion cells, the function-structure relationship is hard to capture within the Craver/Bechtel mechanistic framework. I argue that we can better capture such cases by replacing the notion of mechanistic componential constitution with the more general notion of enabling constraints.

2 The requirements of mechanistic explanation

Craver (2008) sharply distinguishes between two traditions of understanding scientific explanation: reductive explanation and systems explanation. According to Craver, the first tradition accepts a version of the covering law model of explanation (Hempel 1965) whereby one explains regularities at a given level of organization by showing how these regularities (the laws describing events and their relations) can be derived from theories holding at lower levels. Put differently, one explains a phenomenon of interest by showing how it is to be *expected* based on the laws governing activity at lower levels of organization. This tradition is reductive because when such explanations are successful, one can strictly speaking *do without* the higher-level laws. However convenient they may be for understanding or predicting higher-level phenomena, the higher-level laws do not add, capture, or explain any facts that are not already contained in the lower-level laws. The lower-level laws are scientifically sufficient.

In contrast, in the systems tradition, a phenomenon of interest ψ exhibited by a system S is explained by identifying a set of component parts $\{X\}$ and showing how they are organized such that $S \psi$ s. A systems explanation is similar to reductive explanation in that it too relies on the identification of levels of organization, since it requires identifying the parts of the system S , but, as I note below, it does not aim thereby at the reduction or explanatory absorption of one level by another. Craver & Bechtel write:

In levels of mechanisms, an item X is at a lower level than an item S if and only if X is a component in the mechanism for some activity ψ of S . X is a component in a mechanism if and only if it is one of the entities or activities organized such that $S \psi$'s. For that is what mechanisms are: they are entities and activities organized such that they exhibit a phenomenon. Scientists discover lower levels by decomposing the behavior of a mechanism into the behaviors of its component parts, decomposing the behaviors of the parts into the behaviors of their parts, and so on. (2007, pp. 548–549)¹

As already noted, S is the system that ψ s, or that exhibits phenomenon. It is, for instance, the car (S) that accelerates (ψ), and to explain car acceleration will require identifying the components $\{X\}$ that matter to $S \psi$ -ing. To identify these components and their organization is to explicate the mechanism M that accounts for $S \psi$ -ing. The target of mechanistic explanations of this sort is ψ : “mechanistic explanations are framed by the explanandum phenomenon” (Craver 2008, p. 121) and “[t]he explanandum of a mechanistic explanation is a phenomenon, typically some behavior of a mechanism as a whole” (Craver 2008, p. 139).

In mechanistic explanation, a given X is a component of the mechanism M if and only if it is one of the entities organized such that S exhibits some phenomenon ψ . So the engine, the accelerator, and the gas tank, but not the mudflaps or the windshield wipers are components of M that explain the car accelerating, even though these are *all* parts of the car S . In an

¹ There is a terminological issue that needs to be raised at the outset to avoid confusion. Craver & Bechtel (2007; Craver 2008) usually, but not always, use S to refer to a *mechanism*. In contrast, I will always use S to refer to the *system* or entity exhibiting the explanandum phenomenon ψ , and I introduce the symbol M to refer to the responsible mechanism. I do this because M and S are clearly not identical. Moreover, they *are* (or at least appear to me) to be distinguished in this passage, at least on one reading. I think it is unfortunate that neither Craver nor Bechtel formally and consistently distinguish the system S and the mechanism M in their analysis, for reasons that will become clear at the end of this section. Here I'll attempt to faithfully capture the essence of the Craver–Bechtel mechanistic framework, were it to have included this important distinction.

ideal explanation, the mechanism defined by the parts $\{X\}$ will contain *all* and *only* the components relevant to $S \psi$ -ing (see Craver 2008 for a discussion of constitutive relevance in this context). To identify the parts of M is thus to specify *both* a hierarchical and a functional relationship between M and its parts, and between M and S .

But although mechanistic explanation involves essential reference to hierarchical relationships between levels of organization, it is not thereby a species of *reductive* explanation because in a successful systems explanation nothing is rendered inessential or redundant. The phenomenon ψ is neither *derived* nor *derivable* from laws governing the parts of M ; rather, the parts $\{X\}$ and their relationships simply *are* M , and together explain why $S \psi$ s. The explanatory relationship is not rational derivation, but functional composition: M is physically and functionally *constituted* by its parts, and $S \psi$ s in virtue of that constitution.

Mechanistic explanations are constitutive or componential explanations: they explain the behavior of the mechanism as a whole in terms of the organized activities and interactions of its components. Components are the entities in a mechanism—what are commonly called ‘parts’. (Craver 2008, p. 128)²

Given all this we can add one more criterion for a given X being a part of the mechanism M : each X must be not just a functional but also a *spatial* sub-part of M . As a component of M , X will be at a *lower level* than M , and *smaller than* M : “[b]ecause mechanisms are collections of components and their activities, no component can be larger than the mechanism as a whole, and so levels of mechanisms are ordered by size” (Craver & Bechtel 2007, pp. 549–550). Craver and Bechtel conclude: “[m]ost fundamentally, levels of mechanisms are a species of compositional, or part-whole relations” (Craver & Bechtel 2007, p. 550). In the overall framework developed by Craver

and Bechtel, functional levels and spatial levels generally align.

Thus, although componential mechanistic explanations are not reductive, they generally *are* what one would call “bottom-up”, or perhaps better in this context, “level-restricted”: one explains the phenomenon ψ in S by reference to entities and relations at a lower level of organization, but never the reverse. In componential explanations of this sort, the intrinsic properties of and interactions between the mechanism’s components account for a system’s actions (where “intrinsic” means that such properties—such as the charge of an ion—are either basic to the entity or accounted for by reference to entities and properties at a still lower level of organization). Good mechanistic explanations on this view will not include references to unanalyzed properties of the whole S or M , its “shape” or overall organization, as the relations between the components $\{X\}$ at the lower level will already account for (in fact constitute) these.

This account of mechanistic explanation seems to me a clear and, indeed, compelling model of one kind of explanatory practice in the neurosciences. To satisfy the norms of mechanistic explanation, one must:

1. Identify the phenomenon of interest ψ
2. Identify the system S that ψ s
3. Identify the relevant spatial sub-parts $\{X\}$ of M (and their relevant intrinsic properties)
4. Describe how the parts $\{X\}$ are organized such that $S \psi$ s

At least *prima facie*, a number of instances of successful (albeit incomplete) explanatory models in the neurosciences appear to neatly fit this description. Craver (2008) extensively discusses the mechanistic model of the action potential. Briefly, following the steps above:

1. The phenomenon ψ is the action potential, which consists of the rapid depolarization of neural cells from a resting membrane potential of approximately -70mV toward (and in many cases significantly exceeding) 0mV ; an

² Note that within this framework “componential mechanism”, “constitutive mechanism”, and “compositional mechanism” are synonymous.

equally rapid repolarization; a period of hyperpolarization, where the cell overshoots the normal resting potential; and a gradual return to the resting equilibrium (note that as even this simplified sketch illustrates, ψ will often be in and of itself complex, with many aspects that any adequate model must capture).

2. The system S that ψ s is the neuron.
3. The parts in virtue of which S ψ s include elements of the cell and its surrounding ionic milieu: positively charged K^+ and Na^+ ions; gated, ion-specific membrane channels; and the Na^+/K^+ pump.
4. Finally, the organization that explains ψ includes the following: The resting potential is in fact an equilibrium between two opposing forces: a chemical concentration gradient that pushes Na^+ into the cell and K^+ out of it, and an electrical gradient that pushes K^+ into the cell, each maintained by the selective permeability of the cell to Na^+ and K^+ . Na^+ channels change their conformation in response to current flow (they are voltage-gated) such that they open to allow Na^+ to flow into the cell. As Na^+ flows into the cell this reduces the electrostatic pressure on K^+ , and opens voltage-gated K^+ channels, allowing K^+ to flow out of the cell. The net effect is to push the cell initially toward the electrochemical balance point for Na^+ , which is about +55mV. However, as the membrane potential drops, the Na^+ channels close, thus slowing and eventually stopping the depolarization. The diffusion of K^+ out of the cell combines with the activity of the Na^+/K^+ pump to repolarize the cell, which however overshoots the resting potential due to the fact that the K^+ channels close later than the Na^+ channels, thus allowing K^+ to diffuse out of the cell for an extra millisecond or so during which the cell is hyper-polarized.

Obviously, this remains a sketch (see Craver 2008) or any basic neuroscience textbook for more detail), but it illustrates the main elements of a mechanistic explanation. The intrinsic prop-

erties, actions, and interactions of M 's spatial sub-parts together comprise the mechanism that allows S to ψ and thus explain how S ψ s. One can likewise plausibly sketch the mechanisms that account for spatial long-term memory (e.g., the ability of an animal to return to some location in its environment) in terms of long-term potentiation of synapses in the hippocampus (Craver 2008), although it is worth noting that a more complete account of the functions of hippocampus will have some of the features I describe in 3 and 4 (Buckner 2010; Anderson 2015). Still, the fact that *some* explanations in neuroscience are like this is not under significant dispute.

But this brings us to the question of why I have distinguished M and S in my treatment. Because Craver (2008) does not formally distinguish these, he is never led to ask what the precise relationship is (or could be) between M and S (and between their respective parts). In fact, for Craver the symbol S usually (but not always) refers to what I have been calling M , and he frames his analysis of mechanistic composition entirely in terms of ψ and its mechanism. When he does mention the larger system it is generally to emphasize the fact that not every part of a system S is relevant to the mechanism in virtue of which it ψ s. So what might the committed mechanist say about the relationships between S , M and $\{X\}$? One possibility is: all the parts $\{X\}$ of M will be on a lower level than S . That would be in keeping with the level-restricted character of the framework, and its characteristic alignment between spatial and functional levels. It is certainly a feature of all the examples discussed in its support, including the model of the action potential outlined above. A slightly stronger possibility would be: all the parts $\{X\}$ of M will be spatial sub-parts of S . I don't think anyone would or should endorse this stronger condition, but seeing why will be instructive, and will lead us to the reasons to reject the weaker formulation as well.³

3 On my reading, the framework developed in (Craver 2008) implicitly assumes the weaker condition, although most likely not the stronger one. But for my purposes here it is not crucial to pin this down. If the framework *does* assume the weaker condition, what follows should be read as arguing (contra this model) that there are systems for which functional

The immediate trouble with the stronger formulation is that it collides with a fact noted by Craver (2008), but not otherwise discussed: the mechanism that accounts for S ψ -ing may contain parts that are extrinsic to S (although not to M). For instance, in the mechanism for the action potential, the Na^+ and K^+ ions that are clearly part of M are (at least sometimes) extrinsic to S ; and in embodied accounts of some cognitive processes like mathematics, the mechanism that accounts for a person (P) multiplying (ψ_m -ing) contains parts that are *always* extrinsic to P , such as pencil and paper (Clark 1997; see also [this collection](#)). These entities would arguably *not* be components of the systems that ψ , although they would be components of the mechanisms in virtue of which they ψ . At the very least, this suggests there are some details yet to be worked out about the necessary physical relationships between M and S that implement the hierarchical and functional relationships in virtue of which M can account for S ψ -ing. There will be (presumably rare) cases in which M and S are identical; cases such as the accelerating car where M contains only parts of S ; and cases such as the action potential where M and S cross-cut one another, sharing some but not all of their parts.⁴ There may also turn out to be cases in which they share no parts, perhaps because the parts of M and the parts of S are individuated by different criteria, or because S 's ability to ψ is imposed by or inherited from an entirely extrinsic mechanism (indeed I'll discuss a potential instance of this class of cases later in the paper).

But distinguishing M and S in this way *also* allows one to ask whether all the parts of M need to be at a lower level than S . If not

every X needs to be a spatial sub-part of S , then there is little reason to suppose that each X needs to be on a lower level than S , either. Indeed, I claim that in fact for some systems S the mechanism M will contain items that are neither intrinsic to *nor at a lower level than* S . For instance, I often use other people to help me remember things, in the easiest case by asking them to remind me at some future time. In such a case, this other individual is arguably part of the mechanism responsible for my remembering, but is certainly not for that reason on a lower ontological level than I am, qua remembering system. Moreover, as I will argue when looking at the case discussed below, some relevant parts of M (and certainly M itself) are at a *higher* organizational level than S . Now of course, Craver & Bechtel *define* the concept of lower level in terms of being a part of the mechanism: "an item X is at a lower level than an item S if and only if X is a component in the mechanism for some activity ψ of S " (2007, p. 548). I agree that this holds for the constitutive relationship between *mechanisms* and their parts. But it only holds for all systems S if we assume that all the parts of M are parts of S , and we have seen that this is not always the case. Thus although I think that Craver correctly analyzes the relationship between mechanisms and their parts in terms of constitution, I argue that the more capacious notion of *enabling constraint* better captures the relationship between mechanisms and the systems whose activities they enable.

In any case, with this as background, I now turn to the case of the SAC. In 3, I describe what we know about how the mechanisms in virtue of which the cell operates, and in 4 I discuss the implications of this case for componential mechanistic explanation.

3 Direction selectivity in SAC dendrites: Beyond componential constitution

Starburst Amacrine Cells are axonless neurons found in the retina of mammals and numerous non-mammalian species. Their morphology is planar, with multiple dendrites arrayed, as the

and spatial levels in fact dissociate. If it does not, then what follows should be read simply as offering an account of some of the possible functional relationships between mechanisms and systems, an issue not explored in the original analysis. Either path leads to the same recommended modification of the original model.

⁴ In the case of the action potential, one *might* mount the argument that the system that ψ s is *strictly speaking* $S + \{\text{the nominally non-}S \text{ parts of } M\}$, including the surrounding extracellular fluid. That would make M part of S in this case, but it is not clear to me that this move will be equally attractive in every such case, nor do I think the mechanist is *forced* to adopt this strategy.

name suggests, in a starburst pattern around the cell body (Figure 1).

Figure 1: Micrograph of a Starburst Amacrine Cell. Calibration bar 50 μ m. Reprinted from Tauchi & Masland (1984).

SACs form dense, highly overlapping, co-fasciculating layers in the “on” and “off” levels of the inner synaptic layer of the retina, nestled physically and functionally between bipolar cells and direction-selective ganglion cells. Among the most numerous neural cells found in the mammalian retina, they represent a large proportion of the total neural volume in the eye; in the rabbit retina, for example, as much as six meters of SAC dendrites occupy each square millimeter of retinal surface—higher coverage than any other retinal cell by an order of magnitude (Masland 2005; Tauchi & Masland 1984; see Figure 2).

SACs are interesting for multiple reasons. Despite lacking axons, they synthesize and release both excitatory and inhibitory neurotransmitters (ACh (acetylcholine) and GABA (-Aminobutyric acid)) from the distal regions of their dendrites. Both the role and relative proportion of excitatory and inhibitory synaptic connections change over time. Cholinergic synaptic connections between neighboring SACs disappear over development, and GABAergic connections between SACs begin as excitatory but later become inhibitory. However, excitatory cholinergic syn-

apses between SACs and ganglion cells remain (Masland 2005).

Figure 2: Depiction of the SAC network in peripheral retina. Calibration bar 50 μ m. Reprinted from Tauchi & Masland (1984).

Functionally, SACs play an important role in motion detection, and are part of the overall network for multiple uses including optokinetic eye movement and motion perception (Yoshida et al. 2001). In fact, each dendrite of the SAC acts independently of the others, and signals the presence of stimuli moving centrifugally, that is, from the cell body out in the direction of the signaling dendrite (Euler et al. 2002; see Figure 3). Put differently, each SAC dendrite is a directionally selective spatial sub-part of the overall cell, and this is the functional property that will interest us here. As with so much in the neurosciences, the mechanism that explains this function is complex and not fully understood. It is, however, possible to offer a sketch of it.

As mentioned above, SACs lie between bipolar cells and direction-selective ganglion cells. Bipolar cells thus mediate the initial stimulus such that a moving light causes them to fire in turn as the stimulus moves across the retina. The bipolar cells make excitatory synapses onto the SAC dendrites.⁵ With these basic anatomical facts in view, we can turn to describing

⁵ In fact there are two classes of bipolar cells, “on” and “off”, functionally differentiated by their disposition to respond to stimulus onset vs. stimulus offset—i.e., one responds to light and the other to dark—and anatomically distinguished by whether they synapse onto the “on” or “off” level of the inner synaptic layer (Figure 4). As the mechanisms for direction selectivity in SAC dendrites are the same regardless, I’ll ignore this detail in what follows.

three different aspects of the overall mechanism for direction selectivity: wiring specificity between bipolar cells and the SAC dendrites; lateral inhibition between neighboring SACs; and active elements in the dendrites themselves.

Figure 3: Depiction of direction selectivity in SAC dendrites. Reprinted from Masland (2005).

First, the axonal projections of bipolar cells largely preserve the topography of their inputs, such that neighboring axons come from cells with neighboring inputs, and make neighboring synapses onto post-synaptic cells. What this arrangement means for SACs is that neighboring synapses on the dendrite are likely to come from neighboring bipolar cells, so that when a moving stimulus activates one cell, and then another immediately to its left (say), this will tend to activate a given synapse, and then another immediately to *its* left. Thus, in the case where such a stimulus moves along the direction of a dendritic process, the successive excitatory inputs to that dendrite will tend to reinforce (Demb 2007; Lee & Zhou 2006). This is an important part of the overall mechanism, but is not sufficient by itself to produce the observed directional selectivity, as these inputs would tend to reinforce even during centripetal motion, although this would result in a weaker response at the *distal* process of the dendrite (Hausselt et al. 2007).

Another important part of the mechanism for directional selectivity involves mutual inhibition between neighboring SACs (Figure 5). As a stimulus moves so as to stimulate the centrifugal dendrite of SAC1 (in Figure 5A), reinforcing inputs will cause the release of GABA onto the centripetal dendrite of SAC0, such that even when the light stimuli begins to excite the centripetal dendrite of SAC0, the leading inhibition dominates the signal. Similarly, as the stimulus moves to the *centrifugal* dendrite of SAC0, the successive excitatory inputs from the bipolar cells reinforce, and any inhibitory inputs from the neighboring SAC2 come too late. Moreover, SAC0 will largely inhibit SAC2's response (Figure 5B; Lee & Zhou 2006). An important element of this mechanism involves the relative time-course of ACh and GABA: ACh response from the bipolar cells ramps up and decays fairly quickly, while GABA response is relatively delayed and prolonged (Demb 2007). This temporal asymmetry helps ensure that when inhibition leads it dominates, and vice-versa. The distance between SACs also plays a role. The likelihood of synaptic connections between the distal portion of the dendrites of two SACs—where inhibitory connections are most effective—depends on the distance between the cell bodies. Cells that are very close together or very far apart will thus not mutually inhibit one another (Figure 5C).

Finally, direction selectivity depends upon properties of the dendrite itself. The dendrites are electrically isolated from one another, as a result of both overall cell morphology and the low impedance of the cell body. The uneven distribution of synaptic inputs and outputs also contributes: excitatory inputs from the bipolar cells are distributed along the length of the dendrite, but synaptic outputs are confined to the distal ends (as implied by the two aspects of the overall mechanism described above). A third, active aspect of the local dendritic portion of the mechanism appears to involve voltage-gated calcium channels. These channels lead to amplification of the ACh response beyond what the passive reinforcement caused by successive synaptic transmission from bipolar cells can account for (Hausselt et al. 2007).

Figure 4: Schematic representation of the layered structure and synaptic relationships between bipolar cells and SACs. Reprinted from Yoshida et al. (2001).

All of these elements combine to produce the direction selectivity of the SAC dendrite. Bipolar cells successively synapse onto the dendritic process, resulting in passive reinforcement of excitatory input that preferentially promotes neurotransmitter release in response to motion in the centrifugal direction. Surrounding SACs selectively inhibit centripetal excitation,

as a result of the different temporal activation profiles of GABA and ACh; the asymmetric distribution of input and output synapses; and the relative spatial placement of the SACs. And voltage-gated calcium channels in the dendrite actively amplify the centrifugal signal. Although this sketch leaves out many of the known details, and there remain many details still to be worked out, I believe it is sufficient to warrant the conclusion that this is (a) an instance of mechanistic explanation that (b) does not have the level-restricted character of the (canonical) mechanistic explanations laid out above. I spell out the reasons for this conclusion in the next section.

4 Constitution and constraint

We can most readily see why this case represents an interesting challenge for componential mechanism by fitting it to the four steps outlined in section 2, above.

1. Identify the phenomenon of interest ψ
2. Identify the system S that ψ s
3. Identify the relevant spatial sub-parts $\{X\}$ of M (and their relevant intrinsic properties)
4. Describe how the parts $\{X\}$ are organized such that $S \psi$ s

The specific phenomenon of interest ψ_{ds} is direction selectivity or, more precisely, the release of neurotransmitter in and only in response to motion in a specific centrifugal direction. The system S_{ds} that exhibits ψ_{ds} is the dendrite of the SAC. It is also easy to say what the parts $\{X_{ds}\}$ of the mechanism M_{ds} are in virtue of which the dendrite ψ_{ds} , and how they are organized. I have provided that sketch above. Finally, it seems right to say, following Craver (2008), that the relationship between M_{ds} and its parts $\{X_{ds}\}$ is one of componential constitution, such that all the parts $\{X_{ds}\}$ are at a lower level than M_{ds} , and together constitute M_{ds} . But now it gets interesting for componential mechanistic explanation as currently developed. For only some of the parts of M_{ds} —including the voltage gated calcium channels, and the input and output synapses—are at a lower (spatial) level than the

dendrite S_{ds} . The inhibitory dendrites of the neighboring SACs are at the same level as S_{ds} , the bipolar cells and their spatial relations are arguably at a higher level than S_{ds} (although one might wish to screen these off as mere *inputs* to the mechanism), and the mechanism M as a whole in virtue of which S_{ds} ψ_{ds} s is *certainly* at a higher level than, and is in no way a physical or functional component of S_{ds} .

I think this example demonstrates that not every mechanistic explanation will have the “bottom-up” or “level-restricted” character that the mechanism for the action potential has, where function is built entirely from the capacities of lower-level components and their interactions. In the SAC dendrite, we appear to have a case *not* of a system that ψ s in virtue of the capacities and relations of its components (and that could in turn be thought of as a component supporting the activities of a larger functional system), but rather very nearly the reverse: a system that ψ s in virtue of the properties of and interactions in the higher-level system of which it is a part. That is, the SAC dendrite is not functionally related to its surrounds as a component to a higher-level system; nor is the higher-level system related to the SAC dendrite as one of *its* components. Instead, I want to say that the higher-level mechanism M acts as an *enabling constraint* on S .

Before providing a bit more in the way of substantial analysis of the concept of an enabling constraint, let us pause to consider one way in which a supporter of componential mechanistic explanation might resist this conclusion by redefining the system S_{ds} to include the mechanism M_{ds} . I think this is not a viable option for a number of reasons. First, it would appear to violate standard usage: neuroscientists speak of direction-selective dendrites, and *not* of a directionally selective network spanning several retinal layers. The debate in the neuroscientific literature concerns *not* the definition of the direction-selective system, but the relative role of intrinsic and extrinsic mechanisms for dendritic direction selectivity in SACs (Hausselt et al. 2007; Lee & Zhou 2006).

Second, it appears that the mechanism as a whole is *not* direction selective. Any given

SAC, for instance, and certainly the network as a whole, signals motion in *all* directions. Even if we restrict the definition of M_{ds} to the entities in virtue of which *one* particular SAC dendrite is directionally selective, the symmetry of the mechanism—the fact that SACs *mutually constrain* one another and the same bipolar cells synapse onto more than one SAC dendrite—strongly suggests that *very same mechanism* generates right direction selectivity in the rightward-reaching dendrite in SAC0, and left direction selectivity in the leftward-reaching dendrite in SAC2 (e.g., in Figure 4). The mechanism, that is, does not have the same direction selectivity as either of the dendrites. Rather, it’s as if when you turn the crank one way (i.e., the stimulus moves one way) the mechanism produces one output; and when you turn it the other way, it produces the other output.

This suggests a different way to illustrate the limitations of componential mechanism as formulated. Craver writes that the explanandum phenomenon ψ is “typically some behavior of the mechanism as a whole” (Craver 2008, p. 139), and he thus might insist, contra my way of formulating his framework in 2, that it is the mechanism M and not the system S that exhibits ψ . In this case, because I have agreed that the parts $\{X\}$ in fact constitute M , any conflict between functional and spatial levels disappears. But in the case before us it seems that the mechanism *responsible* for, say, rightward direction selectivity does not in fact *exhibit* rightward direction selectivity. So the functional puzzle reasserts itself in a different guise.⁶

One might nevertheless insist on distinguishing these mechanisms in subtle ways—perhaps M_{ds0} includes these synapses from bipolar cells, but not those synapses, while M_{ds2} includes those synapses but not these. I doubt whether this can work, because explaining direction selectivity in *either* direction will require reference to the excitatory inputs from bipolar cells to the centrifugal dendrite, and the inhibitory inputs from the overlapping centripetal dendrite, which are in turn a result of the excitatory inputs from the *very same* bipolar cells synapsing

⁶ Thanks to an anonymous reviewer for pointing out this way of expressing the matter.

onto the centrifugal dendrite. But let us take the possibility as granted. Then one seems forced to say something along the following lines: the mechanism as a whole ψ s, but *signals* ψ -ing with the dendrite.

Figure 5: Lateral inhibition between neighbouring SACs contributes to direction selectivity in the dendrites. Reprinted from [Lee & Zhou \(2006\)](#).

Let us consider this possibility carefully. As I intimated above, scientists debate the relative importance of intrinsic and extrinsic mechanisms for dendritic selectivity in SACs. [Hausselt et al. \(2007\)](#) note that direction se-

lectivity in SAC dendrites persists in the presence of GABA and glycine receptor antagonists, which would deactivate the portions of the normal mechanism that involve mutual inhibition between neighboring SACs. In these circumstances, one might argue that *only* the portions of the original mechanism *intrinsic* to the dendrite matter in the explanation of direction selectivity, and in such a case it is clearly the dendrite that ψ s. What shall we say, then, when we remove the antagonists from the system and reapply the same directional stimulus, resulting in neurotransmitter release from this dendrite? One option is: whereas before the dendrite ψ 'd, now it merely signals the ψ -ing of the larger mechanism. But it seems clear to me that, if the dendrite can ψ , then adding network interactions that *aid and enhance* (that is, do not in any sense prevent) ψ -ing can hardly cause it to *not* ψ , but only signal ψ . This points to a fourth and final reason to reject the general move to extend the neural system S to include the mechanism M whenever it is (or contains entities that are) on a higher level than S : one would apparently need the ability to rigorously distinguish between ψ -ing and *signaling* ψ in an overall system where to ψ is generally also to signal it—that is, where signaling and doing are deeply intertwined. Thus, I believe we must insist: the dendrite ψ s.

For all these reasons, I do not think it is wise to hold onto level-restricted explanations and componential composition by fiat. Instead, it is time to expand the scope of mechanistic explanation by considering the various ways in which systems S relate to the mechanisms M that enable their activities. I think the case of SACs is especially important because it illustrates one way in which local selectivity in parts of a network can be the result of the interplay of excitation and mutual inhibition between non-selective parts of that network, which is clearly something that we need to understand better if we are to accurately characterize the functional mechanisms at work in both small and large-scale brain networks ([Anderson et al. 2013](#)). But other structure-function relationships appear to call equally for a broader account of mechanistic explanation. For instance,

the direction-selective ganglion cell DSGC (Direction-Selective Ganglion Cell), mentioned briefly above, responds to stimuli moving only in its preferred direction (which of course varies cell-to-cell). In this case, there do not appear to be *any* intrinsic mechanisms for the direction selectivity of the DSGC. Rather, SAC dendrites selectively synapse onto DSGCs with preferred stimuli antiparallel to the SAC dendrite preference (Briggman 2011) thus suppressing responses to motion in the non-preferred direction. DSGCs seem to simply *inherit* their selectivity via their synaptic contact with SACs—and, in fact, elimination of SACs from the retina abolishes direction selectivity in DSGCs (Yoshida et al. 2001). Here I just don't see any case for a compositional relationship between the mechanism (or its parts) and the selective system. Instead, the relevant mechanism synapses onto the relevant system, and by suppressing a sub-set of its response tendencies, induces selectivity.

This brings us finally back to the notion of “constraint”, which I think may help us understand the full range of mechanism/system relationships in the brain. The term constraint has been used in myriad ways in the literature on scientific explanation. In evolutionary biology, scientists refer for instance to stability constraints (Schlosser 2007) and both universal and local developmental constraints on evolvability (Maynard Smith et al. 1985). There are also law-like constraints on the possible states of physical systems generally (Lange 2011). None of these capture the sense of “constraint” that will be most helpful to us here.

One notion that gets us close is the idea of a “capacity constraint”, that is, a limitation on the capacity of a process that might take the form of changing the relative probabilities of the range of possible process outcomes (Sansom 2009). This certainly has the right flavor, for in the mechanism under discussion above it appears that the excitatory and inhibitory interactions between bipolar cells and neighboring SACs bias the outcome of the dendritic processing of the moving stimulus. But insofar as a capacity constraint is generally conceptualized in terms of the reduction

of some pre-existing whole ability—in Sansom's (2009) example, being handcuffed limits one's ability to move one's hands—this does not offer quite the right organizing frame for explanation in neuroscience.

The reason is that in the neurosciences we want to understand not just the capacities of entities, but how the structured interactions between entities give rise to *functions*, which are, crucially, *differential* and *differentiating* processes (that is, they differ from one another, and they differentiate between stimuli). Capacities in the sense of general powers (the capacity to generate an action potential, say) are necessary conditions for functions, but they are not yet functions; the DSGC is strictly speaking *non-functional* in the absence of SACs, even though it will continue to exercise its capacity to fire action potentials in response to inputs from bipolar cells. Constraints of the sort under investigation here serve to limit capacities, but in so doing they enable functions; they result in an *enhancement* (not a reduction) of the abilities of the system (and the organism).

For this reason I propose to analyze the general functional (and, crucially, *non-hierarchical*) relationship between mechanisms and systems in the following way: an *enabling constraint* is a relationship between entities and/or mechanisms at a particular level of description and a functional system at the same or a different level, such that the entities/mechanisms bias (i.e., change the relative probabilities of) the outcomes of processing by the system. Such enabling constraints offer necessary but not sufficient conditions for the instantiation of differential function in neural systems. Because enabling constraints are synchronic rather than diachronic, the idea shares the same explanatory advantage that the relation of constitution has over the relation of “causation” (when understood, e.g., as an event involving the transmission of some property, power, or conserved quantity from one entity to another). As Craver & Bechtel (2007) point out, such a conception of causation does not accommodate interlevel functional relationships well, because these are often synchronic and symmetric, whereas causa-

tion of this sort is temporal and asymmetric.⁷ In addition, enabling constraints can be *mutual*, which gives the idea an advantage over both causation and constitution as an analysis of functional relationships in the brain.

Enabling constraint =_{Df} A physical relationship between a functional system S and entities $\{X\}$ (and/or mechanism M), at the same or different level of description, such that $\{X\}$ (and/or M) changes the relative probabilities of various possible functional outcomes of activity in S .

To understand function not just in systems like SAC dendrites and DSGCs, but also in the large scale networks that are partially constituted by the Transiently Assembled Local Neural Subsystems TALoNS (Transiently Assembled Local Neural Subsystems) crucial to the functioning of a dynamic brain (Anderson 2015), we need to accept that there is a broader range of relationships that mechanisms can have to functional systems, beyond componential constitution. Function in TALoNS results not from structured interactions between stable, autonomous low-level components, but rather from the interplay between the capacities of lower-level entities and higher-level network dynamics. That interplay, I argue, is best analyzed in terms of the mutual constraint that exists between bottom-up and top-down, feed-forward and feed-back mechanisms in the brain.

5 Conclusion

Although mechanistic explanation as developed by Craver & Bechtel (2007; Craver 2008) does seem to accurately characterize one kind of explanation in neuroscience, and one kind of func-

tional arrangement in neural systems, I've argued here that the formulation is not wide enough to capture the variety of mechanisms in the brain. When we formally distinguish the system S from the mechanism M in virtue of which S exhibits the explanandum phenomenon Ψ , we see that although it seems correct to describe the relationship between M and its parts $\{X\}$ in terms of constitution, it will only sometimes be the case that S is (partially) constituted by $\{X\}$.

As an alternative to the relationship of componential constitution, I have offered the notion of an *enabling constraint* that can exist between a system and the mechanism(s) in virtue of which it has its various functions. SAC dendrites appear to have their function in virtue of the enabling constraints imposed by entities at the same and higher levels of organization; and DSGC function is enabled by the constraints imposed by the SAC dendrites. In neither case is it appropriate to describe the relationship between the mechanism M and the relevant system S in terms of constitution, nor are all (or, in the case of DSGCs arguably any) of the parts $\{X\}$ of M components of S .

Overall, I hope to have made the case that moving beyond level-restricted mechanistic explanation will allow us to better capture the variety of neural systems that emerge from the constant, constraining, biasing interplay between feed-forward, feedback, bottom-up, and top-down processes in the dynamic brain.

⁷ For instance, what explains why a neuron has a particular functional property cannot be an event involving the transmission of some property, power or conserved quantity from the parts of the neuron to the whole, because if causes must precede their effects, this would appear require that there be a time prior to which the neuron did not have the functional property conferred by its parts. Interlevel functional relationships do not generally appear to be temporal in this way. Rather, for Craver and Bechtel, what explains the functional property of the neuron is the way it is *constituted* by its parts. Enabling constraints are also synchronic in the relevant way, and so the view I am advocating here is also able to accommodate such cases of interlevel functional relationships.

Carving the Brain at its Joints

A Commentary on Michael L. Anderson

Axel Kohler

When neuroscientists explain the biological basis of a phenomenon of interest, they usually try to identify the parts of a system that seem to do the relevant job, and propose a model of how those parts interact to produce the phenomenon. This mechanistic framework of explanation is widely used and has been investigated from a philosophical point of view by different authors. In his target article, Michael Anderson poses a challenge to the currently dominant version of mechanistic explanation as advocated, e.g., by Carl Craver. Taking empirical results and explanatory models from studies on retinal starburst amacrine cells as a starting point, Anderson suggests that the current framework for mechanistic explanation should be extended to include a differentiation between systems and mechanisms, which would allow more leeway in understanding processing in the nervous system. Mechanisms can then be seen to provide enabling constraints on the functioning of systems, where the mechanisms do not need to be subsumed under the system and do not even have to be on the same organizational level. Although Anderson's proposal is interesting and worth exploring, I am unconvinced that this extension conforms to real-world explanatory practice and/or is necessary for accommodating the understanding of direction-selectivity in the retina. I examine another sample of research on starburst amacrine cells, where the integration of empirical data and computational models shows that, on close inspection, it is distributed networks to which certain characteristics are ascribed—a situation that can be handled with the available tools of mechanistic explanation.

1 Introduction

One of the dominant frameworks of explanatory practice in the neurosciences and the biological sciences in general is the model of mechanistic explanation proposed in its modern form by Bechtel & Richardson (1993) and recently extended by Carl Craver (2007). Mechanistic explanations describe entities and activities that together bring about a phenomenon of interest (Machamer et al. 2000). When we are interested in how vision works, for example, we try to localize the relevant parts of the brain, and identify components and their types of interactions in order to understand how we can see things (Bechtel 2008). This model of mechan-

istic explanation is thought to capture the dominant explanatory practice in the biological sciences (Bechtel & Richardson 1993), but normative claims are also made with respect to the adequacy of explanatory accounts. Craver (2007) proposes a number of constraints on constitutive mechanistic explanation in order to decide whether a mechanistic model is viable or not.

In his target article, Michael Anderson (this collection) takes current models of mechanistic explanation as a starting point for proposing an important extension of the existing accounts. In previous models, the system that

exhibits a phenomenon and the mechanism that explains the phenomenon were not separated. Sometimes parts of the system can be screened off with respect to the phenomenon at hand. The windshields of a car and its radio components are not really important in order to understand how it drives, for example. It's fine to say that the whole car drives, but that only the relevant components (engine, axles, tires) are doing the mechanistic work. Focusing on the essential components of a mechanism within a larger system is unproblematic. But Anderson worries about more complex cases in the neurosciences where the system displaying a phenomenon does not encompass the relevant mechanism producing the phenomenon and might not even be on the same level of description as the mechanistic components.

Anderson wants to demonstrate that componential constitution is not sufficient as a model of mechanistic explanation for the processing of directional selectivity in the retina. Mechanisms computing direction of motion are already available at the earliest stages of the visual hierarchy. The vital components of direction selectivity in the retina could be identified. In particular, in recent discussion starburst amacrine cells (SAC) have been viewed as a mechanistic substrate of motion processing. The SACs receive input from bipolar cells, which are not themselves directionally selective, and provide output to direction-selective ganglion cells (Zhou & Lee 2008). The SACs themselves seem to be the core component for retinal motion selectivity (Park et al. 2014; Yoshida et al. 2001).

Examining the current models of how direction selectivity is created in SACs, Anderson takes note of a discrepancy between how direction selectivity is mechanistically achieved and to which parts it is ascribed. He argues for a distinction between the system S that Ψ s (that is, exhibits direction selectivity) and the mechanism M that accounts for S 's Ψ -ing. For the case at hand, the SACs themselves or even just single dendritic compartments of SACs Ψ , but a much broader network of neighboring SACs and bipolar cells needs to be considered in order to provide a mechanistic account of SAC direction

selectivity. Anderson proposes this distinction as an important extension of Craver and Bechtel's model of mechanistic explanation. This has two major advantages, according to Anderson: (1) there can be entities and actions that play a role for M , but are not necessarily parts of S . This allows a certain flexibility in defining the system that displays Ψ , while at the same time including all relevant components in the mechanistic account of S 's Ψ -ing. (2) But if there are parts of M that don't need to be spatially subsumed under S , neither do they need to be at a lower level than S . So even the requirement of componential constitution might be relaxed to allow for higher-level mechanistic components that play an important role in S 's Ψ -ing.

As an alternative account of the relationship between mechanisms M and the respective systems S , Anderson proposes that M acts as an enabling constraint on S :

[A]n enabling constraint is a relationship between entities and/or mechanisms at a particular level of description and a functional system at the same or a different level, such that the entities/mechanisms bias (i.e., change the relative probabilities of) the outcomes of processing by the system. (this collection, p. 12)

In the case of retinal direction selectivity, the mechanistic interaction between neighboring SACs and BCs acts as an enabling constraint for the direction selectivity of a specific SAC dendritic compartment (i.e., the system).

The most straightforward move by proponents of existing models of mechanistic explanation, as Anderson (this collection) also notes, would be to claim that the differentiation of system and mechanism is vacuous. Only the mechanism as a whole can do the work. Even in complex cases, one just has to pick out the right subparts of the network (specific synapses, specific compartments of neurons) that together produce the phenomenon of interest. Anderson provides a number of arguments against this way of extending the concept of mechanism/system, which I would like to briefly summarize:

1. Neuroscientists just don't talk about complex directionally selective networks, but about the direction selectivity of certain dendritic branches.
2. The mechanism as a whole does not display a specific direction selectivity (it is not rightward-selective etc.), it only contributes to the specific selectivity in the respective SAC dendrites. The mechanism contributes to different kinds of selectivities in different dendrites.
3. Making fine-grained distinctions between subparts (synapses, axon branches, dendrites etc.) of the very same neurons that contribute to different directional selectivities is implausible.
4. When the whole network is said to be direction-selective (i.e., it Ψ s), what about the dendrite itself? Is it supposed to only signal direction selectivity (signal Ψ -ing)? It is unlikely that a clear distinction between Ψ -ing and signaling Ψ -ing can be made.

The aim of this commentary is twofold. First, I would like to argue that the described cases can be handled by current models of mechanistic explanation when one considers the options of reconstituting the phenomena and top-down causation. Second, using another example of research on SACs, I would like to show that the straightforward ascription of direction selectivity to the SAC dendrites is at least debatable. When looking at how empirical results are often integrated with computational models of direction selectivity, it becomes clear that those phenomena can only be understood by considering the distributed nature of the involved networks.

2 Reconstituting the phenomena and top-down causation

Anderson proposes a separation between systems and mechanisms. No matter whether the system is constrained to be a dendritic compartment or whether it is extended to encompass all mechanistically relevant parts, there are tools available to describe the respective situation. The mechanistic model does not necessarily consider systems in isolation from the environ-

ment or surrounding processes. Even if the system is defined as the dendrite only, factors influencing dendritic processing as well as the embedding of the system in the overall economy, its organization, have to be considered in order to arrive at an understanding of the system's functioning (Bechtel 2008, pp. 148–150). On the other hand, I would like to argue that we have good reason to extend the boundaries of the system to encompass all the contributing parts. This is a situation in which the original ascription of a function to a system part has to be revised to accommodate new findings. This process is termed *reconstituting the phenomena* by Bechtel & Richardson (1993). Although direction selectivity was thought to be bound to or even intrinsically generated in SAC dendrites, it turns out that the system can only be understood in combination with other neural elements that vitally contribute to the mechanism in question.

One advantage that Anderson suggests comes with the differentiation of system and mechanism is that mechanistic components can then be set at a different level of organization than the relevant system. The SAC dendrite is at a lower level compared to the input from bipolar cells and the network structure (bipolar cells and neighboring SACs) that enables SAC direction-selectivity. But once the question of how exactly we should carve up the brain into systems and mechanisms has been answered, I don't think that complex inter-level relationships are much of an issue for mechanistic accounts. They can be easily accommodated within the framework of top-down causation proposed by Craver & Bechtel (2007). They suggest that any reference to inter-level interactions can be analyzed in terms of within-level causal relationships between parts of entities, where parts and entities are related in a constitutive fashion and entities can be located on different levels. Emphasizing the fact that complex inter-level interactions often need to be considered in order to offer adequate explanatory accounts in neuroscience is important, but it is not outside the scope of current models of mechanistic explanation.

3 Systems and mechanisms for direction selectivity

Since the processing of direction selectivity in the retina is currently a very active research field, there is substantial controversy concerning the relevant entities and activities that contribute to the mechanism, as Anderson points out in his target article. Some accounts focus on local processes within the SAC dendrites themselves (Hausselt et al. 2007), while others draw a broader picture of a multi-component process, where the exact arrangement of cell types and their compartments is vital for direction selectivity (Lee & Zhou 2006). For our purposes here, I would like to use a most recent update on SAC function offered by the group working with Sebastian Seung. The group uses high-resolution electron-microscopy images of brain tissue to reconstruct complete brain networks on a cellular level. Apart from trained reconstruction experts, the project also makes use of so-called “citizen neuroscientists”—volunteers who contribute to the reconstruction process through an online platform that employs gaming features to guide and motivate the community effort (<http://www.eyewire.org>).

In their study, Seung and colleagues used images from the mouse retina to analyze SAC circuitry. They took a closer look at the exact wiring between bipolar cells (BCs) and SACs (Kim et al. 2014). BCs provide input to SACs, but do not show any directional selectivity by themselves. The main point of the article is to show that different BC subtypes display different patterns of connectivity with SACs. By analyzing branch depth and contact area, they could show that one subtype (BC2) has mainly connections close to the soma, while another subtype (BC3a) has more connections far from the soma in the outer parts of the dendrites. Importantly, the BC subtypes, in turn, have different intrinsic visual response latencies. BC2 seems to lag BC3a by 50ms and more. It can be shown that the differential connectivity patterns and the divergent latencies add up to produce selectivity for a preferred direction of movement going out from the soma on the respective dendrite in accordance with empirical results.

What is important about the paper is not just the main result itself. Any empirical observation may be overruled in the (near) future. So it is not particularly relevant whether these exact cell types and this exact type of wiring is vital for the phenomenon at hand. What I found intriguing in this study, however, was how the relevant mechanism was described and how the data were integrated with a computational model of direction selectivity, reflecting a recent trend in the neurosciences to combine biological and computational perspectives in explanatory accounts. It shows how neuroscientists pick out the relevant parts of a system that contribute to a specific phenomenon in question. The proposed computational model (Fig. 1a; Kim et al. 2014) maps the biological entities onto specific parts of the computational circuit. The output element at the lower part of the figure is the SAC. The input stems from BC2 (left) and BC3a (right); their respective response properties are captured as delay values and sustained vs. transient response types. The circuit combines elements of classical models of direction selectivity, the Reichardt (Fig. 1b) and the Barlow-Levick detectors (Fig. 1c). Clearly, the direction selectivity cannot be attributed to any one of the system components in isolation. Mechanistic accounts and the corresponding computational models both point to the whole complex of entities as the relevant system that achieves directional selectivity.

In its computational abstraction, the model can be thought of as a canonical system of directional selectivity. Similar models have also been applied to different hierarchical levels of neural processing and different species. For example, mechanisms of directional selectivity have been studied for a long time in the fly visual system. With very different neural elements and wiring, a system of interconnected neurons achieves directional selectivity with response properties closely resembling the Reichardt-type of motion detector (Borst & Euler 2011). Again, only the combination of elements from different processing stages succeeds in delivering direction selectivity as a system. On a cortical level, direction selectivity has been first described for complex cells of the

primary visual cortex (V1) in the seminal work of David Hubel & Torsten Wiesel (1962). Without offering a quantitative computational model, they nevertheless suggest a hypothetical connectivity pattern between different cell types that might underlie the observed responses to moving patterns in complex cells (Hubel & Wiesel 1962, Fig. 20). The model shares features with other motion detectors; a mapping between components is possible.

Figure 1: Computational models of direction selectivity (a) The selectivity of SACs described in Kim et al. (2014) can be modeled with a computational framework using a combination of sustained and transient response properties as well as excitatory and inhibitory connections. The displayed wiring would lead to direction selectivity for rightwards motion. The proposed model can be considered to combine previous classical models of direction selectivity, the Reichardt detector (b) and the Barlow-Levick model (c). Green dots indicate excitatory and red dots inhibitory synapses. $-\tau$ indicates a temporal lead and $+\tau$ a temporal lag. Reprinted by permission from Macmillan Publishers Ltd: Nature (Kim et al. 2014), copyright (2014).

When it comes to motion selectivity in the brain, one of the most intensively studied cortical areas is the middle temporal (MT) region.

The region was first described in the macaque (Dubner & Zeki 1971; Zeki 1974) and owl monkeys (Allman & Kaas 1971). The human homolog, the human MT complex (hMT+; Tootell et al. 1995; Zeki et al. 1991), turned out to be a collection of areas with related response properties (Amano et al. 2009; Kolster et al. 2010). Again, to understand the direction selectivity of MT, it is necessary to consider the cooperation of cells in MT and the input processing stages, mainly from V1. This cooperation and the need for an integrated perspective is emphasized in empirical studies (Saproo & Serences 2014) as well as computational models of MT functioning (Rust et al. 2006). Only the V1-MT system as a whole is understood to deliver motion selectivity as output of the MT stage.

But in terms of the role of MT in motion processing, a case could be made in support of Anderson's suggested distinction between a system that exhibits a certain selectivity and the mechanism that produces this selectivity. The apparent locality and modularity of motion processing in MT is based on very selective deficits in patients with lesions in and around MT (Zeki 1991; Zihl et al. 1983). And stimulation of MT with transcranial magnetic stimulation (TMS) in healthy participants leads to selective deficits in motion perception (Beckers & Hömberg 1992; Beckers & Zeki 1995; Hotson et al. 1994; Sack et al. 2006). In a recent study, patients undergoing brain surgery near MT could be investigated with electrical stimulation (Becker et al. 2013). Only stimulation of MT and a related area nearby, MST, led to an inability to perform a simple motion-detection task, a rather specific result concerning the relevance. Results of that kind drive the intuition that the system that is responsible for motion perception, independent of any cortical areas that might mechanistically contribute to the processing chain leading up to MT (like V1), are localized in MT.

Lesion and other interference studies (e.g., with TMS) are suggestive, but there are also well-known difficulties with interpreting the results. Lesions mostly affect larger parts of the brain and are rarely limited to a single cortical site. As such it is often hard to identify the actual parts of the complex brain networks that

are affected. The advantage of stimulation techniques is that the interference is temporary and can be precisely targeted on a specific location. But, given the rich connectivity structure of neural networks, stimulation effects can be seen even in remote target sites (Bestmann et al. 2004; Sack et al. 2007). In addition, TMS studies have shown that activity of MT might not even be sufficient for conscious motion perception without the involvement of V1 (Pascual-Leone & Walsh 2001; Silvanto et al. 2005). There are also further empirical as well as philosophical reasons for rejecting the claim that motion perception can be attributed to MT in a stringent fashion (Madary 2013), which I won't discuss here.¹

So while at first glance MT is a very strong candidate for straightforward and very local attribution of function, it seems again that the relevant system is more appropriately described on a network level. The tendency to see system parts as vital for a function may also stem from the limitations of our employed methods. Lesion cases and interference techniques are commonly interpreted as being informative about the relevant gray-matter structures that are affected by the lesion or stimulation. But there is evidence that interference with white-matter connections between network parts can be even more incapacitating than gray-matter damage. It has long been known that frontoparietal areas are implicated in a deficit of visuospatial attention called *neglect*. But very recently Thiebaut de Schotten et al. (2005, 2011) revealed that the properties of fiber connections between frontal and parietal sites are most predictive of visuospatial processing capacities, and that their electrical stimulation leads to severe deficits. Transferring this insight to the case of MT, we simply have most direct access to the cortical gray-matter centers involved in motion processing, and since they are vital components of the system, this also leads to

corresponding deficits when they are affected or stimulated. But this might conceal the fact that motion selectivity is a product of a wider network that crucially depends on integrated processing for proper functioning.

In sum, I think that close inspection of how direction selectivity is investigated and treated in neuroscientific research is in disagreement with Anderson's arguments (1) and (3). Although it is true that investigators sometimes refer loosely to local elements as displaying a certain characteristic, the corresponding detailed and extended accounts of direction selectivity give credit to the distributed nature of the relevant systems that figure in explanations. Even considering the case of conscious motion perception, it is unclear whether the presumed locality of motion representation stands up to stringent tests. Rather, it seems to be a case of localized interference with a distributed system where damage to vital hubs leads to fundamental deficits.

4 Conclusion

In this commentary, I have defended the claim that the current tools of mechanistic explanation are sufficient for accommodating the explanatory goals in current neuroscience, particularly in the special case of direction selectivity in the retina and other neural systems. A closer look at explanatory practice shows that, in representative cases of empirical research, models of direction selectivity have to take a number of components in a distributed network into account in order to provide a full-fledged description of the relevant processes. On the philosophical side, the conceptual tools of "reconstituting the phenomena" (Bechtel & Richardson 1993) and "top-down causation" (Craver & Bechtel 2007), offered by existing models of mechanistic explanation, might be sufficient for capturing the problematic cases to which Anderson ([this collection](#)) points.

On the other hand, Anderson's proposal ([this collection](#)) to extend existing models of mechanistic explanation with the notion of enabling constraints is very interesting and might offer an avenue to more nuanced mechanistic

¹ Madary (2013) uses two sets of empirical results to show that representation of motion cannot be ascribed to MT simpliciter. One is the recent emphasis on spontaneous activity making significant contributions to the state of sensory systems—they add content referring to the attentional or sensorimotor state of the organism to input-derived sensory representations. The other demonstrates that in MT specifically, the response properties of cells can be quite variable and are not consistently related to perceptual content only.

descriptions of systems in their contextual embedding. In almost all relevant cases in neuroscience research, there are various external factors influencing the workings of a system, and it is often difficult to draw clear boundaries between vital and non-vital, but nevertheless highly influential system components. Anderson's framework would offer a viable solution for handling those modulatory constraints. Resolving this debate will also depend on a clear conception of how the entities that display a certain phenomenon are best identified and described.

Functional Attributions and Functional Architecture

A Reply to Axel Kohler

Michael L. Anderson

In his commentary ([Kohler this collection](#)) on my target article ([Anderson this collection](#)), Axel Kohler suggests that componential mechanism ([Craver 2008](#)) in fact suffices as a framework for understanding function-structure relationships, even in complex cases such as direction selectivity in Starburst Amacrine Cells. Here I'll argue that while Kohler is correct that the framework *can* accommodate such cases, this approach misses an opportunity to draw important distinctions between what appear to be different sorts of relationships between functioning systems and the mechanisms in virtue of which they function. I tentatively suggest further that the avenue that one prefers may turn on whether one expects the functional architecture of the brain to be primarily componential and hierarchical ([Craver 2008](#); [this collection](#)) or typically more complex than that ([Pessoa 2014](#)).

1 Introduction

In my target article ([Anderson this collection](#)), I argued that the complexity of the function-structure relationships that give rise to direction selectivity in Direction-Selective Ganglion Cells (DSGCs) and in the dendrites of Starburst Amacrine Cells (SACs) represent a challenge to componential mechanism as currently formulated ([Craver 2008](#)). First, I argued that distinguishing between the system *S* that exhibits the target phenomenon ψ , and the

mechanism *M* in virtue of which it ψ s allows one to paint a more nuanced picture of the various ways entities can be organized so as to give rise to observed function. Second, I suggested that the function-structure relationships in these particular cases appeared to violate the bottom-up hierarchical assumptions at the center of the componential mechanistic framework, which requires that the components of *M* in virtue of which a system exhibits ψ are at a lower level of organization than *S*. In the cases under

discussion, I argued that some parts of the mechanism in virtue of which SAC dendrites function are at a *higher* level of organization than the dendrite, and that parts of the mechanism in virtue of which DSGCs function are at the *same* level. Moreover, I noted that in neither of these cases were all the entities that constituted M constitutive parts (components) of S.

To accommodate such cases, I recommended extending the notion of mechanistic *constitution* with the notion of an *enabling constraint*: mechanisms, we should say, enable function in systems by changing the relative probabilities of functional outcomes of activity in S. I suggested that this change would allow us to more accurately characterize the variety of structure–function relationships in the brain (and in other complex systems). However, in his commentary on my article ([Kohler this collection](#)), Axel Kohler argues that such an extension is unnecessary, for in fact the componential mechanistic framework of Craver and Bechtel ([Craver 2008](#); [Craver & Bechtel 2007](#)) can accommodate these cases.

Kohler is correct. The extension is strictly speaking unnecessary, and componential mechanistic explanation can offer one plausible characterization of function–structure relationships in these cases. In fact, it is probably the case that *no* example or set of examples *ever* forces one to give up on an explanatory framework (certainly not one as well-motivated and useful as componential mechanism). What examples such as these *can* do, however, is illuminate the potential *advantages* of a new approach, and I would like to use the opportunity offered by this reply to reiterate what I take some of those advantages to be.

2 Three possible system-mechanism relationships

In my target article ([Anderson this collection](#)) I suggested that once one distinguishes between the system S that ψ s and the mechanism M in virtue of which it does so, it is easy to see that there are three possible relationships between M and S. First, the components of M can all also

be components of S, such that M is a relevant sub-component of S. Let's call this relationship R1. A relationship of type R1 obtains between the drive-train of an automobile and the automobile as a whole. Second, (R2), M and S can be identical. I can't think of an uncontroversial example of this relationship, and imagine that such a case is relatively rare. Third and finally, (R3), M and S can cross-cut in various ways, sharing some but not all of their parts. In my view, for instance, it is the neuron the fires an action potential, but not all of the entities that comprise the mechanism for generating action potentials are also part of the neuron. For example, the ions in the extracellular fluid that are crucial for establishing the membrane potential are not part of the neuron, although they are clearly part of the mechanism. Similarly, I argued in my target article that in the case of direction-selectivity in SAC dendrites, although it is the dendrite itself that is directionally selective, many of the parts of the relevant mechanism are not in fact parts of the dendrite. Moreover, in the case of DSGCs, the cell and the mechanism in virtue of which it is direction-selective share at most *one* part: the synapse between the SAC dendrite and the DSGC.

One advantage of making these distinctions, I believe, is that it allows one to see quite clearly when top-down constraints are responsible for function, as I argued is the case for direction selectivity in SAC dendrites. But Kohler suggests that appearances may be misleading here. In fact, he argues, we should “reconstitute the phenomenon” by recognizing that the relevant direction-selective system is *not* the SAC dendrite, but is rather the dendrite + the non-dendritic elements of the mechanism, including other SACs. This larger system can be then be treated within the standard framework of componential mechanism. We can call this approach to addressing these sorts of cases “the Kohler strategy”.

As I noted in my target article, the Kohler strategy is certainly open to the mechanist. It does, however, have the following effects. First, it tends to make the systems of the brain to which functions are attributed relatively *larger* and more diffuse, which arguably reduces preci-

sion. Second, it would in effect turn all apparent instances of R3 into instances of R2.¹ I noted above that I thought the class of R2 would be small. If I am right about the prevalence of R3 functional relationships in the brain, then this strategy would make R2 very large. But it would do so essentially by legislation, as a way of preserving the universal applicability of the componential mechanist framework. How forced this appears will depend on how closely one believes the guiding assumptions of that framework match the architectural facts of the brain. We will return to this last point after reviewing some of the considerations that appear to favor the Kohler strategy.

3 Motivations for the Kohler strategy

Kohler maintains that actual scientific practice in fact supports the Kohler strategy. Exhibit A in his argument is a recent article (Kim et al. 2014) detailing part of the mechanism for visual motion detection. Kohler reproduces a figure depicting their model, and argues that the inclusion of the distributed network in the model suggests that the authors are strictly speaking attributing function to the whole system as depicted:

Although it is true that investigators sometimes refer loosely to local elements as displaying a certain characteristic, the corresponding detailed and extended accounts of direction selectivity give credit to the distributed nature of the relevant systems that figure in explanations. (Kohler this collection, p. 6)

I agree that this is one possible interpretation of the practice. But here is another: these scientists are distinguishing between the system that exhibits the phenomenon and the mechanism that produces it, and are open to different sorts

of relationships between them. Consider the following from the paper Kohler discusses:

Research on [the visual detection of motion] has converged upon the SAC. An SAC dendrite is more strongly activated by motion outward from the cell body to the tip of the dendrite, than by motion in the opposite direction. *Therefore an SAC dendrite exhibits DS*, and outward motion is said to be its ‘preferred direction’. Note that it is incorrect to assign a single such direction to a SAC, because each of the cell’s dendrites has its own preferred direction. DS persists after blocking inhibitory synaptic transmission, when the only remaining inputs to SACs are BCs, which are excitatory. As the SAC exhibits DS but its BC inputs exhibit little or none, *DS appears to emerge from the BC–SAC circuit*. (Kim et al. 2014, p. 331; emphases added)

Far from seeming loose, the attribution of direction-selectivity to the dendrite appears to me clear and precise. Moreover, note that in the final sentence quoted above, the attribution of direction-selectivity to the cell is reinforced, even in the context of a reference to the mechanism as the “BC-SAC circuit”. Indeed, I would argue it is natural and permissible to gloss the last clause in the following way: “DS *in the dendrite* appears to emerge from the BC-SAC circuit.” On this reading, of course, the authors of this article would be proposing an R3 functional relationship such that parts of the mechanism are on a higher level of organization than the system exhibiting the phenomenon.

That these authors are open to R3 relationships of various sorts appears to be reinforced by a line later in the paper:

Previous research suggests that On–Off direction-selective ganglion cells *inherit their DS from SAC inputs* owing to a strong violation of Peters’ rule. (Kim et al. 2014, p. 335; emphasis added)

Here again we see the same pattern: a clear attribution of direction-selectivity *to the DSGC* in

¹ Actually, there are some questions here, for there seem to be *obvious* instances of R3 with which the mechanist is and should be entirely comfortable, e.g., the neuron and the mechanism of the action potential. So presumably this strategy would be employed *only* when the relationship appeared to violate the “lower-level entity” constraint. I’ve not the space to pursue this further here, so will note only that *selectively* pursuing the Kohler strategy would need separate justification.

the same sentence as a reference to the distal mechanism (the SACs), in the context of what is obviously an R3 relationship between system and mechanism. Thus, while I agree that the Kohler strategy is viable, I don't see that consideration of scientific practice forces us to adopt it, or even necessarily favors it.

So what might be other reasons for adopting the Kohler strategy over extending mechanism to include enabling constraints? As I mentioned at the end of the previous section, the matter might come down to how closely one thinks the architectural facts about the brain match the guiding assumptions of the componential mechanistic framework. If one expects that the brain is at root a decomposable or nearly-decomposable system of well-defined interacting components, then componential mechanism does indeed seem like a very appropriate framework for capturing at least the majority of its functional relationships (with the few exceptions to be dealt with perhaps as secondary elaborations or special cases). If, however, one takes seriously the notion that the brain is a massive network marked by multiple, nested, cross-cutting, dynamic hierarchies interacting in bottom-up, top-down, feed-forward and feedback fashions (Pessoa 2014), then one might wish for some of the explanatory flexibility that the notion of enabling constraints appears to offer. I, of course, am in this latter camp (Anderson 2015).

4 Conclusion

As Kohler correctly points out, it is possible to accommodate these complex cases of function-structure relationships within the componential mechanistic framework, by reconstituting the phenomenon and ascribing function to the whole mechanism that produces it. I have tried to indicate what I think some of the costs are to the Kohler strategy, including an apparent conflation of R2 and R3 functional relationships and a potential loss of grain in our ascriptions of function to structure. For some, paying these costs will be preferable to the proposed alternative, which might appear to require the admission of spooky top-down causes into our ontology.

For those who instead want to maintain the greater attributional specificity that appears to conform to scientific discourse, and in the current case to explain direction selectivity *in the SAC dendrite*, then I would argue that the most promising strategy is to recognize the ways in which functional parts (including networks) can impose constraints on other functional parts, at whatever relative level of organization. Adopting this strategy will of course focus attention on the nature of these constraints, whether bottom-up, top-down, or synpedionic. I would hope that the careful study of such R3 relationships as those showcased here would result in a better understanding of the varieties of causal interactions in complex systems.

What a Theory of Knowledge–How Should Explain

A Framework for Practical Knowledge beyond Intellectualism and Anti-Intellectualism

Andreas Bartels & Mark May

We argue against both intellectualist and anti-intellectualist approaches to knowledge-how. Whereas intellectualist approaches are right in denying that knowledge-how can be convincingly demarcated from knowledge-that by its supposed non-propositional nature (as is assumed by the anti-intellectualists), they fail to provide positive accounts of the obvious phenomenological and empirical peculiarities that make knowledge-how distinct from knowledge-that. In contrast to the intellectualist position, we provide a minimal notion of conceptuality as an alternative demarcation criterion. We suggest that conceptuality gives a sound basis for a theory of knowledge-how which is empirically fruitful and suitable for further empirical research. We give support to this suggestion by showing that, by means of an adequate notion of conceptuality, five central peculiarities of knowledge-how as compared to knowledge-that can be accounted for. These peculiarities are its context-bound, impenetrable and implicit nature, as well as the automatic and continuous forms of processing that are connected to it.

1 Introduction

In this paper, we shall argue against both intellectualist and anti-intellectualist approaches to knowledge-how,¹ for their failing to provide a suitable framework for empirical research on the subject of practical knowledge. Anti-intellectualists propose, following Ryle (1949), that intelligent action embodies “practical knowledge”, which is distinguished from “theoretical knowledge” by its manifesting abilities or dispositions. Intellectualists, in contrast, claim that there is only one sort of knowledge that is characterized by having propositional content (e.g., Stanley 2011b). Practical knowledge, according to intellectualists, is rather distinguished by how propositional contents are *applied* in action. Whereas intellectualist approaches (e.g., Stanley 2011b), we shall argue, are right in denying that practical knowledge can be convincingly demarcated from theoretical knowledge by its supposed non-propositional nature, nevertheless they fail to provide a conceptual framework in which the peculiarities by which practical knowledge stands out could be made visible.

On the other hand, anti-intellectualists (e.g., Newen & Jung 2011) often present phenomenologically-motivated identifications of forms of practical knowledge with certain representational formats. Classificatory schemas without theoretical foundation—that is, without a general conceptual framework within which these classifications naturally emerge, and without any clear-cut specification of the explanatory tasks that have to be fulfilled by that classification—have only limited value as a manual for empirical research. Such schemas cannot even be judged according to explanatory productivity or completeness.

The first part of the paper (sections 2, 3, and 4) will be concerned with the shortcomings of both intellectualist and anti-intellectualist approaches, partly programmed by Ryle’s famous, but also somewhat misleading, exposition of the subject. The perception of these deficiencies of both intellectualist and anti-intellectual-

ist approaches leads us to the conclusion that a philosophical framework for practical knowledge, in order to provide a basis for further empirical research, has in the first instance to lay some firm meta-theoretical ground.

The second part of the paper (sections 5, 6, and 7) will provide necessary elements for such a ground by identifying some central behavioral peculiarities of practical knowledge that must be explained by any empirically-adequate theory of knowledge-how. As will be seen, this is, above all, its *context-bound*, *impenetrable*, and *implicit* nature, as well as the *automatic* and *continuous* forms of processing that are connected to it. These five peculiarities will, in turn, be illustrated by examples stemming from the realms of sensorimotor knowledge (Milner/Goodale), intuitive knowledge (Damasio), and expert versus novice knowledge (Anderson), among others. We proceed by proposing a possible realization for the explanatory tasks identified in the meta-theoretical part: here we will argue that it is not by recourse to (non-)propositionality in any of its different senses that the peculiarities of practical knowledge can be explained; instead, we shall argue, *conceptuality* is a more suitable criterion for demarcating practical from theoretical knowledge, and for explaining their respective peculiarities. By “explaining” the peculiarities of practical versus theoretical knowledge we do not mean a kind of logical “derivation”. “Explaining” here is rather to be understood as showing how the realization of necessary conditions for the possession of concepts coincides with those conditions that have to be fulfilled in order to achieve the step from practical to theoretical knowledge, each characterized by their respective peculiarities. In other words, we search for “*how-possible-explanations*” of the peculiarities of practical versus theoretical knowledge. The driving role of conceptuality would also explain, in that sense, why the contents of practical knowledge cannot be easily verbally expressed, let alone abstractly represented. Such abilities only enter the scene, we argue, when knowledge reaches the conceptual level.

¹ Ryle, in his seminal approach, uses the term “knowing how” instead of “knowledge-how”. We don’t follow his usage because we think, contrary to Ryle, that know-how-phrases ascribe *genuine* knowledge, i.e., knowledge of truths (see section 2).

2 The shortcomings of intellectualist approaches

Ryle (1949), in his seminal work on knowledge-how, established a tradition of thinking that knowledge-how, as opposed to knowledge-that, is essentially characterized by its *non-propositionality*. That an action is intelligent, and thus embodies practical knowledge, comes not in virtue of its being “controlled by one’s apprehension of truths”, according to Ryle, but instead in virtue of its manifesting an ability or a disposition. Thus, Ryle’s notion of propositionality of knowledge is from the start coupled with a specific model of knowledge-application. Since this model cannot be true, practical knowledge cannot be employed by applying propositions. Indeed, if a person, in order to apply knowledge had first to “consider a proposition”, stored in his or her memory, this very act of considering a proposition would itself be an instance of practical knowledge and thus would be in need of a further act of considering a further proposition, and so on ad infinitum. Note that this means, at most, that practical knowledge cannot be manifested by virtue of *this* sort of application of propositions. But, as Fodor has remarked, “[if] the intellectualist says that, in tying one’s shoes, one rehearses shoe-tying instructions to oneself, then the intellectualist is wrong on a point of fact” (1968, p. 631). Thus, in order to avoid the whole debate turning out as a non-starter, we first have to disentangle the claim of propositionality of practical knowledge from the Rylean model of knowledge-application. But in what other sense, then, could practical knowledge be propositional?

The answer is that practical knowledge could be propositional in the sense that a person has practical knowledge by virtue of there being a rule that has a symbolic, language-like (“propositional”) representation, which is not accessible to consciousness, and which is not in need of being consciously “considered” in order to be applied in action. The knowledge embodied by this rule is instead applied in action by means of some kind of sub-personal processing of the representation. Fodor (1968) has defended such an intellectualist answer to Ryle’s

challenge by suggesting that the non-conscious representation governing the application of practical knowledge embodies “tacit knowledge”; since such tacit knowledge is applied by means of automatic mechanisms (not by intentional acts), it cannot fall victim to Ryle’s regress argument.

If we ignore the vagueness of this reading with respect to the *units of processing* in which this symbolic representation should appear, the foregoing may be a good answer to the question of how practical knowledge could possibly be propositional knowledge. In the eyes of Stanley (2011b), a more general conclusion could be drawn. According to him, since this argument that knowledge-representations need some automatic mechanisms (and not something like “considering” a proposition) in order to be applied in action, is true irrespective of the kind of knowledge involved, symbolically represented or not, all kinds of knowledge are completely *on a par* with respect to their representations—whatever they are—having to play some functional roles, mediated by an automatic mechanism, in order to be applied in action. Thus, Ryle’s analysis, according to which practical knowledge has a *dispositional* nature, can be accepted, but only at the price of accepting it for all sorts of knowledge. As such, not only can practical knowledge be propositional, but the whole distinction between propositional and non-propositional knowledge turns out to be irrelevant for characterizing sorts of knowledge, and *a fortiori* cannot be used to ground the distinction between practical and theoretical knowledge.

In other words, it is important to hold apart the thesis that knowledge is propositional in the sense of its being based on language-like representations, accessible to consciousness or not, from the empirically implausible Rylean model of knowledge application, which presupposes an act of “considering” a proposition. If we keep this distinction in mind, we find that propositionality *per se* does not provide a criterion for the theoretical versus practical knowledge distinction. Instead, all kinds of knowledge have to be “dispositional” in some sense, irrespective of their being based on symbolic, language-like representations or not.

Some anti-intellectualists, following Ryle, use the notion of “propositionality” of knowledge to refer to the fact that a person has *conscious access to linguistic propositional representations* (that is, that a person has sentences “in her mind”). Thus, for example, Michael Devitt, in a recent paper (Devitt 2011), argues that intuitively “to attribute any propositional attitudes to the ant [who has the skill of finding its way back to its nest by virtue of some neural processing] simply on the strength of that competence seems like soft-minded anthropomorphism” (Devitt 2011, p. 208). But the impression of anthropomorphism only occurs if we constrain the notion of a propositional attitude to refer to a conscious act by which a person relates to a linguistic propositional representation. The impression disappears as soon as we replace this interpretation of “propositional attitude” with a version in which the “proposition” is a rule, represented by symbolic encoding to which the ant is related by virtue of her neural mechanisms processing this encoding (or by virtue of her neural mechanisms being structured in such a way that they realize some implicit rule). That the ant “grasps a proposition” appears to be a strange description only under the presupposition that guidance by propositions implies the conscious possession of linguistic entities.

Moving from these “intuitive” considerations to arguments from the “science of knowledge-how” (cf. Devitt 2011, p. 207), Devitt identifies a “folk distinction between knowledge-that and knowledge-how” with the “psychological one between ‘declarative’ and ‘procedural’ knowledge” (2011, pp. 208-209). Now, declarative knowledge, according to Devitt, is characterized (according to what he sees as a consensus in psychology) by *conscious representation* of what is known (cf. Devitt 2011, p. 210). For example, a person has declarative knowledge of arithmetic rules only if she consciously represents those rules. Concerning procedural knowledge, Devitt refers to the distinction from computer science between “processing rules that govern by being represented and applied and those that govern by being simply embodied, without being represented” (2011, p. 210). Since

there is, according to Devitt, no decisive empirical evidence to tell us whether skills involve representations of the governing rules or not, he takes the recent picture that psychology paints of procedural knowledge “as constituted somehow or other by embodied, probably unrepresented rules that are inaccessible to consciousness” (Devitt 2011, p. 213). Finally, he argues that empirical evidence from cognitive ethology confirms this distinction between declarative and procedural knowledge by indicating that the “surprisingly rich cognitive lives” of desert ants, western scrub jays, or bottle-nosed dolphins can be understood as based on forms of procedural knowledge (to be identified with the folk notion of “knowledge-how”), but not on declarative knowledge (“knowledge-that”).

Thus, surprisingly, the anti-intellectualist Devitt and the intellectualist Fodor would agree to subsuming sub-personal knowledge, whether represented in explicit or implicit form, under the heading of knowledge-how. But the first would classify it as non-propositional, the latter as propositional knowledge. The real dissent seems to be about the question whether representations being *conscious* (and being accessible in linguistic form) or *non-conscious* makes a relevant difference for sorts of knowledge. We think that conscious availability/unavailability expresses a relevant difference for sorts of knowledge, but a difference *that can only be explained* by recourse to some fundamental distinction between practical and theoretical knowledge. Phenomena indeed indicate that the boundary between practical and theoretical knowledge coincides pretty well with conscious availability/non-availability. But Devitt’s distinction just *repeats* this phenomenon, rather than explaining it.² What we look for is a deeper reaching distinction that would be able to explain phenomenal differences such as conscious availability/non-availability and, as a consequence, verbalizability/non-verbalizability.

2 In the same way, Adams (2009) argues for a knowledge-that/knowledge-how distinction on the grounds of empirical evidence that takes recourse to experimental findings showing that declarative and procedural memory can operate independently from each other. We think that such empirical phenomena constitute explananda of the searched-for distinction, but cannot provide decisive evidence for the existence of a fundamental difference between knowledge-how and knowledge-that.

Thus, the propositionality criterion appears again unsuited for drawing an empirically-interesting distinction between practical and theoretical knowledge. As far as the intended distinction concerns the *transfer of knowledge into action* (this aspect is exactly that to which Ryle's distinction refers), *ways of representing knowledge* seem to be "on a par" and thus insensitive with respect to the distinction.

According to Stanley, it is the *semantic* notion of propositionality, with respect to which all sorts of knowledge can be subsumed as "propositional" (knowledge-that), be they based on conscious or non-conscious representations, by explicitly represented or simply embodied rules. Thus, Stanley has argued that the way in which a piece of knowledge is *implemented* (or *represented*) has nothing to do with a distinction between two *kinds* of knowledge. Therefore, the distinction between "declarative" and "procedural" knowledge as it is widely used in psychology should not be misunderstood, according to him, as providing some ground for the knowledge-that versus knowledge-how distinction: "the latter is a putative distinction between two *kinds of state*, rather than a distinction between *two ways of implementing a state*" (cf. Stanley 2011b, p. 151). Paradigmatic examples of practical knowledge, in the sense of knowledge being manifested by intelligent conduct, could turn out to be represented in a language-like way (without any conscious mediating act of "considering a proposition"), whereas clear examples of theoretical knowledge could fail to have any language-like representational background.

Stanley's *semantic* reading of propositionality is concerned with the reference of "know how"-phrases by which we ascribe knowledge-how to persons. According to our best available linguistic theories, as Stanley argues, know how-phrases have to be understood to refer to propositions. But this fact, in the first instance, does not include anything about the role those propositions play in the intelligent action of a person who knows the propositions. In particular, it does not follow that such a person possesses language-like symbolic representations that guide the person's intelligent action, or that such a person "considers" the proposition

in order to apply his knowledge in action. If the correct understanding of the semantics of knowledge-phrases, no matter whether it is theoretical or practical knowledge that is ascribed by them, is that they refer to propositions, then this propositional nature of knowledge, according to this reading, cannot be used to draw any distinction between theoretical and practical knowledge.

Now, someone could object that Ryle's distinction is concerned with the *nature* of knowledge, e.g., how knowledge is represented in a person, but not with what is involved in knowledge *ascriptions*. Thus the semantic reading of propositionality would be irrelevant for the theoretical versus practical knowledge distinction. But note that Ryle's analysis of practical knowledge actually starts by asking questions like: "When the person is described by one or other of the intelligence-epithets" (Ryle 1949, p. 28), what sort of knowledge is this description imputing to the person? That is, Ryle asks for the semantics of knowledge-ascriptions for typical cases of practical knowledge. Therefore, it is not at all clear that a semantic reading of propositionality is irrelevant for his analysis. On the contrary, the sense in which Ryle is concerned with the "nature" of knowledge is expressed, by him, by means of an analysis of the role that knowledge-phrases play in actual linguistic practice.³

It has now been shown that both possible readings of "propositionality", that is, the *representational* and *semantic* readings, are *relevant* for Ryle's proposed theoretical versus practical knowledge distinction, but neither is suited to grounding the distinction: Whether a piece of knowledge is a case of practical or of theoretical knowledge does not depend on whether it is supported by language-like structures or not; and, since *all* knowledge is semantically propositional (if Stanley is right) it does not depend on its semantic propositionality either.

³ Contrary to this, Noë (2005) argues that "Ryle's distinction is not a thesis about the sentences used to attribute propositional and practical knowledge, respectively". He claims that "Ryle was not an ordinary language philosopher". How then, would Noë, for example, understand Ryle's appeal to linguistic use in his deflationary account of the "will"?

Thus, it seems as if no criterion for the distinction between practical and theoretical knowledge could be available from the intellectualist point of view. But, we shall see that, from Stanley's revised dispositional analysis of knowledge, rather surprisingly a new possible criterion emerges. Let us, therefore, follow the path of this analysis, which is intended by the author to show how, contrary to Ryle, the (semantic) propositional nature of knowledge is compatible with its dispositional nature.

According to Stanley (2011b), even if we accept Ryle's general claim that knowledge has to be understood as dispositional,⁴ "there still need to be automatic mechanisms that mediate between dispositions (and abilities) and the manifestation or execution of these dispositions and abilities" (Stanley 2011b, p. 26). What has to be true of theoretical knowledge, namely the existence of mechanisms that mediate the application of that knowledge, has to be also true of practical knowledge. The complex of dispositions on which the ability to catch the fly ball rests may be completely intact, even if the player sometimes does not succeed in catching the ball because he has become tired or has momentarily lost concentration. When that happens, his executing mechanisms can fail. As has often been identified in the debate on knowledge-how, having the right dispositions (and thus having the right sort of practical knowledge) does not always guarantee successful performance (cf. Snowdon 2004).

Even if, from the intellectualist point of view, all forms of knowledge—be they "practical" forms of knowledge or not—could be, and indeed have to be, analyzed with respect to their dispositional nature, the question seems, by the very phenomenology of practical know-

ledge, to be more urgent than for cases of theoretical knowledge: How can knowledge be dispositional and propositional at the same time? Stanley & Williamson (2001) have suggested that cases of practical knowledge can be captured by means of a "practical mode of thinking", by which a person who has practical knowledge has access to propositional contents. If, for example, a person knows *that a certain way of riding a bike is a way for her to ride a bike*, then her thinking of that proposition is in a peculiar way self-directed, it is a "first-person-way" of thinking the proposition. Stanley (2011b) has developed this suggestion further into a dispositional theory of knowing a proposition.

Gareth Evans (1982), in his analysis of "demonstrative knowledge", has provided a useful framework of first-person dispositions: My thinking is a demonstrative belief about a perceptually-presented object if I will be disposed to have changes in that object affect my belief (Stanley 2011b, p. 110). Thus, my thinking of an object in the world as "myself" involves a permanent disposition to let my thoughts and actions be determined by my own bodily perceptions. Now this schema seems to fit the practical way of thinking that occurs when it comes to propositions like "This way of riding a bike is a way to ride a bike for me": A person manifests knowledge of this proposition by, while riding a bike, manifesting the disposition to react to certain kinesthetic sensations mediated by her own bodily movements by means of adequate motor commands.

We accept this as an adequate way of describing the phenomenological peculiarity of "practical ways of thinking" a proposition. Indeed, when described in this way, practical knowledge can be propositional and dispositional at the same time. But this analysis does not tell us—and indeed is not meant to tell us—how the distinction between practical and theoretical knowledge can be grounded. That there is such a distinction seems obvious *inter alia* on the basis of the functional characteristics peculiar to practical knowledge, such as its domain-specific nature, its limited transferability, its non-penetrability, and so on. Stanley's

⁴ Contrary to what Noë (2005) has claimed, Stanley thus does not attack Ryle's identification of "knowledge how" with the possession of abilities *tout court*. What Stanley objects to is the supposed opposition between knowledge as the possession of abilities and propositional knowledge on which Noë, assuming that propositional knowledge necessarily entails understanding of propositions, insists. Even the earlier work (Stanley & Williamson 2001) tries to account for the dispositional nature of practical knowledge by introducing the concept of a "practical mode of thinking". On the contrary, any unrestricted identification of knowledge-how with abilities confronts the problem of how to account for cases in which practical knowledge survives the loss of ability. The distinction between dispositions and their manifestation by means of executing mechanisms accounts for this problem.

dispositional theory fails, at least at first sight, to deliver any resources for *explaining why* practical knowledge is distinct from theoretical knowledge on the basis of these functional characteristics. The main shortcoming of recent intellectualist approaches, in our opinion, is not that they simply neglect the peculiarities of practical knowledge. Rather they are deficient insofar as they do not provide an explicit positive demarcation criterion of practical versus theoretical knowledge that would go beyond capturing the well-known phenomenological peculiarities and make it compatible with the proposed fact that all knowledge is (semantically) propositional. Before we go back to Stanley's analysis, in order to show how some explicit demarcation criterion could possibly be drawn from it, we ask whether recent anti-intellectualist approaches do a better job of providing a demarcation criterion.

3 The shortcomings of anti-intellectualist approaches

The anti-intellectualist position has recently been supported by, among others, [Toribio \(2008\)](#), [Young \(2011\)](#) and [Newen & Jung \(2011\)](#). Newen and Jung assume that Ryle's distinction between knowledge-how and knowledge-that should be taken as referring to the *nature* of knowledge. From a naturalist point of view, the most general way to characterize knowledge is to say that it is based on mental representations. Thus the distinction between practical and theoretical knowledge, from that perspective, has to be spelled out as a distinction between *ways of representing* something, or between representational formats. Now, theoretical knowledge, according to [Newen & Jung \(2011\)](#), can be identified with the propositional representational format, whereas they hold that practical knowledge comes in two (non-propositional) varieties, one characterized by the format of *sensorimotor* representations, and the other by what they call *image-like* representations.

Concerning the first of these representational formats, namely the propositional format, we are confronted with the same problem we

faced when considering Ryle's notion of propositionality. What does it mean to say that a representation is propositional? It should not mean that the content of the knowledge is or can be made available to the person in the form of consciously-accessible *linguistic structures*. Even if the property of *explicitness vs. implicitness* of knowledge is often used to distinguish between theoretical and practical knowledge, this merely descriptive criterion does not help to *explain* the theoretical versus practical distinction, but preferably should be explained by the more principled criterion we are looking for. If, on the other hand, we take "propositional" to mean that the kind of *processing* connected to a piece of knowledge has a language-like structure, how do we identify the units of processing to which this characterization is supposed to refer? Even if it were possible to precisely identify the level of processing that accounts for propositionality, it would be far from clear how the characteristics of theoretical versus practical knowledge could be explained by means of that supposed representational fact. As we have already pointed out in discussing Ryle's notion of propositionality: Why should it be the case that "theoretical" knowledge is necessarily connected to propositional representations, and, correspondingly, practical knowledge to non-propositional ones?

According to [Young \(2011\)](#), what we call "knowledge-how" may appear in different forms, which are accompanied by more or less comprehensive linguistic mastery of propositions. The sort of knowledge a guitar player manifests in his playing may be either such that he is able to *articulate* that, for example, G should be played rather than G#, or such that he may only be able to *experience* his performance as appropriate guitar playing ([Young 2011](#), pp. 57f.). In the latter case, his knowing how to play guitar is constituted by specific dispositions to react in particular ways to the conscious auditory and motor experience of his own playing. Even this form of knowledge may be reducible to propositional knowledge, however, since the player is potentially able to instruct himself with the help of demonstrative pronouns denoting parts of his actual auditory experiences. Whereas

those forms of knowledge-how may, according to Young, be reducible to propositional knowledge, he thinks that there is a clear case of *irreducible* knowledge-how that is constituted by “purely” sensorimotor abilities, and that is exercised without being supported by any kind of propositional knowledge. Such kinds of sensorimotor abilities are exemplified, according to Young, by the case of DF in the Milner/Goodale-experiments.

Patient DF is impaired in her ability to recognize objects, despite showing intact basic visual processing abilities. Milner and coworkers presented to DF a letterbox in which the slot through which one inserts letters could be rotated to vertical, diagonal, or horizontal orientations. DF had problems when she was asked to visually match the orientation of the slot to different alternatives. However, when asked to actually insert a letter, she was able to reach towards the slot while orienting her hand in accordance with the spatial orientation of the slot. Thus, DF has the ability to use visual information in purposeful object manipulations without being able to consciously visually process or experience them. On the other hand, another patient, IG, showed conscious visual awareness of objects without being able to practically manipulate them. Apparently, then, there are two independent neural pathways for processing visual information: the ventral path, leading to visual identification and corresponding to conscious experience, and the dorsal path, used for non-conscious action control and execution. In pathological cases, one or the other (DF vs. IG) of these pathways does not work, whereas the other remains intact (Milner & Goodale 1995, 2008).

What is the reason for Young’s assuming that the case of DF exhibits “irreducible” knowledge-how? The reason seems to be that DF is not able to use linguistic propositions—in whatever rudimentary form—to refer to aspects of the visual scene. She simply has no conscious access to the visual scene whatsoever. Young thus takes “propositionality” of knowledge to be constituted by conscious access to—possibly rudimentary forms of—linguistic propositions. But, as we already have seen, lacking conscious access to linguistic propositions accompanying

the performance of knowledge-how does not exclude the “propositionality” of that knowledge-how in the semantic sense of “propositionality”, and neither does it exclude the “propositionality” of that knowledge in the sense of being based upon symbolic language-like processing.

Toribio (2008) gives a similar argument against the possible propositionality of DF’s knowledge. She argues that

DF has no conscious awareness of this visual information [the information available on the dorsal route] and has no phenomenal experience as to the appropriateness of her own performance, but she has proprioceptive awareness of the features that govern her visually guided action in this particular task. (cf. Toribio 2008, p. 13)

This situation, according to Toribio, is relevantly different from the example of Hannah’s knowing how to ride a bike. In the latter case, Hannah has not only proprioceptive, but also *conscious* awareness of the sensory information available. Why does this difference matter? It matters, Toribio suggests, because in order to make plausible that a person’s knowledge-how is somehow “guided” by a proposition, this guidance has to be spelled out by a real process of “entertaining” or “contemplating” the proposition by the person. Suggesting a propositional reading of Hannah and DF’s knowledge without being able to point out some possible realization of “entertaining a proposition” in these cases “threatens to make us lose our grip on what propositional knowledge is” (cf. Toribio 2008, p. 13). But Stanley & Williamson (2001), Toribio claims, are unable to provide such a possible realization in the case of DF:

DF couldn’t possibly entertain such a proposition because she cannot grasp one of its constituents – she cannot perceive the features, e.g. the orientation, that governs her motor behavior in the posting task, and hence couldn’t recognize them as in any way constituting a reason for her action. (cf. Toribio 2008, p. 9)

We think that Stanley's elaboration on "practical ways of thinking a proposition" is able to overcome this objection. We can very well understand what it means that a person thinks a proposition p without being able to sensually identify the objects constituting p . Sensual identification ("grasping") is a precondition for *conceptual* apprehension of the constituents of a proposition, but it is not a precondition for non-conceptual attitudes to propositional contents, by way of proprioceptive information.

What the performance of DF in the Milner/Goodale-experiments indeed shows is that sensorimotor processing of visual information is sufficient for entertaining practical abilities and does not require any conscious processing, in particular no *linguistic* processing, if we suppose that linguistic processing is necessarily conscious.⁵ This result does not imply that sensorimotor processing is independent of (and opposed to) propositional processing. Sensorimotor processing could use "propositional" representations, only if these propositional representations were not linguistic representations (cf. Fodor 1968). Thus, the case of DF cannot be understood as supporting the sensorimotor-propositional processing-classification of knowledge. There is still no indication that there are two independent types of cognitive processing, a propositional and a sensorimotor one, to say nothing about the possible explanatory virtues of such a distinction.

That the sensorimotor vs. propositional classification is lacking any theoretical foundation that could determine whether this distinc-

tion is already complete or has to be completed in certain ways becomes obvious when further classificatory distinctions are proposed. For example, Newen & Jung (2011) introduce, in addition to the sensorimotor and propositional format, a third representational format, called *image-based knowledge*, which they think can supplement the knowledge-how variety. An example of image-based knowledge, according to the authors, is a high jumper's generation of a mental image of his planned jump before his running up. The authors argue that the mental image can take the role of controlling the performance of the action. The action, in cases of image-like knowledge, is thus "guided" by an image, just as motor reactions to bodily experience supposedly guide actions in the case of sensorimotor knowledge, and propositions supposedly guide actions in the case of propositional knowledge. Now, we think that it is far from clear how mental imagery or real images can "guide" actions. Even if we could clarify what "guiding" here means, there is at least a possible alternative interpretation of the role of mental images in acting, namely a common cause interpretation, according to which the performance of the action and the occurring of a corresponding mental image have a common cause, namely the neural processing that is the real cause of the different aspects of the performance, which thus "guides" the action. If such an interpretation was correct, the mental image would not be a "guide", but would merely be an epiphenomenon of the processing that produces the action (cf. Pylyshyn 1984). That this alternative interpretation exists shows that there is no clear indication that "image-based knowledge" is an independent third kind of knowledge that would legitimately supplement the classification.

On the other hand, research in psychology and cognitive neuroscience indicates that it is possible for non-conscious and non-linguistic types of knowledge (e.g., intuitive knowledge) to guide actual behavior, and which cannot be classified as "sensorimotor" knowledge.⁶ As long

⁵ Note that this does not necessarily mean that there is also no *conceptual* processing involved. As Stanley points out, declarative knowledge is sometimes defined as "knowledge that can be consciously and intentionally recollected", as opposed to procedural knowledge, which is taken to be "knowledge expressed through experience-induced changes in performance" (Stanley 2011b, p. 154). This reading of the procedural-declarative distinction proposes to fix it by translating it into the "explicit" versus "implicit"-distinction, where it seems to exactly match the distinction of two pathways of processing that are exhibited in the Milner/Goodale-experiments. But it cannot be taken as grounding the theoretical versus practical knowledge distinction. We agree with Stanley, who claims that practical knowledge can have a propositional content that is able to be verbalized—the subject can be able to linguistically express what she knows. Stanley's example is that of "physicians skilled at a procedure, who are also very good at describing to others how they do it"—they "possess explicit procedural knowledge" (2011, p. 159). Thus knowledge may be procedural in the sense of the above definition, and at the same time conscious and linguistically expressible.

⁶ A further type of practical knowledge that fulfills this criterion seems to be expert knowledge in areas that are not reducible to sensorimotor processing: e.g., chess or financial stock markets.

as there is no theoretical principle or framework from which the classification of possible forms of knowledge-how can be derived, there is in our opinion no reason to exclude such types of knowledge from the knowledge-how variety.

To give an example of non-sensorimotor knowledge-how: Bechara et al. (1997) examine the behavioral, subjective, and physiological states involved in intuitive decisions. Participants played a card game (known as the *Iowa gambling task*) in which they had to repeatedly (up to 100 times) pick cards from four different decks that could lead to wins as well as losses. In the long run, drawing from some decks led to smaller or larger winnings, and others to smaller or larger losses. The goal was to maximize one's play money on the basis of a \$2000 starting sum. Unknown to the participants, the card decks were pre-organized so that all decks would lead to wins in the first few draws. During the game two good decks turned out to be relatively safe (i.e., small wins and losses) leading to an overall net win, while two bad decks turned out to be relatively risky (i.e., large wins, but also large losses) leading to overall net loss.

The hidden win-loss dynamics and relations between the outcomes allowed the researchers to separate different periods of card-drawing behavior (standing for different knowledge states) during the game. A first *pre-punishment period* stood for the phase of early wins, a second *pre-hunch period* for the phase in which subjects started to get a feeling that there were differences between decks in terms of safety vs. risk-taking, a third *hunch period* for a phase in which subjects started liking or disliking certain decks without exactly knowing why this was the case, and a last *conceptual period* in which subjects were able to articulate their preferences and the reasons for these preferences between different decks. Not all participants reached the *hunch* or the *conceptual* period of the game.

Of foremost interest were observations made in the *pre-hunch period*. Normal participants, as opposed to participants with prefrontal damage, began to develop behavioral preferences for the good and less riskier card decks during this phase, and also showed anti-

cipatory skin conductance responses (reflecting minimal perspiratory reactions standing for fear responses) when planning to draw from riskier decks, although they were not consciously aware of these preferences, or of any physiological reactions during this phase of the game. Showing these non-conscious and involuntary responses during the *pre-hunch period* was prerequisite for subjects to advance to the *hunch* as well as the later *conceptual period*. A control group of prefrontally-damaged participants⁷ did not show any of the described physiological skin responses during the experiment, and their card-drawing behavior as well as their subjective reports showed no sign that they had developed knowledge of the riskier behavior associated with picking cards from certain decks.

The intuitive knowledge that is reflected in this study makes up for a further possible form of knowledge-how (for other examples of intuitive knowledge see Myers 2004; for intuitive core knowledge about geometry, numerosity, and ordering see Spelke 2000; for intuitive knowledge of experts see Dreyfus & Dreyfus 1986). Instead of adding new forms of knowledge-how in some arbitrary way, we think that it is more promising to look for a general criterion for knowledge-how that has the potential to explain the salient characteristics of knowledge-how, and at the same time is suited to give a framework for the possible surface forms in which knowledge-how may appear, including the sensorimotor and intuitive forms described above. We suppose that the most promising candidate for such a criterion is *non-conceptuality*.

4 How can propositional knowledge be non-conceptual?

How can it be true that the knowledge held by a person is “propositional” in its semantic sense⁸ without being conceptual? Would not the per-

⁷ Several studies (e.g., Barch et al. 2001; Bechara et al. 2000; Halligan et al. 2004; Stuss & Alexander 2007) indicate that lesions of the prefrontal cortex can lead to a number of cognitive and affective problems, most notably working memory problems, deficits in executive functioning such as planning, goal selection, task monitoring, deficits in inhibiting thought and action impulses, problems in outcome anticipation, and risk-taking behavior.

⁸ Note that we have accepted Stanley's thesis that all knowledge is propositional in *that* sense.

son necessarily need a grasp of the concepts a proposition is “composed of” in order to have knowledge of that proposition? The answer is that in order to have *conscious* knowledge of a proposition given in *linguistic* form it is necessary to have a grasp of the concepts of which the linguistically-given proposition is composed. But Stanley’s notion of knowing a proposition is not restricted to linguistically-given propositions. For example, if Hannah knows the proposition that “this way is a suitable way for me to ride a bicycle”, her way of knowing this proposition is a *practical* way of knowing that does not include knowledge of linguistic entities, but shows up by manifesting dispositions to react to certain kinds of bodily experiences. Thus, as much as knowledge-how is involved, it is possible to have knowledge of a proposition without being able to grasp the concepts the proposition is “composed of” when given in a linguistic form. The case can be made plausible by looking again at the Milner/Goodale-experiments: although the patient DF knows “how to put a card into a vertical slot”—and thus knows a proposition—due to a defect in her ventral pathway she is not able to have a conceptual understanding of the linguistic components of that proposition.

Stanley (2011b) has formulated objections to conceptions of non-conceptual content, at least when they are directed against propositionality *tout court*, as for example in Dreyfus (2007), according to whom “embodied skills [...] have a kind of content which is non-conceptual, non-propositional, non-rational [...]” (p. 360). His main argument is that ascriptions of knowing-how create opaque contexts (Stanley 2011b, p. 168). But this argument does not seem very strong, if seen from Stanley’s own perspective of a dispositional reading of ways of knowing a proposition in the case of knowing-how. How the objects occurring in the propositional content are conceptualized does not make any difference to the subject’s knowing the proposition, namely his being disposed to react to his own bodily experiences in a certain way (think of the guitar player). Thus, the dispositional reading of propositional knowledge is simply not compatible with the proposed fact that proposi-

tional contents are individuated by concepts. Instead, it implies that, in case of knowledge-how, persons have propositional knowledge that is indeterminate with respect to any conceptualization of the objects occurring in the propositional content. We therefore object to Stanley’s claim that “I cannot be said to know how to ride a bicycle if I have no clue what a bicycle is” (Stanley 2011b, p. 170). Someone can be able to manifest a well-determined disposition with respect to riding a bicycle, whatever conceptual understanding, if any, he has about bicycles.

In face of the DF-case in the Milner/Goodale-experiments, Stanley admits that:

[...] DF cannot accurately report on the orientation of the slot, whereas the normal agent can. DF’s knowledge of how to put a card into a slot is propositional knowledge that is based on a non-conceptual understanding of the orientation of the slot, understood here in the sense of an understanding of the orientation of the slot that is not available to conscious apprehension. She is able to have propositional attitudes about a way of posting a card into a slot in virtue of this non-conceptual understanding of orientation, yielded by her intact dorsal processing pathway. In contrast, the normal agent does have consciously available knowledge of the orientation of the slot before she acts. This is a difference between DF and the normal agent, but not one that can be used to deny that DF’s action is guided by propositional knowledge of how to put a card into a slot. (Stanley 2011b, p. 172)

In the remaining sections, we will follow the path opened by the suggestion that knowledge can be propositional without being conceptual. Whereas we hope to have shown that the propositional/non-propositional-distinction is not fruitful for explaining practical knowledge, we argue that the conceptual/non-conceptual distinction does have this potential. The idea, following Stanley’s proposal, is that knowledge-

how is, in general, knowledge of propositions by way of non-conceptual understanding. But we do not stick to the definition of “conscious apprehension” that in the DF-case indeed coincides with conceptual grasp. There can be conceptual grasp even in the absence of conscious apprehension (as it seems to be the case for certain animal species where the presence of consciousness is at least doubtful). Instead we take recourse to a minimal conception of “conceptuality” that has been developed by Newen & Bartels (2007) in the context of animal concepts. This minimal conception does not depend on consciousness. First, however, we shall explore the already-noted peculiarities of practical knowledge. It is these peculiarities that a fruitful conception of knowledge-how, based on the contrast between “conceptuality” and “non-conceptuality” needs to be able to explain.

5 The peculiarities of practical knowledge

An adequate meta-theory of human knowledge should be able to account for empirical differences observed when people use practical rather than theoretical knowledge in the most general terms, and be able to deliver an explanation for these differences. The starting point for the need to distinguish between practical and theoretical knowledge is the behavioral and neurological differences or dissociations in performance in different sensory, motor, or cognitive tasks, e.g., performance differences between experts and novices, between normal and prefrontal patients, between DF and IG. In actual research observed behavioral or neurological differences and dissociations are often accounted for by describing them in terms of polar opposite knowledge attributes or effects. In our understanding this is a first step in the direction of a theory of knowledge-how, even if it is still short of delivering a satisfactory explanation of the observed behavioral and neurological differences.

In the cognitive science and psychological literature, one finds the following polar opposite ascriptions of attributes of knowledge-how as opposed to knowledge-that:

A. Context-bound versus context-free knowledge. Knowledge-how is specific to the domain or the situation of its use, whereas knowledge-that is not. In other words, knowledge-how is about *situational* skills, while knowledge-that is about *general* facts (e.g., Clark 1997; Clancey 1997). For example, throwing a javelin and anticipating its movement when it leaves the hand is a case of context-bound knowledge, whereas calculating the biomechanical forces needed for optimal performances (e.g., the ballistics of an optimal flight trajectory) is an instance of context-free knowledge. Chess experts as compared to novices have superior context-bound knowledge of constellations of chess figures, which helps them to reproduce specific shortly-presented board situations from memory. However, their superior knowledge does not help expert chess players to reproduce random constellations of chess figures from memory, as their skill for applying context-bound perceptual chunking mechanisms on meaningful constellations of figures does not prove beneficial.

B. Impenetrability versus penetrability of knowledge. Knowledge-that is penetrable by other cognitive processes or meta-processing, whereas knowledge-how is impenetrable (Pylyshyn 1984, 1990). Impenetrability means that use of knowledge-how is not changed by internally (e.g., beliefs, goals) or externally (e.g., distracting stimuli) triggered cognitive processes. One example is subitizing, i.e., the rapid, accurate, and confident estimation of the number of displayed elements (e.g., stones), which works fine and is robust against internal or external distractions. In contrast, the use of knowledge-that to determine the number of regularly arranged objects by counting them or doing mental arithmetic (e.g., adding over rows of elements $3+5+4+2+\dots$) is prone to interferences from internally- or externally-activated cognitive processes. If athletes change the order of different sensorimotor sub-processes (e.g., in technical sport disciplines such as high-jumping or hitting a golf ball), they can encounter considerable problems and might need additional time and effort to build up new

knowledge-how. Not so well-trained movements (e.g., dancing steps in beginners) can be more easily rearranged.

C. Implicit versus explicit knowledge. Use of knowledge-how takes place largely outside of awareness and hence cannot be verbalized, while knowledge-that is to a large degree consciously available and can be verbalized. In the last decades psychological research has made substantial progress in distinguishing between implicit and explicit forms of human learning, memory, and information processing (e.g., [Dijksterhuis & Nordgren 2006](#)). People learn the grammar of natural language or internalize their society's norms implicitly, that is, without conscious knowledge of the principles that guide their language use or their social behavior (e.g., [Reber 1989](#)). Implicit memory is, for example, displayed in cases of amnesia, in which patients are not able to explicitly recall previously-presented items or events from memory, while performances on tasks that do not require explicit memory such as perceptual priming or sensorimotor skills are undisturbed and virtually normal (e.g., [Tulving & Schacter 1990](#)).

D. Automatic versus effortful processing. Use of knowledge-how is automatic in the sense that it requires little attentional monitoring or guidance, and in the sense that its demands on working memory are quite low ([Bargh & Chartrand 1999](#)). Use of knowledge-that is generally more effortful, and can be shown to require significant attentional as well as working memory resources ([Hasher & Zacks 1979](#)). Good examples of the distinction between the automatic and effortful use of knowledge can be found in the domain of spatial cognition: Blindfolded navigators (animals as well as humans) complete triangles by returning to the starting point on the basis of automatic vestibular and kinesthetic path-integration mechanisms (knowledge-how), while only humans are able to use effortful geometrical calculations (knowledge-that) to find their way back to the origin of the outbound travel. Experiments show that simultaneous secondary tasks (e.g., to-be-ignored spatial movements vs. counting operations) differentially affect the one or the other type of knowledge processing ([May & Klatzky 2000](#)).

To give another example from research on spatial cognition: Wayfinding on the basis of multimodal sensory inputs from the surroundings and from automatic updating is very different from the quite effortful and highly disturbable use of knowledge-that that results from listening to verbal route-descriptions or maps ([Montello 2005](#)).

E. Continuous versus discontinuous processing. Use of knowledge-how expresses itself in smooth and continuous processing, while knowledge-that is normally reflected in step-by-step processing along a discontinuous path of intermediate knowledge states. Recent dynamic systems accounts of the sensory, motor, and cognitive processes underlying human knowledge use describe these differences in terms of different attractor landscapes of mental or neural state spaces ([Spivey 2008](#)). Research into children's cognitive development, for example, reveals that there are two levels of spatial location coding in memory. In a first phase, children learn to code the metric distance between locations (e.g., allowing them to find previously hidden objects in terms of distance from the sides or the corners of a rectangular sandbox). In a second phase, children attain the ability to impose organization on their spatial knowledge (e.g., allowing them to divide the spatial layout in hierarchical subsections or regions). The shift from the first to the second level reveals itself in changes in the types of spatial errors (discontinuous vs. continuous distributions) children commit when locating hidden objects ([Newcombe & Huttenlocher 2000](#)).

This list of opposing attribute pairs is probably not complete, but seems a good starting point for our purposes. It can be thought of as a general description and characterization of practical knowledge in contrast to theoretical knowledge. Not every single case of knowledge use will be easily describable by means of the list, or will even require a full description along all opposing attribute pairs. However, chances are good that the overwhelming majority of cases will be adequately described by using such a set of opposing attributes, and, generally, the profile over the five attributes will correctly apply. We will ar-

gue that this list of attribute pairs, together with their predominant assignment to the one or other knowledge variety, is what an adequate and fruitful theory of knowledge-how vs. knowledge-that should be able to account for.

6 Conceptuality as a demarcation criterion for knowledge-that versus knowledge-how

We propose conceptuality as a demarcation criterion for knowledge-that in relation to knowledge-how that is able to account for the peculiarities of both knowledge types outlined in the last section. In order to show that conceptuality can do the job, we have, in a first step, to establish a notion of *concept* that does not *presuppose* in an obvious way characteristics of knowledge-that, i.e., the notion we look for should not entail that concepts are essentially linguistic entities enabling persons to verbally express knowledge-that. What we then need, in a second step, is a notion that entails some fundamental and (hopefully) non-contentious assumptions about necessary conditions for concept possession in terms of abilities. Characterizing concepts in the form of abilities necessary for concept possession should enable us to show that having those abilities necessary for concept possession is exactly what is needed for the subject to overcome the peculiar limitations accompanying knowledge-how, and thus to gain access to the level of knowledge-that (see section 5).

In shaping the sought-for notion of conceptuality we take recourse to work by Allen & Hauser (1991), Pylyshyn (1990), and Newen & Bartels (2007). Allen and Hauser have claimed that, from the perspective of interpreting the behavior of systems including human and animal organisms as much as artificial systems, the ascription of genuine concepts requires “evidence supporting the presence of a mental representation that is independent of solely perceptual information” (Allen & Hauser 1991, p. 231). The criterion of independence, as called for by these authors, is that it enables the system to show flexible

behavior, in contrast to the performance of rigid mechanisms:⁹

[I]ndependence in this sense entails that the responses of the animal to a certain stimulus are not just ‘driven by’ that stimulus, and are also not to be explained as cases of stimulus generalization, i.e., discrimination by a mechanism responsive to a single basic stimulus. (Newen & Bartels 2007, p. 287)

If the reactions of a system to a given stimulus can be modified by the presence of additional stimuli representing the peculiarities of the situation in which the reaction occurs, the system will be first able to *generalize*—as rudimentary as that ability may be—the information received. It is then that we can legitimately ascribe the possession of concepts: “First, an organism whose internal representations are concept-like should be able to generalize information obtained from a variety of perceptual inputs and use that information in a range of behavioral situations” (Newen & Bartels 2007, p. 287).

We thus arrive at a *criterion for conceptuality*, which can be called, following Allen (1999), the “transcendence of particular stimuli” or, in terms given by Pylyshyn (1990), the “criterion of informational plasticity”. Essentially the criterion requires the “possibility of the modification of a response in the light of additional information” (Allen 1999); the kind of response has to depend, crucially, on other sources of information (cf. Newen & Bartels 2007, p. 287).

The criterion considered above is still not sharp enough. As long as we do not further specify the “modification of a response” occurring “in the light of additional information”, each sort of extension of the processing capacities of an individual would count as reaching the level of “conceptuality” if only this extension enables the individual to integrate some additional

9 One example of a “rigid mechanism” is the behavior of ants responding to the presence of acidic byproducts from the decomposition of dead con-specifics: in tests they rigidly remove anything from the nest that is painted with oleic acid, even live con-specifics.

source of information into its behavioral repertoire. Thus *diversification* of processing capacities could then not be distinguished from *transition* from non-conceptual to conceptual processing capacities.

To get a criterion for conceptuality it is required that the “modification of a response” mentioned above concerns *classificatory* behavior. The “additional stimulus”, in that case, not only has to work as a switching point, opening one or the other pathway for a response *within* a non-conceptual behavioral pattern, it also has to stand for a *category*, according to which the actual behavioral pattern can be classified.

One example of additional stimuli characteristics standing for a category has been described by Newen & Bartels (2007) with respect to the conceptual abilities of the grey parrot Alex (Pepperberg 1999). In order to be able to form elementary color concepts, for example the concept “green”, Alex should not only be able to generalize over a class of similar stimuli and thus to identify a sample of different green objects, but should additionally be able to represent green *as a color*. Only then could we ascribe to him the ability to classify green objects according to a well-determined class concept.

The test items by which Pepperberg examined the classification abilities of the animal were, for instance, “What color?” or “What shape?”. These questions should

[...] determine if he [Alex] could respond not only to specific properties or patterns of stimuli [e.g., to green objects], but also to classes or categories to which these specific properties or patterns belong [...]. Could he, for example, go beyond recognizing what is, or is not, ‘green’ to recognizing the nature of the *relationship* between a green pen and a blade of grass? (cf. Pepperberg 1999, p. 52)

It happened that Alex was indeed able to classify the given “key” stimulus, e.g., a green, round object, visually presented to him, as “green” or “round” according to different dimensions (e.g., color or shape) represented by

additional auditory stimuli. His choice of response (“green” or “round”) turned out to depend crucially on the “additional information” given in form of the auditory stimulus. As such, Newen and Bartels concluded that “Alex was able to represent different properties while having only one and the same visual input of an object.”¹⁰

With this example in view, Newen & Bartels (2007) formulated the following requirements for the possession of concepts—for instance, the concept “red”: A cognitive system has the concept “red” only if (i) it has relative stimulus independence such that it depends on some additional mechanism—which detects and weighs stimuli other than the key stimulus of redness—to determine that the system focuses on redness while perceiving a red square, in contrast to some other property; and (ii) the property of being red is represented as an instance of the dimension “color”.¹¹

Note that the above-mentioned definition of conceptuality does not only require the existence of some “additional stimulus” to which the individual has to be responsive, but that there has to be some additional internal *mechanism* of processing by which the individual is able to “detect and weigh” a specific additional stimulus as standing for a *category* (e.g., “color”). The responsiveness of the individual to that stimulus shows up when it focuses its attention on those aspects of a scene, or to those items of a behavioral pattern, which exemplify the respective category.

Another example would be the balancing of coffee cups by a waiter in a restaurant. Let us assume that the waiter for some time possesses the ability to balance cups of different shapes without spilling coffee, and without consciously attending to a particular cup, or the

¹⁰ Cf. Newen & Bartels (2007), p. 293. That the auditory stimuli “What color?” or “What shape?” were really understood by Alex as asking for the respective category was tested by Pepperberg using additional auditory signals of the form “What’s same?” and “What’s different?” The correct response would be the label of the appropriate category, e.g., the mastery of categories could be verified in the sense that Alex successfully identified the essential functional role of category terms like “color” or “shape” as dividing the objects of the world into “sameness” equivalence classes.

¹¹ Cf. Newen & Bartels (2007), p. 296. These conditions are only two of a total of four conditions. But only these two matter with respect to our discussion.

shape of a particular cup that he is currently dealing with. At some point he is told that there are essentially two different kinds of cups, one high and cylindrical, and the other flat and bowl-shaped (this information is the “additional stimulus”). The waiter “detects and weighs” the additional stimulus by focusing his attention, from that time on, to his own specific handling of cups, depending on the sort of cup a particular exemplar belongs to. He might then detect that he had previously managed to deal with both kinds of cups efficiently and without spilling coffee without even noticing that liquids in both reacted in different ways to his movements. The waiter’s behavior has switched from a former “non-conceptual” dealing with coffee cups to a form of behavior that is “conceptual” in the sense of exhibiting an additional ability, namely the ability to classify his own performance in balancing coffee cups according to a category (in this case the cups’ shape).

How does such a notion of conceptuality relate to Evans’ notion of non-conceptual knowledge in terms of first-person dispositions that we made use of in sections 2 and 4? If the possession of concepts is constituted (in contrast to non-conceptual cognitive processing) by the gaining of additional abilities, it should be made plausible how those additional abilities connect to a non-conceptual basis in Evans’ theory.

In our treatment of his theory, we followed an interpretation of Evans’ work as implying that non-conceptual knowledge relies on the disposition to have one’s own motor reactions be determined by sensory and kinesthetic information that is mediated by either some external object or by one’s own body. Again, the waiter dealing with the coffee cups may help to illustrate the point. The waiter’s experienced handling relies on a disposition to have his motor actions determined by the multimodal sensory information that is mediated by holding coffee cups in his hands. The waiter’s knowledge-how to balance the cup might be completely independent of any conceptual reference to coffee cups. He could be the experienced waiter that he is—at least with respect to his balancing ability—without even knowing in a conceptual way “what a coffee cup is”. Reference to the ob-

jects he is dealing with was accomplished only by being able to react in a coordinated way to sensorimotor information originating from handling these objects.

At the time he is told that coffee cups come in two different shapes, his cognitive system enables him to use that information such that he begins to rely on a category (i.e., a cup’s shape) in order to refer to coffee cups, and to classify his own balancing behavior according to the objects thus categorized. He reaches, in some minimal way, the level of conceptual knowledge, since he now begins to identify both, that is, the objects and his behavior with respect to these objects, by conceptual means.

7 Explaining the peculiarities of knowledge-how by means of conceptuality

Equipped with an adequate notion of conceptuality, we now proceed to show that concept-possession is exactly what is needed for a cognitive system to overcome the specific limitations associated with knowledge-how, and hence be able to gain access to the level of knowledge-that. Why exactly is it necessary for a system to possess concept-like representations in order to have knowledge-that as opposed to knowledge-how?

1. *Context-bound versus context-free knowledge.* For this polar contrast the answer, in short, will be that conceptual representations are precisely those representations which make the subject able to generalize information over a range of different behavioral situations. Conceptual representations are, as we have seen above, representations whose functional role is to classify aspects of a scene, or items of a behavioral pattern, according to a certain category. This is the reason why only conceptual knowledge (whether verbally expressible or not) can enable overcoming the limits of situationally-bound use. Intuitively sampling objects, for example, on the basis of some salient similarity criterion, is a manifestation of knowledge-how, because it depends on situational features—for instance

that the situation represents some sort of average type to which the corresponding behavior is adapted. To overcome such situational limitations, categorical distinctions have to be introduced that enable the subject to transfer his or her knowledge partly to new situations that deviate, for instance, with respect to the objects that have been treated in standard situations. For example, a waiter who starts to work in a new restaurant using only coffee cups of one type, that is slightly higher than the large type used in the former restaurant, might fail in balancing the cup as long as he only takes recourse to his knowledge-how; but he might be more successful if he relied on a conceptual understanding of a distinguished large-cup-technique. In the same way, anticipation of the flight of a javelin is a situation-bound ability, since it depends on relatively rigid processing of visual information and proprioceptive mechanisms that are well-adapted to a range of standard cases, but fail for cases outside that range. If the case is exceptional (e.g., strong wind from behind), the subject can only attain success by analyzing the influence that this particular external condition will have on the standard performance. The same applies for knowledge-how expert chess knowledge, which fails in cases of random constellations because the experts' expertise in evaluating the scene is dependent on average situational features. The occurrence of "new" constellations requires extracting general properties from the scene, and thus has to be done by means of conceptual representations.

2. *Impenetrability versus penetrability of knowledge* is a contrast almost built into the notion of conceptuality that we propose. Non-conceptual representations are non-receptive for additional stimuli that could yield classificatory behavior. They have to be non-receptive ("impenetrable") in order to avoid interferences that could disrupt the more or less rigid mechanisms by which some well-defined type of behavior is regularly produced. Impenetrable knowledge-how, for example, is manifested by navigating ants cal-

culating their way home according to some rigid computational processes that are deployed on the basis of a small number of parameters. If the experimenter interferes with the process by repositioning the ant, the mechanism still works as it would have done without relocation, with the result that the ant misses the nest by exactly the distance and direction to which it has been repositioned by the experimenter (see Bartels & May 2009). In contrast, conceptually-based processing has to be penetrable in order to guarantee that categorical information can be extracted from the scene according to specific stimuli (in this case the repositioning stimuli) and used in evaluating the result produced by rigid processing up to the time of repositioning.

3. *Implicit versus explicit knowledge*. This distinction refers to whether or not the knowing organism has knowledge of the *rules* governing its knowledge application. For example, people learn the grammar of their natural language or internalize their society's norms implicitly, that is without knowledge of the principles that guide their language use or their social behavior. In such cases people represent rules only *indirectly*, by means of dispositions to have their reactions determined by the linguistic or social information in a way that can be recognized by their fellow subjects as to be in accordance with the rules. In contrast, explicit knowledge requires *direct* representation of rules, objects, or properties. The waiter in the restaurant, for example, after having achieved knowledge—that about his balancing of coffee cups, is able to refer directly to two sorts of cup shape, the high and cylindrical or the flat and bowl-shaped, respectively. In other words, he must be able to represent properties; if so, the waiter would, for instance, be able to draw inferences from the contents of his knowledge. Now, a person's ability to produce attribute-representations of objects presupposes the ability to apply *categories* to his or her own experience. For example, the waiter is able to represent coffee cups as high

and cylindrical objects because his capacities include the ability to apply the category of shape to the objects he is balancing. Thus, a person's possession of *conceptual capacities* is a condition that has to be fulfilled for his or her knowledge to be explicit. Moreover, given that the additional conditions for *conscious* processing of cognitive representations are fulfilled, the subject would then be able to consciously think about and to draw conscious inferences about the objects. In addition, *verbalizability* of knowledge depends on the presence of this conscious form of explicit knowledge.

4. *Automatic versus effortful processing.* As we have argued in (B), conceptuality entails openness to penetration. Now, if cognitive processing is receptive to penetration, additional costs in terms of attention and additional processing necessarily occur. If the ant's navigation mechanisms were receptive to a certain type of repositioning, it would have to use additional computational pathways for processing "repositioning information" and would be in need of additional calculation to determine the influence of the particular repositioning on the result produced by rigid calculation of the expected path back home.
5. *Continuous versus discontinuous processing.* Knowledge-that is characteristically used in a step-by-step manner with intermediate knowledge states (discontinuous), whereas knowledge-how appears to be grounded in smooth and fluent processing without intermediate states (continuous). The difference can be accounted for by the fact that knowledge-that is grounded in concept-based processing allowing for and instantiating discrete inferential steps, whereas knowledge-how is based on concept-free processing without clearly-defined intermediate knowledge states. An observable consequence of the continuous nature of knowledge-how is that lapses in knowledge use result in graded errors, or continuous distributions of errors (e.g., gradual precision losses of sensorimotor movements),

while lapses in use of knowledge-that express themselves in categorical errors, or discontinuous error distributions (e.g., switches of categories or total failures to come up with a result).

It is beyond the scope of the present article to give an outline of a research agenda for empirically confirming and underpinning the present account of knowledge-how compared to knowledge-that. Different examples of potential research areas and experimental paradigms have been pointed out in the preceding sections (e.g., numerosity judgments, spatial memory, intuitive knowledge use). The most convincing way to support the adequacy of the conceptuality criterion for distinguishing between knowledge-how and knowledge-that will be to run new experiments in these or other research areas that reveal behavioral and/or neural dissociations that comply with the distinction between concept-driven vs. concept-free knowledge-use along the lines of the different peculiarities of practical knowledge outlined above.

8 Conclusion

We have shown that *propositionality* is, in none of its three main senses, an adequate and useful demarcation criterion between knowledge-how and knowledge-that.

First, in its *semantic* sense (e.g., Stanley 2011a), propositionality applies to both knowledge-how and knowledge-that, and thus *a fortiori* cannot be successfully used as a demarcation criterion.

Second, in its "*language of mind*"-sense, propositionality applies to knowledge representation. As we have shown, the way in which a particular piece of knowledge is represented is independent from the type of knowledge exemplified by this piece of knowledge. Thus, again, this sense of propositionality is not useful as a demarcation criterion.

Third, propositionality in the sense of *linguistic, consciously available propositions* is without doubt a central phenomenological trait of knowledge-that as opposed to knowledge-

how. On the one hand, this sort of propositionality offers a rather trivial demarcation criterion. On the other hand, as a mere replication of a well-known phenomenological distinction, it can in no way be used to *explain* the different peculiarities characteristic of knowledge-how versus knowledge-that. *Anti-intellectualists* have tried to fill the void corresponding to non-propositionality, according to this third sense of propositionality, by declaring specific knowledge formats such as *sensorimotor or image-like* knowledge (Newen & Jung 2011). In our view, it is doubtful whether, with such an eclectic way of characterizing knowledge-how, a satisfactory and complete classification of knowledge-how could be achieved. We have, for example, argued that “intuitive” knowledge would be a further legitimate candidate for the list, and that it is, in all probability, not the only further candidate. Identifying different forms of knowledge-how without any well-grounded theoretical basis for the different forms will probably be of limited use for empirical research in cognitive science, neuroscience, and psychology.

In sum, “propositionality” can in none of its different senses provide a useful demarcation criterion for an empirically-fruitful theory of knowledge-how. Therefore, we go with the *intellectualists*, at least with respect to rejecting the propositionality criterion, but we depart where intellectualists fail to provide positive accounts of the obvious phenomenological and empirical peculiarities making knowledge-how distinct from knowledge-that. In contrast to the intellectualist position, we have provided a minimal notion of *conceptuality* as an alternative demarcation criterion. We suggest that conceptuality gives a sound basis for a fruitful theory of knowledge-how, and we have tried to provide support to this suggestion by showing that by means of an adequate notion of conceptuality, five central peculiarities of knowledge-how as compared to knowledge-that can be accounted for. Future research will have to show whether the framework for practical knowledge described here fulfills the empirical promise we think it has.

The Semantic Reading of Propositionality and Its Relation to Cognitive-Representational Explanations

A Commentary on Andreas Bartels & Mark May

Ramiro Glauer

Bartels and May propose an explanation of the difference between practical and theoretical knowledge in terms of the involvement of non-conceptual and conceptual representations, respectively. They thereby want to alleviate a shortcoming of Stanley's intellectualist theory of knowledge-how that cannot explain this difference. In this paper it is argued that an appreciation of the fact that both Stanley and Bartels and May employ a semantic reading of propositionality makes clear that their endeavors follow quite different goals. While Stanley gives an analysis of how we talk about knowledge-how, Bartels and May are interested in underlying cognitive representations. From Stanley's analysis of knowledge-how, nothing can be inferred about cognitive representations. The semantic reading of propositionality is then spelled out with the help of the idea that ascriptions of propositional attitudes are (like) measurement statements. Some considerations from measurement theory show how propositions can be used to reason about psychological states without themselves having to play any role in a person's psychology.

1 Introduction

Bartels and May's paper presents the outlines of a theory of practical knowledge. The paper consists of a discussion of intellectualist and anti-intellectualist approaches to knowledge-how, a characterization of a range of behavioral particularities of practical knowledge, and the outlines of a theory that attempts to explain these behavioral particularities in terms of involved underlying mental representations. The discussion is remarkably clear, and the explicit exposition of what is to be explained by a theory of practical knowledge is a great virtue of the paper. For our purposes here, a discussion of the initial characterization of practical knowledge and its attempted explanation in terms of conceptual and non-conceptual capacities would help us assess the import of this paper. To my valuation, however, the discussion also reveals some very important features of the relation between knowledge ascriptions (and, to that effect, ascriptions of propositional attitudes in general) and descriptions of underlying cognitive structures and representations. Most importantly, Bartels and May employ Stanley's semantic reading of propositionality, according to which the propositionality of some mental state depends on whether a proposition is mentioned in the ascription of that state. As a result, questions concerning cognitive structure and underlying representations are largely detached from considerations concerning ascriptions of propositional attitudes. I think this is a great advantage, because we are not led to read back the relational grammatical structure of ascriptions of propositional attitudes onto psychological states themselves. Here I want to focus on this semantic reading of propositionality and ask about its effects on the relation between Bartels and May's proposed explanation of practical knowledge and Stanley's theory of knowledge-how. The result will be that Stanley and Bartels and May attempt to explain quite different things. While Stanley proposes a theory of how we ascribe knowledge-how to each other, Bartels and May are interested in underlying cognitive processes. The semantic reading of propositionality, however, only goes halfway towards disen-

tangling these different endeavors. A further step can be made with the help of the idea that ascriptions of propositional attitudes are (like) measurements. I will call this the *measurement view* of ascriptions of propositional attitudes. Considerations from measurement theory can then be used to shed further light on the relation between ascriptions of propositional attitudes and the underlying cognitive representations. The result will be that nothing can be inferred about cognitive structure from the structure of ascriptions of propositional attitudes alone. Propositions need not play any role in a theory of cognition. Nonetheless, there is a clear sense in which propositional attitudes are real. They are the measurement-theoretic representatives of behaviorally relevant states. In closing I will note that, given the close connection between concepts and propositions, a semantic reading of conceptuality might be desirable. For Bartels and May, this would mean that the difference between practical and theoretical knowledge should not depend on the conceptuality of the underlying representations. But given their definition of conceptuality, this would merely require a change in nomenclature.

Before going into the discussion of a semantic reading of propositionality, of measurement and its bearing on the relation between Bartels and May's proposed explanation of practical knowledge and Stanley's theory of knowledge-how, I will briefly summarize Bartels and May's line of argument.

2 The semantic reading of propositionality and the explanation of practical knowledge

Bartels and May set out to clarify what a theory of knowledge-how should provide and begin to give the outlines of such a theory. In their view, a theory of knowledge-how should explain the difference between practical and theoretical knowledge, the former being characterized by a number of distinguishing features. The proposal, then, is to explain this difference in terms of the reliance on non-conceptual capacities (or repres-

entations) in the case of practical knowledge and on conceptual capacities in the case of theoretical knowledge, instead of using propositionality as the main criterion. Their account of what is to be captured by a theory of know-how, and their proposed solution, are preceded by an illuminating discussion of the shortcomings of each side of the intellectualism vs. anti-intellectualism debate.

2.1 Merits and shortcomings of intellectualism

In short, Bartels and May claim that the intellectualists are right to concede that the distinction between knowing-how and knowing-that cannot be made in terms of the propositionality of knowing-that. Three readings of propositionality are distinguished:

- a representational reading, according to which the propositionality of some mental state depends on a sentence-like mental representation being tokened,
- a conscious-availability reading, according to which propositional representations are consciously available and can be expressed linguistically, and
- a semantic reading of propositionality, according to which the propositionality of some mental state depends on whether it is attributed as a propositional attitude.

It is argued that all three readings of propositionality are inapt for making the distinction between practical and theoretical knowledge. I take it that both the representational reading and the conscious-availability reading are implausible for independent reasons—the representational reading presupposes a language of thought, while the conscious-accessibility reading can arguably be undermined by considering cases in which someone would be said to know something she need not be able to express verbally, in terms of the proposition in question (this might involve some non-obvious logical consequences of one’s occurrent beliefs). In addition, the semantic reading is what our best in-

tellectualist account of knowledge-how, namely Stanley’s, employs, and Bartels and May follow Stanley’s analysis here.

According to the semantic reading of propositionality, whether some psychological attitude is propositional depends on the semantics of the locutions used to ascribe such attitudes. And our best current theories of the semantics of knows-wh locutions—i.e., of locutions that involve the verb “know” and some question word such as “who”, “where”, “what”, “when”, or, to that effect, “how”—tells us that knowledge-how is propositional—just as knowledge-that is. But as a result, it is argued, intellectualists are not able to explain the respective peculiarities of practical and theoretical knowledge—both are propositional. This is identified as the major shortcoming of intellectualism.

2.2 Merits and shortcomings of anti-intellectualism

The anti-intellectualists, on the other hand, lack a systematic criterion for the distinction between knowledge-how and knowledge-that. The introduction of different kinds of knowledge, based on different representational formats, by some anti-intellectualists is taken to be *ad hoc* (e.g., image-based knowledge and sensorimotor knowledge by Jung & Newen 2011). It is not based on an independently identified set of underlying representational formats that would explain the characteristic behavioral differences. Instead, it merely attempts to find alleged mental representational formats that intuitively fit the distinction (cf. Bartels & May this collection, p. 7). Further arguments to the effect that intellectualism is a non-starter are ineffective against Stanley’s (2011) version of intellectualism (cf. Bartels & May this collection, pp. 10-11). An attack from Toribio (2008, reference taken from Bartels & May this collection) to the effect that Milner & Goodale’s patient DF (cf. Milner & Goodale 1995) could not possibly have propositional knowledge of how to put a card into a slot presupposes that knowledge-how involves a *conceptual* grasp of how something is done or of what is acted upon. Roughly, Toribio argues that DF does not have proposi-

tional knowledge of how to put the card into the slot because she cannot report on the orientation of the slot. But Stanley acknowledges that some propositional attitudes involve the *non-conceptual* grasp of relevant states of affairs. In the case of DF, this involves the non-conceptual grasp of the orientation of the slot (cf. Stanley 2011, p. 172).

As a result, neither intellectualists nor anti-intellectualists provide a satisfactory account of knowledge-how. But both get some things right. The intellectualist is right in taking both knowledge-that and knowledge-how to be propositional. And the anti-intellectualist is right in requiring an explanation of the difference between these two kinds of knowledge, presumably in terms of underlying cognitive structures or kinds of mental representation.

2.3 Non-conceptual capacities as an explanation of practical knowledge

Bartels and May, then, pick up on the idea that practical knowledge might involve non-conceptual capacities, while theoretical knowledge is conceptual. They list a number of received peculiarities of practical knowledge that are to be captured by a theory of practical knowledge. And it is proposed that these peculiarities are the same peculiarities that result from a reliance on non-conceptual representations. Among the differential features of practical knowledge are its being context-bound, implicit, and automatic and effortless. Non-conceptual capacities, it is argued, just have these features. The result is a position that is intellectualist in form, because all kinds of knowledge are propositional, but anti-intellectualist in spirit, as the distinction of practical vs. theoretical knowledge is maintained. Practical knowledge is not reduced to theoretical knowledge; rather, the former is a non-conceptual form of knowledge while the latter is conceptual.

One effect of drawing the distinction between practical and theoretical knowledge in terms of *conceptuality* is that Bartels and May must follow Stanley in accepting non-conceptual forms of propositional knowledge. Patient DF cannot report on the orientation of the slot, but

nevertheless she non-conceptually grasps its orientation such that she is able to put the card into the slot. Due to her successful performance, she is said to know how to put the card into the slot, making this particular form of knowledge-how non-conceptual. This somewhat departs from tradition, where concepts are usually taken to be the constituents of thoughts, while thoughts are likely understood in a Fregean way as the intensions of sentences, i.e., propositions. It makes sense, though, because propositionality is understood semantically while conceptuality is not. Whether some cognitive capacity is conceptual or non-conceptual is thought to depend upon the kind of mental representation involved.

3 Knowledge ascriptions and mental representations

3.1 Analyzing knowledge ascriptions vs. explaining cognitive capacities

Now, it's easy to believe that the whole debate around propositions, concepts, non-conceptual representations, and cognitive structure is highly convoluted and that it is difficult to properly disentangle the different issues that lie behind a larger number of related debates. One important distinction, I take it, which is not always properly made, is whether one is concerned with what *someone* does (the whole person) as opposed to what his or her *cognitive system* does. What happens between Stanley's and Bartels and May's discussion of kinds of knowledge, then, is a shift from a personal-level perspective to a level at which the cognitive system is described.

Stanley formulates a theory of knowledge-how on the basis of an analysis of ascriptions of knowledge-how. And the subject of clear cases of appropriate knowledge-how ascriptions are persons. Their brains (or whatever else might realize their cognitive systems) can at best derivatively be said to know how to do something. This is made especially clear in Stanley's analysis, according to which knowledge-how involves first-person thought (cf. 2011, Ch. 3). If someone knows how to do something he knows

that a certain way of doing something is a way in which he could do it himself. It is hard to see how someone's cognitive system could have this kind of first-person thought in a non-derivative way.

Bartels and May, on the other hand, want to explain the particularities of practical and theoretical knowledge in terms of the involved underlying representations. As they put it at the outset of their discussion, “‘Explaining’ here is rather to be understood as showing how the realization of necessary conditions for the possession of concepts coincide with those conditions that have to be fulfilled in order to achieve the step from practical to theoretical knowledge, each characterized by their respective peculiarities. In other words, we search for ‘how-possibly-explanations’ of the peculiarities of practical versus theoretical knowledge” (Bartels & May [this collection](#)). “How-possibly-explanation” is a term from mechanistic accounts of explanation that characterizes attempted mechanistic explanations that are not yet well corroborated by an independent identification of the components of the alleged mechanism. Bartels and May clearly appeal to structures underlying cognitive abilities. In addition, they employ a notion of concepts that is further developed in Newen and Bartels (Bartels & Newen 2007), where it is made clear that concepts are kinds of mental representations (cf. [ibid.](#), p. 284). Their interest thus lies in the differences between the cognitive architectural realization of practical and theoretical knowledge, not in the ascription conditions of kinds of knowledge to persons. And, as said, among the virtues of Bartels and May's paper is the clarity of the exposition of what is to be explained by a theory of practical knowledge in the first place: the behavioral or functional peculiarities of practical knowledge.

I understand that making a distinction between different endeavors in philosophy of mind in terms of personal vs. sub-personal level explanations is not always a particularly attractive way to go about the problem. The personal level brings with it a number of loaded presumptions, for instance, concerning the import of norms for action and belief. And I do

not want to claim that such a rich conception of persons is involved in Stanley's discussion. Nonetheless it should be clear that Stanley is not interested in what the brain does, what its functional architecture is, or on which states it operates. He is interested in knowledge-how. And knowledge-how is something *someone* has: it's personal-level at least in the parsimonious way that it is something we attribute to each other.

In realizing that Bartels and May are really interested in the structure of cognitive systems possessing practical knowledge it becomes clear why they come to a conclusion that seems to be diametrical to what some other participants in the knowledge-how debate suggest. Bengson & Moffett (2007), for instance, argue that knowing how to do something is a matter of having a guiding conception of the way in which the subject of knowledge-how is to perform an activity. This captures that action guided by knowledge-how is a form of intelligent action—as opposed to something done by reflex, mere habit, or rote. It is an intellectual achievement to know how to do something. Bengson & Moffett (2007) argue that knowing how to do something requires an understanding of the activity at hand, and that understanding, in turn, is equivalent to the reasonable mastery of the concept that guides the action. Understanding is clearly something *someone* has; it is not a trait of his or her cognitive system that might rather be said to enable or mediate such understanding.

While the discussion in Bengson & Moffett (2007) sticks to the vocabulary of intellectual appraisal employed in the Rylean treatment of the topic, Bartels and May take a cognitive-psychological approach to the matter. For them, concepts are kinds of mental representations that serve to explain why someone has some ability. The notion of understanding does not figure prominently in their account. The difference to Bengson and Moffett's account can thus be traced back to different notions of what a concept is, which result from an interest in different perspectives on knowledge-how. Bengson and Moffett are interested in the conditions under which someone can be said to know how to do something, while Bartels & May want to ex-

plain the cognitive-psychological difference between practical and theoretical knowledge. When we adopt a semantic reading of propositionality and follow Stanley's analysis of knowledge-how, it becomes clear that these are very different endeavors. A theory of knowledge-how involves an analysis of what it is to ascribe such knowledge to someone; it is an investigation of the semantics of knowledge-how ascriptions and of our ways of talking. An explanation of the difference between practical and theoretical knowledge, on the other hand, tells us how corresponding abilities are realized by the cognitive system in terms of the employed representations.

One of the great virtues of a semantic reading of propositionality, then, is that it liberates us from drawing conclusions concerning cognitive architecture from the structure of ascriptions of mental states to subjects. Given that whether some mental state is propositional depends on the form of its ascription, there is no need to assume that the cognitive states described as propositional have to fulfill very specific conditions as to their structure and content. The correctness conditions for ascriptions of knowledge-how need not make reference to cognitive-architectural features of the subject of the ascription. And according to Stanley's analysis they don't. A knowledge state that is ascribed as propositional to some subject need not have propositional content itself nor be in any way structured such as to provide a vehicle for a propositional content. Indeed, Stanley (cf. 2011, p. 159) claims to have shown that having propositional knowledge states is entirely compatible with even an anti-representational conception of the mental. Nonetheless, knowledge-how is taken to be behaviorally real and efficacious, since it is implicated in certain actions and allows for explanations and predictions of behavior. We will shortly see how this can be so.

The liberation from cognitive-architectural commitments is somewhat occluded by Stanley, however, when he writes that he is interested in the *nature* of knowledge-how and that "[d]iscussions of semantics are often in fact discussions of metaphysics, carried out in the formal mode"

(Stanley 2011, p. 144). This appears to imply that ascriptions of propositional attitudes are understood realistically, and this in turn seems to be possible only if we take such ascriptions to describe real relations among subjects and mental representations to have the propositional content in question. This is the main motivation for a representational theory of mind (cf. Fodor 1987). Thus, an investigation into the *nature* of knowledge-how that comes to the conclusion that knowledge-how is propositional seems to employ a representational reading of propositionality.

Fortunately, this strong form of correspondence between ascriptions of propositional attitudes and the mental states that are thus described is not the only way to take such ascriptions to describe real mental states. We are not condemned to instrumentalism by adopting a semantic reading of propositionality when we recognize that ascriptions of propositional attitudes might share their logical structure with measurement statements.

3.2 Saving realism about propositional attitudes while employing a semantic reading of propositionality: A measurement view

At least since the late seventies a number of researchers have argued that having a propositional attitude is not a matter of standing in a certain cognitive relation to an abstract object, i.e., some particular proposition, but that ascriptions of propositional attitudes describe (intrinsic) psychological states with the help of a domain of abstract representatives, i.e., the domain of propositions. Propositions play the same role in ascriptions of propositional attitudes as numbers play in measurement statements (cf. e.g., Churchland 1979; Davidson 2001; Beckermann 1996; Matthews 2007). Let's call this the measurement view of propositional attitudes.

According to the measurement view, ascriptions of propositional attitudes have a non-relational logical form. The attitude verb and its propositional complement together form a complex predicate that refers to an intrinsic

psychological property of the subject of the ascription. Thereby the difficulty that propositional attitudes must be understood as a relation between a subject and a proposition is avoided: they could just as well be properties of the subject. A weaker form of the measurement view is exhausted by this claim (cf. e.g., Churchland 1979; Davidson 2001).

A stronger form of the measurement view in addition holds that ascriptions of propositional attitudes really are measurements in the sense that a formal measurement theory can be formulated for propositional attitudes (Matthews 2007). And indeed a further investigation of the analogy between ordinary measurement statements and ascriptions of propositional attitudes reveals how abstract objects can be used to refer to causally efficacious properties of objects without themselves playing any causal role. A measurement theory shows that one formal structure, the so-called *empirical structure*, can be homomorphically mapped onto another formal structure, the *representational structure*, the empirical structure being a formal theory about the domain of objects of interest (cf. e.g., Krantz 1972). The details of this mapping determine what can be inferred about the empirical structure from the representational structure. In length measurement, for instance, ratios between numbers correspond to ratios between lengths of objects.

Propositional attitudes figure in the explanation and prediction of behavior. Thus, in the case of propositional attitudes, the empirical formal structure has to be a formal theory of, presumably, the psychological states that are causally involved in the production of behavior. The representational formal structure has to be an adequate formalization of the structure of propositions. Leaving open what the two structures eventually turn out to be, it is the stronger claim that ascriptions of propositional attitudes really are measurements that I want to endorse here. In particular, I take it that propositions are the elements of a representational structure of a measurement theory for propositional attitudes. Let us have a brief look at measurement theory.

In ordinary measurements, numerical scales are used to represent systems of certain

measurable properties like length or mass, for example. Numbers are assigned to objects in accordance to a (procedural) rule. Somewhat simplified, in the case of length or mass measurement, a unit element is defined, and the number of unit elements that need to be concatenated in a certain way such as to be of equal length or mass, respectively, as the object that is measured, are counted. For mass the concatenation might be a simple lumping-together in the pan of a scale, while for length measurements unit elements are aligned rectilinearly. The number assigned to an object is equal to the count of unit-elements required. These numbers can then be used to represent relations among objects that are measured in the same way, i.e., on the same scale. An object that takes the number two on some length scale, for instance, is shorter than one that is assigned the number three, and it takes two objects of length two to get a concatenated object of equal length to an object that was assigned the number four on that scale. Thus, the system of objects is mapped with respect to their length onto the formal structure constituted by the natural numbers, including addition and the less-or-equal relation. The result is a homomorphic mapping from objects to numbers that respects certain additive relations among the lengths of objects. Correspondingly, the addition of numbers can be used to reason about the lengths of objects. Other properties of these objects and their relations might not be captured by the homomorphism. Which numerical operations can be used to reason about the objects' properties of interest depends on the scale that is used. In temperature measurement, for instance, most common scales do not respect ratios among temperatures, such that it does not make sense to say, for instance, that the air on a sunny day at 28° centigrade is twice as warm as the air on a day in fall at 14° centigrade.

Importantly, the objects' properties of interest are *holistically* captured by the numbers on a scale. It is in virtue of their position on the scale and the admissible operations that numbers represent certain (amounts of) properties of measured objects. There is nothing intrinsic to the number five that would make it a repres-

entative of a length of five centimeters or a weight of five kilograms. Individually, i.e., without their position on a scale, numbers don't tell us anything about the property they are used to represent—not even when the dimension (length, weight, ...) is added. Thus, which numbers represent which property (or amount of a property) and which operations on these numbers can be used to reason about the property of interest depends on the employed scale. Neither are all relations among objects respected by the homomorphic mapping; nor can all relations among the numerical representatives be read back onto the objects of interest. This much can be said on the basis of basic measurement theory as formulated by [Krantz et al. \(1971\)](#).

Most interestingly for our present purposes, measurement in the sense of homomorphic mapping does not require numerical representatives. Elements of other abstract structures might just as well serve as the targets of such homomorphic mappings. This idea is exploited by [Matthews \(2007\)](#) and [Dresner \(2010\)](#), for instance. In particular, Matthews argues that the structure of propositions, including their inferential and evidential relations among each other and to perceptions, might thus serve as a measurement structure for certain psychological states of subjects: those that are commonly called the propositional attitudes. These psychological states are homomorphically mapped onto propositions—the causal relations among the former being captured by the inferential, and other relations among the latter. The propositions can then be used to identify psychological states and, importantly, to reason about them. Thereby, propositional attitudes can appear in explanations and predictions of behavior without the propositions themselves having to play any causal role in the cognitive system.

I take it that propositional structures represent psychological properties holistically—just as numerical structures represent properties of objects holistically. The homomorphic mapping as a whole respects certain relations among psychological states, and it is in virtue of their position within the propositional structure that

particular propositions can be said to represent some psychological state. According to this view, there is nothing intrinsic to propositions that would relate them to particular psychological states. Thus, a measurement-theoretic notion of propositionality does not require the states that are referred to with the help of propositions to have propositional content themselves. Nonetheless, ascriptions of propositional attitudes can be understood realistically just as ordinary measurements are understood realistically. Once the mapping is fixed, it is an entirely objective question which proposition represents some given psychological state.

Neither numbers nor propositions are themselves taken to be causally relevant, but they are used to pick out a particular causally relevant property (or state) from a range of possible relevant properties (or states) as defined by the scale in use. Numbers on a meter scale are used to identify the length of objects. And it is the length of a pole, say, that is relevant for building a rack, not the number that is used to identify that length. The number is only relevant in relation to the numbers that are assigned to other parts of the rack. Similarly, propositions are used to identify psychological states that are behaviorally relevant. But it is the psychological states themselves that produce behavior, not the propositions that are used to identify them. Using propositions to identify psychological states leaves open how these states are realized within the cognitive system. All that is required is that the homomorphism holds. Indeed, drawing conclusions about the structure of the cognitive system from observations concerning properties of the propositional representatives of psychological states that are not warranted by the representational scheme (or “scale”) arguably amounts to an over-assignment of structure (cf. [Dresner 2004](#)). As noted above, not all properties of the system of representatives are shared by what they represent. The homomorphism holds with respect to some structural features of the represented objects as determined by the used scale.

Stanley appears to be at least sympathetic to such a measurement-theoretic conception of propositions—he mentions [Matthews \(2007\)](#) ap-

provingly. And there is reason to believe that such a measurement account of ascriptions of propositional attitudes is a plausible candidate for a semantic conception of propositionality. As mentioned above, it has the advantage of giving a non-instrumentalist, realist account of propositional attitudes without buying into any direct correspondence between propositions and mental representations that would lead to a language-of-thought-like theory of cognition. While Fodorean Realism presupposes that ascriptions of propositional attitudes can only be correct if the involved terms refer to actual cognitive entities and relations (i.e., a functional/computational relation towards a mental representation, where the former determines the kind of attitude and the latter its propositional content), such a measurement account makes clear how a system of propositions could structurally (i.e., holistically) represent psychological states without having to assume that psychological states themselves have propositional content or, at any rate, are dependent on how they are ascribed. And it eschews some of the difficulties associated with more traditional accounts, such as explaining how propositions can both be the abstract, sharable contents of thoughts and at the same time psychologically real in that what someone does depends on the contents of his desires and beliefs, etc. (cf. Davidson 2001). The mental states represented by some propositional attitude ascriptions are psychologically real; the proposition itself need not be. First of all, it serves as a representative for that state.

The difference between Stanley's and Bartels and May's accounts of knowledge-how and practical knowledge, respectively, can then be understood as follows. Stanley is interested in the structure of the domain of abstract entities that are used to represent psychological structure, while Bartels and May are interested in the structure of the empirical domain of psychological entities and relations that are described in terms of propositional attitudes. Both endeavors are related in that they involve a phenomenon that we might call "knowing how to do something", and both use intuitive examples and empirical evidence as test cases for their accounts. But their respective goal is really quite

different. In analogy to the measurement of length, one might say that Bartels and May are interested in giving a theory of how different bodies behave with respect to their length under some range of (physical) concatenation operations and comparison relations. For instance, welding two rods might have an influence on the resultant length of the composite rod such that it is not equally long as the two aligned but unwelded rods. Or, they might be interested in how length measurement transfers to smaller scales, such as molecular, atomic, or subatomic distances. Stanley, on the other hand, would be interested in the more formal properties of the numerical scales that are used for length measurement. He might ask how different scales relate. Just as the Fahrenheit scale can be transferred into the centigrade scale, knows-wh locutions might be transformed into know-that locutions.

Toribio's above-mentioned attack on intellectualism would then not be successful, because she has not realized that Stanley's theory really is about the structure of the representatives of certain psychological states, and not about the psychological states themselves. She offers some considerations concerning the structure of the psychological states that are meant to show that they could not possibly be propositional. But she does not give us a reason to think that the considered properties of certain cognitive processes face difficulties in terms of being represented by a propositional structure. Stanley then shows that there is no such difficulty. Toribio's discussion, on the other hand, is rather interesting for the development of an account of the cognitive structures that make it the case that someone knows how to do something.

Stanley's and Bartels and May's accounts are thus relatively independent of each other. Stanley's theory of knowledge-how can be seen as a partial investigation of the representational structure that we use to identify certain mental states. The approach of Bartels and May, on the other hand, is an attempt to give an explanation of certain cognitive capacities that are taken to be expressions of knowledge-how in terms of underlying mental representations. Given that propositional attitude ascriptions

measure psychological states, they aim to formulate a theory of the empirical structure. The measurement view first of all serves to disentangle these different endeavors and to shed some light on the relation between them, namely that the search for underlying representations and mental mechanisms is largely unconstrained by the structure of ascriptions of propositional attitudes by themselves and that conclusions about the empirical structure can only be drawn when the mapping is known as well.

This take is in line with both Stanley's theory and Bartels and May's explanation of practical knowledge. Stanley believes that cognitive psychology does not decide whether knowledge-how is propositional and refutes all objections to the contrary. The propositionality of knowledge-how is a matter of the semantics of their ascriptions. And Bartels and May give a characterization of the difference between practical and theoretical knowledge that is independent of Stanley's theory of knowledge-how. Practical knowledge has some behavioral/functional characteristics that are to be explained in terms of mental representations. The measurement view parts company with Stanley in his contention that he provides an investigation into the *nature* of knowledge-how. Rather, the measurement view is an investigation into a part of the representational structure of a measurement theory for a certain range of psychological states. We would not take an investigation of the centigrade scale to be an investigation of the nature of temperature.

4 Some final remarks

What the discussion around knowledge-how mainly shows, I think, is that the relation between propositional attitudes, cognitive structures or representations, and the behavioral evidence for their respective presence are still not well understood. It seems that we find it surprisingly difficult to disentangle our different ways of talking about ourselves and others in terms of what we believe, on the one hand, and in terms of the information that our brains (or some other division of the body-environment) process on the other. The main difficulty seems

to be that we take ascriptions of propositional attitudes to mirror psychologically real relations between subjects and propositions. As such, we feel the need to tell a story about how propositional attitudes are realized in the brain. The measurement view enables us to employ a less committal way of representing someone's psychological states that largely leaves open how the cognitive system manages to coordinate its behavior with the environment. The constraints that are put on cognitive architecture by successful ascriptions of propositional attitudes are really quite weak. To be sure, if the measurement view is to be proven correct, there must be a homomorphic mapping from an empirical structure into the propositional structure. But homomorphisms abound. Any number of homomorphisms can be found between any two structures. And as far as we can tell, the structure of propositions is homomorphic to the course of the sun and the stars. This is why we can employ intentional explanations for just about any system we want. The measurement view becomes informative when we have formalizations of the two structures and a measurement theory that describes the particular homomorphism of interest that holds between them. Then we can tell what we learn about the empirical structure by means of reasoning about propositions. An attempt to infer the empirical structure from the representational structure alone must fail.

In the case of propositional attitudes, I ultimately doubt that the mapping is best conceived as holding between internal cognitive architectural structure and propositional attitude ascriptions. Propositional attitudes might rather be measurements of structures of observable behavior. Propositional attitudes are ascribed on the basis of observable behavior together with some standards of folk psychology—such as that one believes what one sees or what one is told by trustworthy peers. Propositions might provide standardized ways of identifying behaviorally relevant circumstances, including what someone saw, was told, and aims for, that would otherwise have to be identified less systematically by way of particular situations and individual histories. I can tell that you know that the earth is an approximate sphere—you've

certainly learned it somewhere. I do not need to go back in your learning history until I find the moment in which someone uttered a sentence with the respective meaning—which would allow for similar predictions and explanations.

Taking propositional attitude ascriptions to be measurements of structures of observable behavior would also be very much in line with Ryle's original, rather behaviorist discussion of knowledge-how. With reference to our use of mental vocabulary to describe the behavior of others, Ryle writes that "we go beyond what we see them do and hear them say, but this going beyond is not a going behind, in the sense of making inferences to occult causes; it is going beyond in the sense of considering, in the first instance, the powers and propensities of which their actions are exercises" (1949, p.51). The powers and propensities are in turn understood as complex dispositions, describable in terms of their acquisition and manifestation conditions. The move from a structure of observable behavior to a propositional structure would take the place of acknowledging the role of so-called internal states; for now we can exploit inferential relations among propositions for explanation and prediction. But these propositional attitudes need not be understood as internal states. Instead they could be taken as measurement representations of Ryle's powers and propensities. Ryle notwithstanding, however, we need not give up cognitive psychology. Ascriptions of propositional attitudes and cognitive representations would relate via the behavior that each is to explain—they provide complementary explanations of the same behavior. For Bartels and May's explanation of practical knowledge this would mean that it is not part of a theory of an empirical structure for measurements of propositional attitudes. It would be a cognitive-psychological explanation of a behaviorally characterized psychological phenomenon called practical knowledge. The main point of this commentary, though—namely, that Stanley and Bartels and May are up to different things and that little can be inferred about cognitive architecture from Stanley's analysis of knowledge-how—remains untouched.

In closing, I want to mention one reservation that can be held against the particular cognitive-architectural account presented by Bartels and May. Given that concepts remain a vexed issue in contemporary discussion, that they are traditionally closely related to propositions, and that it is notoriously difficult to find good grounds for attributing representations of a certain kind and with a specific content to cognitive systems that are not able to verbally express their beliefs, a *semantic reading of conceptuality* might be worth considering. Concepts might be broadly conceived of as the constituents of thoughts, i.e., (trains) of propositional attitudes. In our case: whatever is a constituent of knowledge-how would count as a concept. One effect of this would be that the reliance on non-conceptual capacities in order to explain certain forms of knowledge-how, like that of patient DF, would not be open to Stanley. But as an alternative, Stanley could accept demonstrative concepts and claim that some forms of knowledge-how are distinguished by their involvement. Admittedly, Bartels & May would have to change their terminology; their abilities approach to concepts is not compatible with concepts being the constituents of propositions alongside a semantic reading of propositionality. But nothing much seems to be lost by this. Quite possibly, mentalistic vocabulary is just not the best way to come to grips with the structure of cognitive systems.

Preparing the Ground for an Empirical Theory of Knowing-How

A Reply to Ramiro Glauer

Andreas Bartels & Mark May

The commentary gives a clear and instructive summary of our main arguments against both, intellectualist and anti-intellectualist accounts of knowing-how. But the aim of our account is not correctly described as an attempt to give an explanation of certain cognitive capacities that are taken to be expressions of knowing-how in terms of underlying mental representations. (Glauer [this collection](#), p.10). What we aim at is not an empirical theory of knowing-how, but a framework that would be useful for cognitive scientific research on phenomena of knowing-how.

1 Answer to the Commentary

First, we want to thank Ramiro Glauer and emphasize that his commentary gives a clear and instructive summary of our main arguments against both intellectualist and anti-intellectualist accounts of knowing-how (see Section 2). As he rightly points out, we are parting ways with

[Jason Stanley \(2011\)](#) with respect to the issue of *propositionality* as an alleged demarcation criterion between knowing-how and knowing-that. There are at least three different conceptions of propositionality, and none turns out to be helpful in making the distinction. In particu-

lar, the semantic reading of propositionality, according to Stanley's thoughtful and impressive account, applies to clear-cut cases of knowing-how. Since knowing-how is no less propositional, according to the semantic reading, than knowing-that, there is no hope of understanding the peculiarities of knowing-how by adopting such a stance.

In Section 3, Glauer then turns to what in his opinion is the main difference between Stanley's and our account. Unfortunately, we don't think that he quite grasps the point that is important to us when he argues that "what happens between Stanley and Bartels & May's discussion of kinds of knowledge, then, is a shift from a personal-level perspective to a level at which the cognitive system is described" (Glauer [this collection](#), p. 4), and later, "Bartels & May, on the other hand, want to explain the peculiarities of practical and theoretical knowledge in terms of the involved underlying representations" (Glauer [this collection](#), p. 5). This, we have to say, is clearly a misrepresentation of our account and the intentions behind our developing it.

To be more specific, we argue that neither the semantic nor the *representational* reading of propositionality is suited to grounding the distinction between knowing-how and knowing-that (Bartels & May [this collection](#), pp. 5–6): "[w]hether a piece of knowledge is a case of practical or of theoretical knowledge does not depend on whether it is supported by language-like structures or not" (p. 6). Thus, contrary to the picture drawn in the commentary, we agree with Stanley with respect to his denial of a *representational* demarcation criterion between knowing-how and knowing-that. We thereby don't want to express any anti-representational reservations (as is also the case, in our opinion, for Stanley). However, we are skeptical with respect to any type of account that, in rather intuitive ways, identifies kinds of knowledge with ways of representing knowledge. This indeed is our main issue of disagreement with the anti-intellectualists (Glauer mentions this on p. 3).

What about the "shift from a personal-level perspective to a level at which the cognitive system is described" that Glauer mentions

([this collection](#), p. 4)? First, we are not quite sure how Glauer would himself mark the difference between a "person" and a "cognitive system", and what relevance he would ascribe to that difference with respect to the issue of knowing-how. Our paper wants to make clear that the *first-person-perspective* is an important constituent in the analysis of the specific dispositional states that characterize "practical ways of thinking"—specific ways of epistemic access to propositional contents when knowing-how is at stake (Bartels & May [this collection](#), p. 6). Thus, we agree that the knowing person, including all of his or her cognitive capacities and behavioral resources, has to be taken into account for a thorough analysis of knowing-how; see, for instance, our example of the waiter in a restaurant balancing different types of coffee cups (p. 16).

In essence, Ramiro Glauer's commentary draws a picture of our account that misses its main intentions. The aim of our account is not correctly described as "an attempt to give an explanation of certain cognitive capacities that are taken to be expressions of knowledge-how in terms of underlying mental representations" (Glauer [this collection](#), p. 9). Instead, our aim is to identify and specify some constituents of an empirically fruitful theory of knowing-how. In a first step, as we argue, this requires a careful description of central epistemic peculiarities that characterize knowing-how *as opposed to* knowing-that, and that thus have to be covered by any adequate theory (see Bartels & May [this collection](#), pp. 12–13). We then ask what general sort of *epistemic capacities* may coincide with the peculiar capacities embodied by knowing-how and knowing-that, respectively. And finally, we suggest that *conceptuality* versus *non-conceptuality* may be the general distinction that coincides with typical knowing-that and knowing-how-capacities, and go on to highlight some of the explanatory virtues of such a proposal. For the last step we use a theory that characterizes conceptual abilities by specific behavioral traits (Newen & Bartels 2007).

Our approach to the problem leaves open by what types of *mental representations* those conceptual abilities may be supported, if at all.

It cannot even be guaranteed that the distinctions drawn within our conceptual framework coincide with any distinctions between representational formats. What we aim at is not an empirical theory of knowing-how, but a *framework* that would be useful for cognitive scientific research on the phenomena of knowing-how. Thus, it may turn out to be useful to fill that framework with psychological or neurological hypotheses concerning representational mechanisms that may produce the epistemic capacities characterizing knowing-how. In Section 7 of our paper (Bartels & May this collection, pp. 16–17) we have provided different empirical examples of mainly psychological research that has already been undertaken in this line.

We are looking at the subject not so much from the perspective of philosophers of mind, but from the perspectives of philosophy of science and psychology. We therefore do not see good reasons to go into any detail of the specific theory that Ramiro Glauer explores in the second part of his commentary (this collection, pp. 6–7), namely the *measurement view* of propositional attitudes (Matthews 2007). Since our contribution does not intend to propose a new theory of knowing-how, it would be quite pointless to compare the potential merits of such a theoretical view with our own account. What we suggest is that psychological research, or cognitive scientific research more generally, may work along the path we have outlined, and thus make progress in explaining knowing-how.

2 Conclusion

We agree to the commentary concerning our main arguments against both, intellectualist and anti-intellectualist accounts of knowing-how. But we disagree with it concerning the picture that it draws of the aim of our account.

Introspective Insecurity

Tim Bayne

This paper examines the case for pessimism concerning the trustworthiness of introspection. I begin with a brief examination of two arguments for introspective optimism, before turning in more detail to Eric Schwitzgebel's case for the view that introspective access to one's own phenomenal states is highly insecure. I argue that there are a number of ways in which Schwitzgebel's argument falls short of its stated aims. The paper concludes with a speculative proposal about why some types of phenomenal states appear to be more introspectively elusive than others.

1 Introduction

There is a curious ambivalence in current attitudes towards our epistemic relationship to consciousness. Some theorists hold an optimistic view of the powers of introspection, regarding judgments about one's current experiences as epistemically secure—perhaps some of the most secure judgments that we make. Optimists rarely claim that we have exhaustive and infallible access to consciousness, but they do hold the epistemic credentials of introspection in high regard, at least when introspection is directed towards the phenomenal character of consciousness. Those inclined to optimism don't doubt that it is possible to mis-remember or mis-report one's experiences, but they tend to assume that one has some

kind of epistemic access to one's experiences simply by having them.¹

Running alongside this vein of optimism is a rather more pessimistic strand of thought, according to which the epistemic credentials of introspection are chronically insecure. Far from regarding introspection as a light that illuminates every corner of consciousness, pessimists suspect that significant swathes of experience are accessible to introspection only with great difficulty if at all.²

¹ Theorists inclined towards optimism include Chalmers (2003), Gertler (2012), Goldman (2004), Horgan et al. (2006), Horgan & Kriegel (2007), Siewert (2007), and Smithies (2012).

² The contrast between "optimists" and "pessimists" is far from sharp, for optimists often grant that epistemic access to consciousness can be (very) challenging, and pessimists often allow that there are experiential domains with respect to which introspection is trust-

Glossary

Introspection	An unmediated judgment that has as its intentional object a current psychological or phenomenal state of one's own.
Discrimination	The capacity to attentively single the state out from amongst the other experiences that one has at the time in question.
Categorize	To categorize a phenomenal state is to locate it within a taxonomy of some kind.
Directly and indirectly introspective judgments	A direct introspective judgment concerns the phenomenal character/content of one's current phenomenal state(s) and is grounded in a single act of introspective attention, whereas an indirect introspective judgment concerns the general nature of one's conscious experience and is not grounded in a single act of introspective attention.
Scaffolded judgments	An introspective judgment is scaffolded if and only if it is accompanied by a disposition to make a first-order judgment (e.g., a perceptual judgment) whose content broadly corresponds to the judgment of the introspective judgment. For example, the judgment that one has a visual experience as of a red tomato in front of one is scaffolded insofar as it is accompanied by a disposition to make the perceptual judgment that there is a red tomato in front of one.
Freestanding judgments	An introspective judgment is freestanding if and only if it is not accompanied by a disposition to make a first-order judgment (e.g., a perceptual judgment) whose contents broadly corresponds to the judgment of the introspective judgment.

According to Dan Haybron, “[...]even the gross qualitative character of our conscious experience can elude our introspective capacities” (Haybron 2007, p. 415). Sounding a similar note, Maja Spener has argued that “philosophers and psychologists routinely overestimate the epistemic credentials of introspection in their theorizing” (Spener unpublished; see also Spener 2011a, 2011b, and 2013). But perhaps the most thoroughgoing pessimist is Eric Schwitzgebel:

Most people are poor introspectors of their own ongoing conscious experience. We fail not just in assessing the causes of our mental states or the processes underwriting them; and not just in our judgments about nonphenomenal mental states like traits, motives and skills, and not only when we are distracted, or passionate or inattentive or self-deceived, or pathologically deluded or when we're re-

worthy. Nonetheless, these terms are useful insofar as they capture the overarching attitude that the two groups of theorists express with regard to introspection.

flecting about minor matters, or about the past, or only for a moment, or when fine discrimination is required. We are both ignorant and prone to error. There are major lacunae in our self-knowledge that are not easily filled in, and we make gross, enduring mistakes about even the most basic features of our currently ongoing conscious experience (or “phenomenology”), even in favourable circumstances of careful reflection, with distressing regularity. (2008, p. 247)

Although Schwitzgebel's pessimism is tempered by moments of optimism, the dominant theme in his work is that introspection cannot be trusted to reveal anything other than the most mundane features of consciousness. Descartes, Schwitzgebel argues, “had it quite backwards when he said the mind—including especially current conscious experience—was better known than the outside world” (2008, p. 267).

I feel the pull of both optimism and pessimism. In my optimistic moments I find it hard

to take seriously the suggestion that I might be guilty of “gross and enduring mistakes” about the basic features of my current phenomenology. But the arguments for pessimism are powerful and not easily dismissed, and I worry that Schwitzgebel is right when he suggests that the allure of optimism might be due to nothing more than the fact that “no-one ever scolds us for getting it wrong” (2008, p. 260).

A central aim of this paper is to provide an overview of Schwitzgebel’s case for introspective pessimism, and to chart a number of ways in which the optimist might respond to it. But although this paper can be read as a defence of a kind of optimism, my central concern is not so much to take sides in this debate as to advance it by noting various complexities that have perhaps been overlooked. But before turning to the debate itself let me make a few comments about its importance. An account of the trustworthiness of introspection is likely to have a bearing on two important issues. Most obviously, it has implications for the use of introspection as a source of evidence regarding philosophical and scientific debates about consciousness. Whether or not introspection is our sole form of access to consciousness, there is no doubt that it is currently treated as a *central* form of such access, and thus doubts about the reliability of introspection engender doubts about the viability of the study of consciousness. A second issue on which the trustworthiness of introspection has an important bearing concerns debates about the nature of introspection, and in particular the relationship between introspection and consciousness. Some accounts of introspection take a person to be necessarily acquainted with his or her conscious states, where acquaintance is an epistemic relationship of a particularly intimate kind (Gertler 2012; Horgan et al. 2006; Smithies 2012). It is fair to say that such approaches are optimistic by nature, and although advocates of such accounts have attempted to accommodate the possibility of introspective ignorance and error (see e.g., Horgan 2012), the success of such attempts is very much an open question. Other accounts of “introspection”—such as those that deny that there are any distinctively first-per-

sonal modes of access to consciousness—can easily accommodate introspective ignorance and error, but they struggle to account for the epistemic security that often seems to characterize introspection. In short, an account of introspection’s epistemic profile would function as a useful constraint on accounts of its nature.

2 Motivating optimism

By “introspection” I mean an unmediated judgment that has as its intentional object a current psychological state of one’s own. Introspection can take as its object a wide variety of psychological states, but here I am concerned only with the introspection of *phenomenal states*—states that there is “something it is like” for the subject in question to be in. In principle one could have any number of reasons for self-ascribing a phenomenal state—for example, it is possible to self-ascribe pain on the basis of neural or behavioural evidence—but introspection involves the self-ascription of phenomenal states on the basis of seemingly “direct” contact with them.³

There are many aspects of consciousness with respect to which we clearly have little to no introspective access. For example, introspection is clearly not a source of information about the neural basis of consciousness or its functional role. But surely, one might think, introspection can provide trustworthy answers to such questions as, “Am I now in a conscious state with such-and-such a phenomenal character?” Roughly speaking, to regard introspection as able to reveal the phenomenal character of one’s conscious states is to have an optimistic attitude towards it. But there is more than one sense in which introspection might be said to reveal the character of consciousness, and thus more than one way to be an introspective optimist.

One way in which introspection can reveal a phenomenal state is by allowing one to *discriminate* it from its phenomenal neighbours. I take discrimination to be bound up with the ca-

³ Introspection may involve direct access to consciousness at a personal level and yet also be inferential and indirect at sub-personal levels of description.

capacity to single the state out from amongst the other experiences—e.g., thoughts, perceptual experiences, and bodily sensations—that happen to populate one’s field of consciousness. Discriminative access to an experience allows one to direct one’s attention towards it and to thus make it the potential target of demonstrative thought—“I wish that *this* experience would stop”. A second mode of introspective access to consciousness involves the deployment of categories. To categorize a phenomenal state is to locate it within a taxonomy of some kind. Categorical access to the experience of an itch, for example, involves recognizing it as a phenomenal state of a certain type—a state, perhaps, that has a certain intensity, bodily location, and relations to other experiences. Categorical access is a more sophisticated form of access than discriminative access. Just as it is possible to discriminate a bird from its surroundings without being able to recognize it as a bird—perhaps all one can do is bring it under the demonstrative, “that thing there in the sky”—so too it may be possible to discriminate a phenomenal state without being able to recognize it as the kind of phenomenal state it is. Mature human beings enjoy some degree of categorical and discriminative access to their phenomenal states, but many conscious creatures—non-linguistic animals and young children, for example—may enjoy only discriminative access to consciousness.⁴

With this in mind, we can distinguish two forms of introspective optimism. Moderate introspective optimism holds that being in a phenomenal state typically brings with it the capacity to discriminate that state from its phenomenal neighbours, while a more radical form of introspective optimism holds that being in a phenomenal state typically brings with it the capacity to both discriminate and accurately categorize it. By the same token, introspective

pessimism can be more or less radical depending on whether its scope is restricted to categorical access (moderate) or includes both categorical and discriminative access (radical). In what follows, I use the terms “introspective optimism” and “introspective pessimism” to refer to the moderate versions of these views unless noted otherwise.

2.1 The phenomenological argument

Although introspective optimism is often assumed rather than explicitly argued for, I think it is possible to discern two lines of argument for it in the literature. Neither argument is conclusive, but taken together they go some way towards justifying the widespread endorsement of introspective optimism.

The first argument is phenomenological: introspection seems to reveal itself as providing a trustworthy source of information about consciousness. In other words, the epistemic security of introspection seems to be something that is manifest in its very phenomenology. Consider [Brie Gertler](#)’s description of what it is like to attend to the experience that is generated by pinching oneself:

When I try this, I find it nearly impossible to doubt that my experience has a certain phenomenal quality—the phenomenal quality it epistemically seems to me to have, when I focus my attention on the experience. Since this is so difficult to doubt, my grasp of the phenomenal property seems not to derive from background assumptions that I could suspend: e.g., that the experience is caused by an act of pinching. It seems to derive entirely from the experience itself. If that is correct, my judgment registering the relevant aspect of how things epistemically seem to me (this phenomenal property is instantiated) is directly tied to the phenomenal reality that is its truthmaker. (2012, p. 111)

I suspect that Gertler’s comments will strike a chord with many readers—they certainly resonate with me. Introspection seems not merely to

⁴ This claim would need to be tempered if as seems plausible discriminative access requires a minimal form of categorical access. Consider again the case of discriminating a bird but failing to recognize it as a bird. This counts as a failure of categorical access insofar as one fails to bring it under the concept <bird> (or related concepts such as <robin>), but it is arguable that in order to discriminate it from its perceptual background one (or one’s visual system) must bind the various visual features together as the features of a single object, which may require a minimal form of categorical access to the object.

provide one with information about one's experiences, it seems also to "say" something about the quality of that information. This point can be illuminated by contrasting introspection with other forms of access to consciousness. Suppose that you believe that you have the phenomenology associated with anger because a friend has pointed out that you are behaving angrily. In cases like this, testimony provides one with a form of access to one's phenomenal states, but this access surely lacks the epistemic security that introspective access typically possesses—or at least seems to possess. It would be very odd to put more faith in "third-person" evidence concerning one's own conscious states than "first-person" evidence.

Now, one might think that even if the phenomenological consideration just surveyed can *explain* why optimism seems so compelling, it surely can't provide any *justification* for it. Appealing to introspection itself in order to establish its epistemic credentials would be as futile as attempting to pull oneself up by one's own shoelaces. If it's introspection itself that is in the dock, how could its own testimony exonerate it?

In considering this objection we need to distinguish two questions. One question is whether introspection makes claims about its own veracity. A second question is what to make of such claims should they exist—that is, whether to regard them as providing additional reasons for thinking that introspection is trustworthy. Beginning with the first question, it seems to me not implausible to suppose that introspection *could* bear witness to its own epistemic credentials. After all, perceptual experience often contains clues about its epistemic status. Vision doesn't just provide information about the objects and properties present in our immediate environment, it also contains information about the robustness of that information. Sometimes vision presents its take on the world as having only low-grade quality, as when objects are seen as blurry and indistinct or as surrounded by haze and fog. At other times visual experience represents itself as a highly trustworthy source of information about the world, such as when one takes oneself to have a clear

and unobstructed view of the objects before one. In short, it seems not implausible to suppose that vision—and perceptual experience more generally—often contains clues about its own evidential value. As far as I can see there is no reason to dismiss the possibility that what holds of visual experience might also hold true of introspection: acts of introspection might contain within themselves information about the degree to which their content ought to be trusted.

The foregoing addresses the first of the two questions identified above but not the second, for nothing in what I have said provides any reason to think that introspection is a reliable witness to its own veracity. It is one thing for introspection to represent its deliverances *as* trustworthy but it is another for those deliverances to *be* trustworthy. But this being noted, it seems to me not unreasonable to think that the claims introspection makes on its own behalf should be afforded *some* degree of warrant. In general, we regard perceptual testimony as innocent unless proven guilty, and even if introspection is not itself a form of perception it seems reasonable to apply that same rule here. (After all, it is not clear why we would have acquired a cognitive capacity if its deployment routinely led us astray.) The phenomenological argument certainly doesn't provide any kind of proof for introspective optimism, but it seems to me to do more than merely explain why optimism is so attractive: it also provides it with some degree of justification.

2.2 The conceptual argument

A rather different argument for optimism takes as its point of origin the very notion of a phenomenal state. By definition, a phenomenal state is a state that there is "something that it's like" for the subject in question to be in. Conscious creatures enjoy mental states of many kinds, but it is only phenomenal states that bring with them a subjective perspective. But—so the argument runs—if a phenomenal state is a state that there is something it is like to be in, then the subject of that state *must* have epistemic access to its phenomenal character. A

state to which the subject had no epistemic access could not make a constitutive contribution to what it was like for that subject to be the subject that it was, and thus it could not qualify as a phenomenal state. Call this the *conceptual argument*.⁵

How compelling is this argument? It seems to me that a lot depends on what is implied by the notion of “epistemic access”. There is little to recommend the conceptual argument if “epistemic access” is understood in terms of categorization, for it seems fairly clear that a subject need not possess the capacity to accurately categorize its phenomenal states in order for them to contribute to its phenomenal perspective. Of necessity any phenomenal state will fall under categories of various kinds, but the nature of these categories need not be transparent to the creature experiencing it.

But suppose that we construe epistemic access in terms of categorization, rather than identification. Might the conceptual argument justify a moderate form of optimism, according to which subjects must have discriminative access to their phenomenal states? To make this clearer, suppose that it is possible for phenomenal states to occur within the modules of early vision of the kind that are concerned with determining (say) texture or colour constancy. Such phenomenal states—assuming that they are possible—would be completely inaccessible to the subject in question. The creature in question would be unable to contrast the phenomenal character of these states with the phenomenal character of any of its other experiences; it would be unable to single such states out for attention, and it would be unable to make them the objects of demonstrative thought. As such, it seems to me that it is very plausible to hold that they couldn’t be genuinely ascribed to the subject in question, but could at best be ascribed only to one of the subject’s perceptual modules. The root of this intuition, I suspect, lies with the thought that a phenomenal state to which the subject has no discriminative access couldn’t be anything “to” the subject—

that in the relevant sense of the phrase there couldn’t be anything “that it’s like” for the subject to have the relevant experiences.

Although attractive, this argument is not without its problems. One challenge comes in the form of creatures that lack introspective capacities. A creature without introspective capacities might be able to use its conscious states to discriminate some features of the world from others, but it would not be able to make its conscious states themselves objects of its own discriminative activities. And yet—the objection runs—it would be implausible to hold that creatures that lack the capacity for introspective discrimination cannot have phenomenal states. Intuitively, having phenomenal states is one thing and being able to discriminate one’s phenomenal states for each other is another—and more sophisticated—thing. Thus—the argument runs—discriminative access to a phenomenal state cannot be a necessary condition for being in that state.

I certainly agree that it would be implausible to restrict phenomenal states to creatures that possess introspective capacities, but perhaps the objection can be met without making such a restriction. What we can say is that when a creature does acquire introspective capacities those capacities bring with them the ability to discriminate its phenomenal states from one another (at least under epistemically benign conditions). So, we can grant that being in a phenomenal state doesn’t require discriminative access to that state, but also hold that creatures with introspective capacities will be able to discriminate their phenomenal states from one another (again, at least when conditions are epistemically benign).

A second objection to the conceptual argument concerns states that occupy the “margins” of consciousness—such as the unnoticed hum of the refrigerator or the background phenomenology of mood experiences. It is arguable that in some cases experiences like this not only fail to fall within the scope of introspection but in fact cannot be brought within its scope, for to attend to them would be to bring them into the “centre” of consciousness and thus change their phenomenal character. Such states serve as po-

⁵ There are echoes here of the claim that phenomenal consciousness entails a certain kind of “access consciousness”. For some relevant discussion see Church (1997) and Clark (2000).

tential counter-examples to the claim that creatures with introspective capacities must be able to discriminate their phenomenal states from one another.

In response, one might grant that even if the phenomenal states that occur in the margins of consciousness cannot be singled out for introspective attention, there is still a sense in which they can be the objects of discrimination. Not only can they be discriminated from one another, they can also be discriminated from those phenomenal states that *do* fall within the scope of attention. Indeed, if such states cannot be discriminated from their phenomenal neighbours in any way then it is unclear what reason we could have for thinking of them as falling within the margins of *consciousness* at all, rather than being completely unconscious.

Where do these considerations leave us? I have suggested that the phenomenological argument provides some reason to take at least a moderate form of optimism seriously. It doesn't, of course, establish that our access to all kinds of phenomenal states is robust—indeed, one might even appeal to phenomenological considerations to motivate the idea that our epistemic access to significant regions of phenomenal space is very poor. (I return to this topic shortly.) The conceptual argument provides little reason to think that we will always be able to *categorize* our phenomenal states, but it does provide some motivation for the idea that being in a phenomenal state brings with it the ability to *discriminate* that phenomenal state, at least when it comes to creatures with introspective capacities. In short, optimism of at least a moderate form is not merely a holdover from Cartesianism but can be provided with some degree of support. With these considerations in mind let us turn now to the case for pessimism.

3 Motivating pessimism

Two distinctions will prove helpful in what follows. One distinction is between forms of pessimism that concern only our capacity to identify our phenomenal states and forms of pessimism that call into question our capacity to both discriminate and categorize our phenomenal states. A

second distinction concerns the *scope* of pessimism. At one end of the spectrum are local forms of pessimism that concern only a relatively circumscribed range of phenomenal states (say, imagery experiences), while at the other end of the spectrum are forms of pessimism that are unrestricted in scope. Perhaps no theorist has ever embraced a truly global form of pessimism—even Schwitzgebel grants that introspection is trustworthy with respect to certain aspects of consciousness—but some forms of pessimism are clearly wider in scope than others. These two distinctions are, of course, orthogonal to each other. One could be a moderate but global pessimist; alternatively, one could endorse a radical but highly local form of pessimism.

So much for the varieties of pessimism—how might one argue for the view? One influential line of argument for pessimism—or at least something very much like it—appeals to the alleged privacy of introspection. Because an individual's introspective judgments cannot be checked by anyone else, it follows—so the argument runs—that it would be inappropriate to trust them. This argument is often used to motivate the view that introspection is scientifically illegitimate, but it could also be used to motivate the view that one should adopt a sceptical attitude towards one's own introspective capacities.⁶ Although it has been influential, I will leave this argument to one side in order to focus on a trio of arguments that aim to establish not merely that there is no positive reason to trust introspection (as the argument just outlined attempts to do), but that there is positive reason *not* to trust it. My presentation of these arguments will draw heavily on Schwitzgebel's work, for he has done more than any other author to develop and defend them.⁷

But before I examine those arguments, I want to consider the overall structure of

6 For critical discussion of this argument see Goldman (1997, 2004) and Piccinini (2003, 2011). In my view the most plausible response to it involves denying that introspection is private in the sense required for the argument to go through. I touch briefly on this idea in section 4.

7 Schwitzgebel is clearly attracted to a fairly global form of introspective pessimism, but (to the best of my knowledge) he doesn't distinguish between discriminative and categorical access, and thus it is unclear whether his version of pessimism is radical or merely moderate. Generally, however, he seems to have something akin to radical scepticism in mind.

Schwitzgebel's case for global scepticism. As I read him, Schwitzgebel employs a two-step strategy (2008, p. 259). The first step involves attempting to establish a form of local pessimism via one (or more) of the three argumentative strategies to be explored below. The second step involves generalizing from the kinds of phenomenal states that are the targets of local pessimism to phenomenal states in general. The second step is clearly required, for without it we would have no reason to regard introspection *in general* as “faulty, untrustworthy, and misleading”—“not just possibly mistaken, but massively and pervasively” (Schwitzgebel 2008, p. 259).⁸

I will consider both steps in due course, but the crucial point to note for now is that, considered in the abstract, the second step of the argument looks somewhat suspect (Bayne & Spener 2010). Even if there are hard cases for introspection—that is, cases in which introspective access to phenomenology is insecure—there also easy cases—that is, cases in which introspective access to phenomenology is clearly secure. Indeed, Schwitzgebel himself grants that introspection “may admit obvious cases” and that some aspects of visual experience “are so obvious it would be difficult to go wrong about them” (Schwitzgebel 2008, p. 253). But if that's the case, then one might well ask why we shouldn't generalize from those cases rather than from the hard cases on which he focuses. Schwitzgebel complains that to generalize about introspection only on the basis of the easy cases “rigs the game”. That's true. But it's equally true that to generalize only on the basis of the hard cases—as Schwitzgebel seems to do—would *also* rig the game. In fact, it would seem pretty clear that any comprehensive account of the epistemic landscape of introspection must

take *both* the hard and easy cases into consideration. Arguably, generalizing beyond the obviously easy and hard cases requires an account of what makes the hard cases hard and the easy cases easy. Only once we've made some progress with that question will we be in a position to make warranted claims about introspective access to consciousness in general. What this suggests is that although there is a formal distinction between the two steps of Schwitzgebel's argument, the steps are not entirely independent of each other, for the fortunes of the second step rest in part on the case that can be made for the first step. With that thought in mind, let us now turn to the arguments for pessimism.

3.1 The argument from dumbfounding

One line of argument that features prominently in Schwitzgebel's work is what I call the argument from dumbfounding.⁹ Arguments of this form involve posing introspective questions that allegedly stump us—questions that we find ourselves unable to answer with any significant degree of confidence. Here's an example of such an argument:

Reflect on, introspect, your own ongoing emotional experience at this instant. Do you even have any? If you're in doubt, vividly recall some event that still riles you until you're sure enough that you're suffering from renewed emotion. Or maybe your boredom, anxiety, irritation, or whatever in reading this essay is enough. Now let me ask: Is it completely obvious to you what the character of that experience is? Does introspection reveal it to you as clearly as visual observation reveals the presence of the text before your eyes? Can you discern its gross and fine features through introspection as easily and as confidently as you can, through vision, discern the gross and fine features of nearby external objects? Can you trace its spatiality (or non-spatiality), its viscosity or cognitiveness, its involvement with conscious

⁸ Another reconstruction of Schwitzgebel's overarching argumentative strategy proceeds as follows. Although the arguments from dumbfounding, dissociation, and variation establish only local forms of introspective pessimism when considered on their own, when taken collectively they provide a good case for a relatively global form of pessimism given that each of the three arguments concerns distinct (albeit, perhaps, overlapping) domains of phenomenology. Thus understood, Schwitzgebel does not need to appeal to a generalization from the “hard cases” to introspection in general. Although this construal provides an alternative route to pessimism, I regard it as less promising than the one outlined in the text—both as a reading of Schwitzgebel's work and as an argument in its own right.

⁹ Following Hohwy (2011), Schwitzgebel (2011) calls this “the argument from uncertainty”.

imagery, thought, proprioception, or whatever, as sharply and infallibly as you can discern the shape, texture and color of your desk? (Or the difference between 3 and 27?) I cannot, of course, force a particular answer to these questions. I can only invite you to share my intuitive sense of uncertainty. (Schwitzgebel 2008, p. 251)

This argument does not appeal to independent evidence in order to motivate pessimism. Rather, it appeals to first-person considerations: introspection *itself* seems to suggest that there are aspects of our own conscious experience that elude our grasp. As Schwitzgebel puts it, “it’s not just language that fails us—most of us?—when we confront such questions [...] but introspection itself. [...] in the case of emotion, the very phenomenology itself—the qualitative character of our consciousness—is not entirely evident” (Schwitzgebel 2008, pp. 249–250).

Before examining the force of this argument, let us first consider what kind of pessimism it aims to establish. Does the above passage call into question our capacity to accurately *categorize* our emotional phenomenology, or is the claim rather that we lack even the capacity to *discriminate* our emotional experiences from one another and from the rest of our phenomenal states? Although Schwitzgebel’s concern seems to include questions of discriminative access—after all, the passage begins by asking if we can even tell whether or not we have any emotional phenomenology—I take his worries to centre on our capacity to accurately categorize our emotional phenomenology. As I read him, Schwitzgebel’s questions focus on our ability to determine how our emotional experience is structured, both internally and in terms of its relations to phenomenal states of other kinds.

I think that the questions Schwitzgebel raises *are* difficult to answer. However, it is not clear to me that this fact provides quite as much support for introspective pessimism as Schwitzgebel thinks it does. Lying behind the dumbfounding strategy is the assumption that the questions being posed have determinate answers—that they are appropriate questions to ask. However, I suspect that in an important

range of cases this assumption may be unjustified. With respect to the phenomenology of emotion it is natural to assume that the boundaries between the phenomenal states associated with emotion are as clean and sharp as the boundaries between our standard ways of categorizing emotional states. We regard boredom, anxiety, and irritation as distinct emotional states, and we also regard each of these states as associated with distinctive forms of phenomenology. On the basis of these two thoughts we assume that the phenomenal states associated with these categories can themselves be cleanly distinguished from one another. Thus, when one finds oneself at a loss to know whether one is in *the* phenomenal state associated with boredom, anxiety, or irritation one naturally assumes that the fault lies with one’s introspective capacities. But perhaps the mistake was to assume that the phenomenology of emotion can be cleanly demarcated into states that are uniquely associated with either boredom, anxiety, or irritation. Perhaps the phenomenal states associated with these emotional states overlap and interpenetrate each other. If this were the case, then although there might be certain contexts in which one’s emotional phenomenology is purely that of (say) boredom, there may also be other contexts in which one’s emotional phenomenology involves a complex mix of the phenomenal states associated with boredom, anxiety and irritation. And if one were in a context like this, one might be at something of a loss to know just how to categorize one’s emotional state. The only categories that might come to mind would be those associated with the folk psychology of emotion—*<boredom>*, *<anger>* and *<irritation>*—but these categories might fail to cut the phenomenology of emotion at its joints. In other words, emotional phenomenology may pose a particular introspective challenge not because introspection does a poor job of acquainting us with emotional phenomenology, but because the structure of the phenomenology of emotion fails to map onto the structure of our folk categories of emotions in a straightforward manner.

Other versions of the argument from dumbfounding raise a different set of challenges

for introspective optimism. Consider the question of introspective access to visual imagery. Schwitzgebel asks his readers to form a visual image of the front of his or her house, and to then consider the following questions:

How much of the scene are you able vividly to visualize at once? Can you keep the image of your chimney vividly in mind at the same time you vividly imagine (or “image”) your front door? Or does the image of your chimney fade as your attention shifts to the door? If there is a focal part of your image, how much detail does it have? How stable is it? Suppose that you are not able to image the entire front of your house with equal clarity at once, does your image gradually fade away towards the periphery, or does it do so abruptly? Is there any imagery at all outside the immediate region of focus? If the image fades gradually away toward the periphery, does one lose colours before shapes? Do the peripheral elements of the image have color at all before you think to assign color to them? Do any parts of the image? If some parts of the image have indeterminate colour before a colour is assigned, how is that indeterminacy experienced—as grey?—or is it not experienced at all? If images fade from the centre and it is not a matter of the color fading, what exactly are the half-faded images like? (Schwitzgebel 2002, pp. 38–39)

I think that this line of questioning poses one of the most significant challenges to optimism. Further, it is doubtful whether this challenge can be resisted in the way that the previous version of the dumbfounding challenge can, for these questions don’t seem to rest on any problematic assumptions. Schwitzgebel isn’t assuming that visual imagery must be pictorial in nature, or that it will always be fully detailed and determinate. Rather, one issue that he explicitly puts on the table is whether the phenomenology of visual imagery can be purely “generic” or “gisty”, or whether it must instead always be specific in some way or another.

But perhaps the dumbfounding challenge can be met in another way. As Jakob Hohwy (2011) has noted, one striking feature of visual imagery is its instability:

In the absence of specific goal parameters for simulations there will be much phenomenal variability because in such conditions subjects must themselves make up the purposes for which they imagine things, or engage in ‘simple’ free-wheeling imagery. For example, there is an indefinite number of purposes for which you can imagine the front of your house (walking up to it, standing close by, assessing its shape, its prettiness, flying around it, how the postman sees it, smelling it, repairing it, buying it, selling it etc), each of these purposes will constrain the imagery, and thus the introspected phenomenology, in different ways. This means that subjects probably do have *variable* phenomenology, and introspectively report so reliably. (2011, p. 279)

Hohwy’s comments are intended to explain the variability in the introspective reports that individuals give, but they also bear on the dumbfounding argument. Perhaps we are not sure how best to describe the phenomenology of imagery because it is so variable. Imagery experiences cannot be pinned down, but are constantly shifting in response to our own imagistic activity. Precisely how much of the scene we vividly visualize “all at once” depends on the goals that constrain the act of visualization. And, as Hohwy suggests, when we have no such goals our imagery may end up “freewheeling”, such that we move from one state to another. Hohwy grounds his analysis in a predictive-coding account of cognition, but his fundamental point is independent of that theoretical framework and should be fairly uncontentious: imagery surely *is* more labile than perceptual experience or bodily sensation. No wonder, then, that its phenomenal structure is that much more difficult to articulate.

I have suggested that the optimist has the resources to meet (or at least “problematize”)

two of the leading versions of the dumbfounding argument. But suppose that my responses are found wanting, and that the pessimist is able to show that our introspective access to both emotional and imagery phenomenology is insecure and impoverished. Even so, there would be a further question as to how such a finding would motivate *global* pessimism. It is certainly true that questions about the nature of certain kinds of experiences (e.g., emotional and imagery experiences) strike us as difficult to answer and may leave us flummoxed, but it is equally true that many introspective questions strike us as easily answered. Indeed, as the quotation from Gertler makes vivid, many of our introspective judgments appear to be accompanied by a sense of epistemic certainty. Why should we generalize from the first set of cases rather than the second? Without an account of why certain introspective questions leave us dumbfounded it is difficult to see why pessimism about a particular range of introspective questions should undermine the epistemic credentials of introspection more generally. So even if the threat posed by dumbfounding arguments were able to establish a form of local pessimism, that threat would appear to be easily quarantined.

3.2 Dissociation arguments

A very different case for introspective pessimism is provided by what I call dissociation arguments. Such arguments appeal to a lack of congruence between a subject's introspective judgments and their capacity to produce reliable first-order judgments—that is, judgments about the objects and properties in their environment. An example of this kind of argument is provided by Schwitzgebel's treatment of the so-called “grand illusion” (Noë 2002). Most people, Schwitzgebel claims, hold that a broad swathe of their environment—perhaps thirty or more degrees—is clearly presented within visual experience with its “shapes, colours, textures all sharply defined”. Schwitzgebel argues that we have good reason to regard such claims as false. In making the case for this claim, he appeals to an example first popularized by Dennett (1991):

Draw a card from a normal deck without looking at it. Keeping your eyes fixed on some point in front of you, hold the card at arm's length just beyond your field of view. Without moving your eyes, slowly rotate the card toward the centre of your visual field. How close to the centre must you bring it before you can determine the colour of the card, its suit, and its value? Most people are quite surprised at the result of this little experiment. They substantially overestimate their visual acuity outside the central, foveal region. When they can't make out whether it's a Jack or a Queen though the card is nearly (but only nearly) dead centre, they laugh, they're astounded, dismayed. (Schwitzgebel 2008, pp. 254–255)

How might we explain the dissociation between subjects' introspective judgments and their first-order judgments? One explanation is that the subjects' introspective beliefs are false, and that people wrongly take themselves to have detailed visual phenomenology outside of the focus of attention. This is the explanation that Schwitzgebel endorses. But as Schwitzgebel (2008, p. 255) himself notes, it is possible to explain this dissociation by supposing that individuals are wrong not about which phenomenal states they are in but only about the *origin* of that state. With respect to the card trick example, the proposal is that subjects do indeed have detailed visual phenomenology outside of the origin of attention, but that this phenomenology derives from background expectation rather than environmental input—that is, it is “illusory”.

Schwitzgebel's account of the dissociation may have more intuitive appeal than the account I have just outlined, but it is not clear how the data furnished by the dissociation argument allows us to choose between them. However, reasons to favour Schwitzgebel's account can be gleaned noting that the judgment on which we have focused—“thirty or more degrees of my visual field presents itself to me clearly in experience with its shapes, colours, textures all sharply defined”—is available to

introspection only indirectly. This judgment is not the direct reflection of any one introspective act, but is a belief about the nature of one's visual experience that one forms by tracking one's introspective capacities over time. Call such judgments *indirectly introspective*. Indirectly introspective judgments can be contrasted with *directly introspective* judgments—that is, judgments of the kind that one makes in the very context of the card trick experiment, such as “I am now experiencing the shape, colour, and texture of this card (which is presented to me slightly off centre) in sharp detail”. We can now see that although there is a dissociation between the first-order judgments that subjects make and their *indirect* introspective judgments, there is no such dissociation between their first-order judgments and their *direct* introspective judgments. Subjects in the card-trick experiment *don't* report experiencing the shape, colour, and texture of cards that are presented slightly off centre to them “in sharp detail”—rather, they claim to lack sharp and detailed experiences of such objects. Direct introspective judgments clearly have more warrant than indirect judgments, and thus there is good reason to prefer Schwitzgebel's explanation of the dissociation over the alternative account.

But although we have found reasons to support Schwitzgebel's analysis of the dissociation, we have seen that these very reasons undermine his pessimistic attitude to introspection in general, for the evidence in favour of Schwitzgebel's account involves an appeal to introspection. In other words, the pressure that the dissociation argument puts on indirect introspective judgments assumes that direct introspective judgments are trustworthy. The card trick case does indeed cast doubt on the epistemic security of our *background* beliefs about our own visual experience, but there is no reason to extend such doubts to include our direct introspective judgments; and it is surely direct introspective judgments that are at the heart of debates about the trustworthiness of introspection. (Indeed, indirect introspection judgments are not really a genuine form of introspection at all.)

Let us turn now to the second step of the dissociation argument: the inference from local pessimism to general pessimism. Suppose that we were to find a dissociation between a certain range of introspective judgments and the subject's capacity to make the corresponding first-order judgments. Suppose, furthermore, that one could show that this dissociation is best explained by assuming that the introspective judgments in question were false. Would one have any reason to think that introspection *in general* ought to be regarded with suspicion? Not as far as I can see. It seems to me that our faith in the robustness of introspective access to domains in which such dissociations are not to be found ought to remain completely untroubled by such a finding. In fact, one might even argue that coherence between first-order judgments and (direct) introspective judgments would provide evidence in favour of introspective optimism. If dissociations between a person's introspective capacities and their first-order capacities can *disconfirm* their introspective judgments (as the dissociation argument assumes), then *associations* between a person's introspective judgments and their first-order capacities ought to *confirm* them (Bayne & Spener 2010). In other words, the fact that a person's introspective judgments cohere with their capacity to produce reliable reports of their environment ought to provide us with positive reason to trust those judgments.¹⁰ And a great number of our introspective reports clearly *do* cohere with our first-order capacities. Although there are cases in which such coherence fails to obtain—for example, Schwitzgebel (2011, Ch. 3) provides a plausible case for the claim that introspective reports of visual imagery are only weakly correlated with the kinds of first-order cognitive capacities that one would expect visual imagery to subserve—such cases

¹⁰ This argument is closely related to an argument presented by Spener (2013) in defence of the idea that we can provide principled reasons for trusting introspection in certain contexts. Spener argues that certain everyday abilities, such as adjusting a pair of binoculars or ordering food in a restaurant, are introspection-reliant—that is, their successful execution requires that the subject have accurate introspective judgments. I find Spener's argument plausible, but, as Schwitzgebel (2013) notes, it is something of an open question just how many of our everyday abilities are reliant on introspection. At any rate, the argument I have given here makes no appeal to that notion.

are striking precisely because they stand out against the backdrop of coherence that characterizes the relationship between our normal introspective reports and our first-order perceptual capacities.

3.3 Arguments from introspective variation

Perhaps the strongest case for introspective pessimism derives from the phenomenon of introspective variation. Such arguments have as their starting point a disagreement about how best to describe some aspect of phenomenology. Pessimists then argue that the best explanation for the introspective dispute is that at least one of the two groups is mistaken about its own phenomenology, and thus that introspective access to the relevant phenomenal domain is insecure: despite their best efforts, at least one of the two parties to the dispute is wrong about its own phenomenology.

Schwitzgebel (2008) examines a number of arguments from introspective variation, but his central case study concerns a debate about the nature of conscious thought—the so-called “cognitive phenomenology” debate (Bayne & Montague 2011; Smithies 2013).¹¹ On one side of this dispute are those who deny that thought has a distinctive phenomenal character. Those who hold this view typically allow that conscious thought has a phenomenology of some kind, but they regard that phenomenology as purely sensory—as limited to the phenomenology of inner speech, visual imagery, and so on. We might call this the conservative account of conscious thought, for it treats phenomenal consciousness as limited to sensory aspects of the mind. On the other side of this dispute are those who adopt a liberal conception of conscious thought, according to which conscious thought is characterized by a range of non-sensory phenomenal states—states of “cognitive phenomenology”. It is tempting to conclude that at least one of these two sides is guilty of a

fairly radical introspective error: introspection either fails to inform conservatives of a wide range of phenomenal states that they enjoy on a regular basis, or it misleads liberals into thinking that they enjoy a wide range of phenomenal states that they don’t enjoy. Either way, introspection would seem to be untrustworthy with respect to what is clearly a central feature of phenomenology.¹²

But before we follow Schwitzgebel (and many others) in embracing this conclusion, we need to consider alternative explanations of the cognitive phenomenology dispute. One possible explanation appeals to group differences in phenomenology. Perhaps the descriptions of conscious thought that both liberals and conservatives give are right when applied to themselves but wrong when taken to describe conscious thought in general. In other words, perhaps both parties to the dispute are guilty of over-over-hasty generalization rather than introspective error.

Although an appeal to group differences might explain (away) some instances of introspective disagreement, it is unlikely to provide the best explanation of the cognitive phenomenology dispute. First, this account requires a degree of variation in phenomenology for which there are few (if any) parallels. This is not to say that phenomenal differences between individuals might not run much deeper than common-sense tends to assume—consider, for example, the phenomenal differences that characterize synaesthesia (Robertson & Sagiv 2005)—but the kinds of phenomenal differences that we already recognize are nowhere near as fundamental as the kinds of differences required by this explanation of the cognitive phenomenology debate, for liberals claim that conscious thought is characterized by a *sui generis* kind of phenomenology—a kind that is non-sensory in nature. Second, the group difference proposal predicts that there are cognitive and behavioural differences between the advocates of cognitive phenomenology and their detractors that simply don’t appear to obtain. In sum, it seems

¹¹ Other examples of recent introspective disagreement concern the apparent shape of the objects of visual experience (e.g., Siewert 2007; Schwitzgebel 2011, Ch. 2), the existence of high-level perceptual phenomenology (Siegel 2006; Bayne 2009), and the satisfaction conditions of the phenomenology of free will (e.g., Horgan 2012; Nahmias et al. 2004).

¹² The conservative view is also known as the “restrictive” (Prinz 2011) or “exclusivist” (Siewert 2011) view, while the liberal view is also known as the “expansionist” (Prinz 2011) or “inclusivist” (Siewert 2011) view.

highly unlikely that the debate about the existence of cognitive phenomenology can be explained by supposing that what it is like to be a liberal is different from what it is like to be a conservative.

But there is another deflationary explanation of the debate about cognitive phenomenology that cannot be so easily dismissed. Perhaps the parties to the debate are operating with very different conceptions of what it would take for thought to possess distinctive phenomenal character, and are thus talking passed each other (Bayne unpublished). On this proposal, liberals are willing to extend the notion of phenomenal consciousness beyond its sensory paradigms in a way that conservatives are not. If this account is right, then the dispute surrounding the existence of cognitive phenomenology is largely verbal. Rather than disagreeing about what introspection reveals, the two sides instead disagree about how the term “phenomenal consciousness” and its cognates ought to be employed.

Why take this proposal seriously? Well, one argument for it is that it would provide a good explanation of why there is such widespread disagreement about the nature of conscious thought—the very terms in which the debate are couched are contested. It is also widely acknowledged that there are different notions of “what it’s likeness” (see e.g., Tye 1996; Flanagan 1992; Georgalis 2005). Although this proposal clearly needs much more defence and development than I can give it here, I think it is not unreasonable to suppose that the disagreement surrounding the existence of cognitive phenomenology might turn out to be largely verbal. At any rate, it seems to me that this account provides at least as good an explanation of the dispute as that which is required by the argument from variation.¹³

¹³ Of course, the pessimist might argue that, even if the disagreement surrounding the phenomenology of thought is fundamentally semantic, it doesn’t follow that the optimist is off the hook. After all, using introspection to ground a science of consciousness doesn’t merely require the reliability of introspection, it also requires intersubjective agreement about its deliverances. And—the pessimist might continue—dispute about how to apply the term “phenomenal consciousness” and its cognates threatens to undermine intersubjective disagreement about what introspection reveals just as surely as introspective unreliability does. This is a

There are, of course, other introspective disagreements besides that concerning the phenomenology of thought, and nothing that I have said here goes any way towards showing that they too succumb to a deflationary analysis. Indeed, I suspect that certain introspective disputes—for example, those relating to the richness of visual imagery—may well be best explained by appeal to introspective error. But even if the argument from variation succeeds in establishing a local form of pessimism, it seems to me there is little reason to think that this pessimism generalizes. Indeed, domains that feature disagreement in introspective reports stand out against a general backdrop of introspective agreement. Arguably many domains of consciousness exhibit a great deal of uniformity with respect to introspective reports once individual differences and verbal disputes are taken into account. Now, although inter-subjective agreement doesn’t entail that the individuals in question are right, it does need to be explained, and it seems plausible to suppose that leading explanations of inter-subjective agreement will appeal to the trustworthiness of introspection.

4 Elusive phenomenology

In the previous section I argued that there are good reasons for resisting Schwitzgebel’s case for global pessimism. However, we also saw that there are domains in which our introspective access to phenomenal consciousness is rather less secure than we might have pre-theoretically assumed. In other words, we saw that there is reason to think that certain kinds of phenomenal states are introspectively elusive. In this final section I want to sketch an account of why certain types of phenomenal states are elusive and others are not.

Let me begin by distinguishing the form of phenomenal elusiveness with which I am concerned from another notion of phenomenal elusiveness that I want to set to one side. In a recent paper, Kriegel uses the label “elusive phe-

fair challenge, but in my view the prospects for securing a solution to the cognitive phenomenology dispute, should it turn out to be fundamentally semantic, are quite high. For further discussion of phenomenal disputes and introspective disagreement see Hohwy (2011) and Siewert (2007).

nomenology” to describe phenomenal states “whose very essence requires the absence of introspective attention” (2013, p. 1171). Among the examples that he gives of elusive phenomenology are the phenomenal states that occur at the fringes or margins of consciousness. As Kriegel notes, such states are elusive in that any attempt to make them the object of attentive introspection would change their nature. Although Kriegel’s notion of elusiveness is closely related to the one that I employ here, the two notions are not identical. (One way of seeing that they are distinct is that Kriegel’s elusiveness is primarily a matter of the phenomenology, whereas my elusiveness is a matter of one’s introspective access to the phenomenology.) Unlike Kriegel, I am interested in a type of elusiveness that is independent of attention. Consider again visual imagery. Although particular instances of visual imagery might be elusive in Kriegel’s sense because they happen to occupy the margins of consciousness, I am interested here in the fact that visual imagery *as such* appears to be introspectively elusive.¹⁴

Why might certain types of phenomenal states be elusive in a way that other types of phenomenal states are not? Broadly speaking, there are two places in which we might look for an answer to this question. On the one hand we might appeal to intrinsic features of the phenomenal states themselves. Perhaps there is something inherent in the very nature of certain kinds of phenomenal states that renders them relatively opaque to introspective access. Another possibility is that the elusiveness of certain types of phenomenal states has nothing to do with their intrinsic nature but instead reflects the structure of our introspective capacities. Just as our perceptual system is geared toward the identification of certain kinds of environmental states rather than others, so too it is possible that our introspective system is geared towards the identification of certain kinds of phenomenal states rather than others. On this view, the fact that our introspective access to some types of phenomenology is more secure

than it is to others tells us more about introspection than it tells us about phenomenal consciousness (as it were).

It is, I think, premature to speculate which of these two accounts might be the more plausible; indeed, it is possible that a full explanation of elusiveness will have to draw on both ideas. But rather than pursue that thought, I want instead to sketch one way in which the structural features of introspection might go some way towards explaining why certain types of introspective judgments are more secure than others. The account in question appeals to a distinction between two kinds of introspective judgments: *scaffolded judgments* and *freestanding judgments* (Bayne & Spener 2010). The distinction is perhaps best grasped by means of examples. Contrast an introspective judgment that is directed towards one’s visual experience of looking at a red tomato with an introspective judgment that is directed towards an experience of visual imagery involving a red tomato in front of one. In the former case, there is a perceptual judgment that one is disposed to make (“There is a red tomato in front of me”) whose content corresponds (broadly speaking) to the content of one’s introspective judgment (“I have an experience as of a red tomato in front of me”). In the latter case, however, there is no such first-order judgment that one is disposed to make whose content might correspond to the content of one’s introspective judgment. In a sense, the former judgment is “scaffolded” by a perceptual disposition in a way that the latter judgment is not.

I suggest that scaffolded judgments are typically more secure than freestanding ones precisely because they are scaffolded. At the very least, it is a striking fact that many of the most epistemically insecure introspective judgments appear to be freestanding. Further, one can tell an attractive story about *why* introspective scaffolding might contribute to epistemic security. In making scaffolded judgments, the subject is able to both exploit the resources that it has for making freestanding judgments and calibrate those resources by drawing on its dispositions to make first-order

¹⁴ Phenomenal domains that are at least somewhat elusive include the phenomenology of agency (Metzinger 2006; Bayne 2008; Horgan et al. 2006) and high-level perceptual phenomenology (Siegel 2006; Bayne 2009).

perceptual judgments.¹⁵ Just as beliefs that are derived from multiple (independent) sources are typically more secure than beliefs derived from just a single source, so too scaffolded introspective judgments might typically be more secure than their freestanding brethren.

5 Conclusion

This paper provides a partial response to Schwitzgebel's case for global pessimism with respect to introspection. I began by outlining two arguments for optimism; the first argument turned on an appeal to the phenomenology of introspection, while the second drew on a conceptual connection between the notions of introspective access and phenomenality. Neither argument comes close to being decisive, but taken together they provide some explanation for—and justification of—the widespread appeal of optimism. I then turned to a detailed examination of Schwitzgebel's case for pessimism, arguing that although his arguments go some way towards justifying local pessimism (particularly with respect to imagery), there is little reason to generalize that pessimistic attitude to introspection more generally.

But perhaps the central lesson of this paper is that the epistemic landscape of introspection is far from flat but contains peaks of security alongside troughs of insecurity. Rather than asking whether or not introspective access to the phenomenal character of consciousness is trustworthy, we should perhaps focus on the task of identifying how secure our introspective access to various kinds of phenomenal states is, and why our access to some kinds of phenomenal states appears to be more secure than our access to other kinds of phenomenal states. I have suggested that the notion of introspective scaffolding might play a role in answering this second question, but that that proposal is at

best only a very small part of a much larger account of introspective insecurity. There is certainly a lot more work to be done before we have a good grip on the epistemic structure of introspection.

Acknowledgements

An earlier version of this paper was presented at a graduate workshop on perception at the City University of New York, and I am grateful to the members of the audience on that occasion for their comments. I also gratefully acknowledge the support of European Research Council Grant *The Architecture of Consciousness* (R115798).

¹⁵ An influential account of introspection holds that introspection involves a semantic ascent routine in which one redeploys rather than represents one's introspective target (Byrne 2005; Evans 1982; Fernández 2013). Although I am not endorsing this account of introspection in general (or indeed of introspective access to perceptual phenomenology in particular), I am suggesting that such procedures might be implicated in introspective access to certain kinds of phenomenal states.

“I just knew that!”: Intuitions as Scaffolded or Freestanding Judgements

A Commentary on Tim Bayne

Maximilian H. Engel

How reliable are intuitive or introspective judgments? This question has produced lively debates in two respective discussions. In this commentary I will try to show that the two phenomena of introspective and intuitive judgments are very closely related, so that the two separate philosophical debates about them can substantially inform each other. In particular, the intuition debate can profit from conceptual tools that have already been introduced to discussions about the reliability of introspection. Especially the distinction between scaffolded and freestanding judgements, which has been developed by [Tim Bayne & Maja Spener \(2010\)](#), can be used to more carefully investigate intuitions with respect to their epistemic reliability. After briefly applying this framework to some paradigm cases of “philosophically interesting” intuitions, I will come to the conclusion that most of these must be regarded as freestanding judgments and thus cannot play the role of reliable sources of evidence that they are supposed to play in some discussions in contemporary epistemology and methodology.

1 Introduction

What is the evidential status of introspective mental states? Can they be used as a source of knowledge like other classical candidates, e.g. experimental data, induction, or visual perception? Over the last few decades these questions have been addressed in philosophy of mind and epistemology in particular.¹ While on the one

hand optimists consider the wide-ranging use of introspection in philosophical debates unproblematic, pessimists on the other hand are very skeptical about the same subject matter. But how far can their skepticism go? Is it really the case that introspective insights are not only sometimes misleading, but generally false? These are the questions underpinning Tim Bayne’s article “Introspective Insecurity”. Here Bayne argues that a total dismissal of introspection as a tool for gaining information about

¹ In fact, [Eric Schwitzgebel \(2008\)](#) points out that there is a new trend of relying on introspection, even though this method itself is not new and its disadvantages were pointed out with the failure of introspective psychology at the beginning of the 20th century (c.f. [Lyons 1986](#)).

one's own conscious states (global pessimism) would not only be tremendously hard to imagine, but is also not warranted by the arguments raised in favour of that position. What these pessimistic arguments show, however, is that not all kinds of introspection can be used without thorough examination of their truth-tracking capacities. The resulting milder form of skepticism is what Bayne calls local pessimism. This distinction is what I consider Bayne's most important contribution to the introspection debate, because it helps to avoid an overhasty dismissal of a source of information that is used widely, not only in theorizing, but also in everyday life. He points out that what the global skeptic is missing is the idea that there are different kinds of introspective judgments, where not all are equally insecure. To distinguish between more secure cases of introspection and less secure ones, Bayne emphasizes a distinction introduced by him and his colleague Maja Spener in their paper [Introspective Humility \(2010\)](#), namely that of scaffolded versus freestanding judgments. While scaffolded judgments about one's introspective states are quite reliable, because their contents match closely with the contents of the non-introspective processes at work (e.g., visual experience), freestanding judgments lack this sort of reliability due to their abstract character. Simply put, the contents of freestanding judgments lack the close connection to what one wants to find out about the world or one's own mental states.

Another prominent, but also controversial candidate for being an epistemically useful source of evidence is intuition. Much like in the case of introspection, there is a large debate about the reliability and usefulness of intuitions in philosophical theorizing. This debate not only concerns epistemology and philosophy of mind, but also methodology, since many people claim that what philosophy does at its core is conceptual work on the basis of our rational (or conceptual) intuitions ([Bealer 1997](#); [Goldman 2007](#)). In the last few years, however, this idea of how to do philosophy has been harshly criticized from many different perspectives. While proponents of the fairly new project called experimental philosophy have tried to investigate the reliability of intuitions by con-

ducting survey studies collecting lay intuitions ([Weinberg et al. 2008](#); [Knobe 2007](#)), others have even gone so far as to argue that we do not use any intuitions at all in philosophical theorizing ([Cappelen 2012](#)). In any case, it is still open to debate whether intuitions can be used as reliable sources of evidence or not. Here I will first argue that this debate can be substantially informed by Bayne and Spener's idea of scaffolded versus freestanding judgments; this will be referred to as the Scaffolded vs. Freestanding Intuitions Thesis (SFIT). I will try to show that this is the case by highlighting some close connections and similarities between intuitions and introspection. Second, I will argue that in fact intuitions are often made accessible to the debates by introspection, namely in form of introspective insight about one's own private concepts.² This will be called the Introspection of Private Concepts View (IPCVC). Thereafter I will make my third claim, namely that many intuitions, at least those relevant in the debates in epistemology and methodology, are best regarded as freestanding judgments and thus should not count as reliable sources of evidence in philosophical debates. This third and last claim will be what I call the Unreliable Freestanding Intuitions Thesis (UFIT). As in the case of introspection, a total dismissal of intuitions is not (yet) warranted, but neither is their wide-ranging use in contemporary methodology. By applying Bayne's framework, i.e., the distinction between scaffolded vs. freestanding judgments, to the phenomenon of intuitive judgments, I will try to use this new conceptual tool to find a possible answer to the question of which kinds of intuitions are trustworthy and which should not be considered as reliable in philosophical debates.

2 Some connections and similarities between intuition and introspection

If one takes a look at the literature on introspection, one can find many metaphors that are derived from visual perception, i.e. that describe

² While in this commentary I will only concentrate on the influence of introspection on intuitive judgments, it is also worth noticing that both phenomena can also influence each other in the opposite direction. One factor that makes introspective insights feel so reliable at first glance is their intuitiveness. This would be a case in which intuition influences introspection.

the phenomenon as a sort of peering into one's own consciousness,³ as well as direct comparisons with visual perception, i.e., stating that the evidential status of introspection is or should be on a par with seeing the outside world. For example, in his depiction of the central idea behind optimism towards introspection, Bayne says that:

Roughly speaking, to regard introspection as able to *reveal* the phenomenal character of one's conscious states is to have an optimistic attitude towards it. (Bayne [this collection](#), my italics)

Or take Schwitzgebel, who, in his arguments against the accuracy of introspection, assesses the phenomenon by the standards of visual perception:

Does introspection reveal it to you *as clearly as visual observation* reveals the presence of the text before your eyes? Can you discern its gross and fine features through introspection as easily and confidently as you can, through vision, discern the gross and fine features of nearby external objects? (2008, my italics)

If one compares this to intuitions, one can see that they are treated in almost the same way. Here, the most prominent historical root of this equal treatment of not only intuitions and perception, but also intuitions and introspection, might be the work of John Locke, who at the beginning of the fourth book of his [Essay Concerning Human Understanding](#) states that all knowledge is at its core introspective and intuitive and can thus be regarded as the perception of agreement or disagreement between two ideas:

Knowledge then seems to me to be nothing but *the perception of connexion and agreement, or disagreement and repugnancy of any of our Ideas*. In this alone it consists.

³ A further hint at the equal treatment of introspection is the Latin origin of the term 'introspicere', which can be translated as 'to examine' or 'to look into'.

Where this Perception is, there is Knowledge, and where it is not, there, though we may fancy, guess, or believe, yet we always come short of Knowledge. (1975, p. 525, italics in the original)

But contemporary discussions concerning intuitions also suggest a similarity to perception. Take for example this short description by Ernest Sosa:

Intuition gives us *direct insight* into the general and abstract. (1998; my italics)⁴

For George Bealer, who is maybe the most radical proponent of an intuition-based philosophical methodology, the two phenomena are so closely related that he mentions them both as equal sources of evidence in philosophical theorizing:

So in this terminology, the standard justificatory procedure counts as evidence, not only *experiences, observations*, and testimony, but also intuitions. [...] When one has an intuition, however, often one is *introspectively aware* that one is having that intuition. On such an occasion, one would then have a bit of *introspective evidence* as well, namely, that one is having that intuition. (1997, my italics)

This similarity in the way of speaking about the two phenomena and their obvious entanglement in the debate about what counts as evidence⁵ gives us information about the explananda themselves. Both intuition and introspection can be consciously experienced by the subject that uses them to make a judgement.⁶ Furthermore, they are judged to be epistemically unproblematic, because the subject has direct access to them.

⁴ Here again the Latin origin 'intueri', which can be translated as 'to view' or also as 'to examine', underlines not only the folk psychological connection between intuition and perception but also the similarity between introspection and intuition.

⁵ For a general discussion of what counts, or should count as evidence, see [Williamson \(2007\)](#).

⁶ This does not mean that one always deliberately introspects or intuitively. This would be trivially false ([Sosa 1998](#)). What is meant is that one can in principle guide one's attention to the relevant mental state if necessary.

A good example is a classical Gettier-style intuition, such as “It *simply seems to me* that the person in that scenario does know that she is getting the job” (Gettier 1963). Not only the immediate reaction to Gettier cases, but also the way in which Gettier’s conclusion (i.e. that his thought experiments show that justified true belief does not sufficiently describe knowledge) were widely accepted among philosophers indicates that intuitive judgements are treated as unproblematic and reliable. The same holds for introspective judgements that do not only occur in philosophical debates but also in everyday-life belief formation. An example of such a belief could be expressed by a sentence like: “I surely can’t be mistaken in believing that I am consciously experiencing a red object in front of me at this very moment.” In the same way as in the case of intuitions, the results of introspection do not seem to require further questioning. In short, the act of introspecting something and the act of intuiting something both have a phenomenal aspect that makes them appear epistemically secure. In the course of this commentary this aspect will be referred to as a phenomenology of certainty.⁷ In fact, I would say that this phenomenal aspect is the reason why the introspection as well as the intuition debate are as controversial as they are. Both phenomena come at first glance with a seeming of epistemic security (or even infallibility), and only after close examination are some insecurities revealed. This phenomenology of certainty, however, does not immediately show that intuitions and introspection inform a subject securely about the truth of a matter. My introspective judgment about the what-it-is-likeness of understanding a sentence in a foreign language or my intuitive judgment about whether a person has knowledge or not are always in need of further justification. It would be a very hasty step to go from the phenomenology of certainty to full-fledged certainty (Metzinger & Windt 2014).

⁷ It is important to notice that the “phenomenology of certainty” presupposes a “phenomenology of knowing”. This is best regarded as the “phenomenology of knowing that one knows”. For my purposes here the “phenomenology of knowing”, though important, is not the interesting phenomenal aspect of intuitions or introspective insights. I hold the “phenomenology of certainty” far more interesting, because I think that it is that phenomenology that leads to the strong sense of infallibility of intuitive, as well as introspective judgments.

So then what can the two phenomena inform a subject about? The least controversial description of what introspective states are would be along the lines of (Schwitzgebel’s description:

A word about ‘introspection’. I happen to regard it as a species of attention to currently ongoing conscious experience, but I won’t defend that view here. The project at hand stands or falls quite independently. Think of introspection as you will—as long as it is the primary method by which we normally reach judgments about our experience in cases of the sort I’ll describe.⁸ (2008)

Thus construed, introspection mainly informs a subject about the qualitative aspects of her experience. Simply put, what we do when we introspect is to pay attention to the what-it-is-likeness of our experience.⁹ This aspect of experience, however, is extremely subjective and private. It is (if even possible) not easy to arrive at scientifically informative generalizations¹⁰ from such subjective data.¹¹ What is needed to secure information of that kind is the right kind of embeddedness in other, more secure ways of gaining knowledge about a subject matter. Such judgments about a subject’s experience are what Bayne and Spener, at least by the way I understand them, refer to as scaffolded judgments (2010; Bayne this collection). For ex-

⁸ The cases he describes in that paper are from the same domains of experience that Bayne discusses in his article for this volume namely emotion, visual perception, and cognitive phenomenology.

⁹ Note that due to restrictions of space I will cover only, the most relevant interpretation of introspection, which can be described as a sort of inward perception. The word “perception” here is to be read in a metaphorical way. It is not meant to express a commitment to something along the lines of a higher-order perception view on introspection (Güzeldere 1995). Rather this inward “perception” can be understood as kind metacognition that helps a subject to conceptualize her own experiences. For a more detailed distinction between different kinds and qualities of introspection, see Metzinger (2003, p. 35).

¹⁰ Though this might not be a problem for relying on introspection in the case of perception, it becomes more pressing when it comes to using introspective data to inform epistemology or methodology.

¹¹ A further methodological problem that needs to be taken into consideration is the fact that when collecting data about introspective or intuitive states one has to rely on a subject’s report about the relevant mental state. This can be a possible source of contamination, which makes an investigation of the phenomena even more difficult (Cummins 1998).

ample, my introspective judgment about my red experience is not exhaustively justified by itself, but by the close match of the content of my introspective state and the non-phenomenal aspects of my visual observation. Only then can introspection play an evidential role,¹² and thus contribute to knowledge about one's own conscious states. But what if there is no such match? If introspection is concerned with more abstract contents, like, for example, the basic structures of intentionality or thought in general, the lack of embeddedness at least increases the insecurity of the judgment and thus makes it an unreliable source of knowledge. Judgments of that kind, again following Bayne and Spencer, are called freestanding judgments.

Let us now turn to intuitions. What are intuitions about? First of all, it is important to say that not all kinds of intuitions are relevant to philosophical debates. Cases of intuitive controls on a smartphone, for example, are not at the core of the debate. What is meant by philosophically interesting intuitions can be most appropriately expressed by the term conceptual intuition. In short, intuitions in a philosophically relevant sense are judgments that are shaped by the concepts a person has of some subject matter or phenomenon. Usually those intuitions are tested by conducting thought experiments in which a case is described that should (or should not) fulfil all necessary and sufficient conditions of a concept. Then one is supposed to take that very concept and check if it applies to the case (or not). This is why Alvin Goldman also refers to philosophical intuitions as “application intuitions” (2007). Probably the most prominent examples of such intuition-testing thought experiments are Gettier cases. Going back to Edmund Gettier's famous paper, Gettier cases describe scenarios in which a person appears to lack knowledge, despite the fact that the classical conditions for having knowledge, namely, having a justified true belief, are met (1963). But can these conceptual intuitions in fact inform us about what knowledge is in general, or do those cases simply inform us about our personal concepts? Findings from the

fairly new field of experimental philosophy, though highly controversial (Cullen 2010), indicate that conceptual intuitions that have been treated as general intuitions, like those in Gettier cases, are in fact highly idiosyncratic, and thus it is still an open question whether they can lead to generalizations about the concept at hand (Alexander 2012).¹³ In other words, one could argue that conceptual intuitions are the reflections of a subject's *idiosyncratic history of concept acquisition* (Bieri 2007).

So intuitions—or more precisely their contents—reflect upon a person's individual, highly subjective concepts. Just like in the case of introspection (which has been shown to be very subjective as well), we need to investigate whether it is possible to move from those personal concepts to general claims about their contents in a reliable way.

I take all of the above-mentioned similarities between introspection and intuition to be sufficient for investigating the reliability of intuitions with conceptual tools and insights that have already been introduced and established to the introspection debate. Thus, I will in the next section try to clarify what counts as an epistemically reliable intuition by applying the distinction between scaffolded and freestanding judgments from the introspection debate to intuitions. In other words, I will investigate intuitions as scaffolded vs. freestanding intuitions (SFIT).

SFIT =_{Df} Due to the similarities between introspection and intuition, one can also distinguish between scaffolded and freestanding intuitions.

3 Philosophical intuitions as freestanding judgments

Before we examine whether philosophical intuitions are best understood as scaffolded or freestanding judgments, it will be helpful to

¹³ In addition to these findings, it is also an advantage of treating intuitions as reflections on personal concepts, because such a view is likely to be naturalized (Goldman 2007). Arguments from obscurity or empirical implausibility of the type that have been raised against other construals of intuition, such as Platonic insights into the laws of nature (Brendel 2004), can thus be avoided.

¹² Even if this role is then obviously a minor one in forming a belief about the world.

take a closer look at how intuitions are treated in philosophical theorizing. For this we go back again to the paradigm case of intuition-based philosophy: Gettier (1963) cases. The expected (and therefore long unchallenged) outcome of those thought experiments is that the person reflecting on the cases admits that they describe instances of justified true belief that at the same time fail to count as knowledge. How do we know they're not knowledge? We just know! Reflecting on that answer one can come to the conclusion that one has an intuition about the concept of knowledge. The next question that then needs to be answered is how a person arrives at that conclusion. I claim that this is done by introspection. As described above, introspection is best understood as the act of paying attention to one's conscious states of experience, or in other words about the phenomenal aspects of experience. In the case of an intuition, this phenomenal aspect would be the above-mentioned phenomenology of certainty. To summarize this, conceptual intuitions are reflected upon by introspecting on one's own concepts and their applicability conditions. This practice is what I call the Introspection of Personal Concepts View of Intuitions (IPCV).

IPCV =_{Df} Conceptual Intuitions are made accessible by introspecting one's own phenomenology of certainty towards the applicability of a certain concept.

Following IPCV, this practice is then of course vulnerable to the same skeptical challenges that have been raised against introspection in general. How accurately can I introspect what constitutes my concept of knowledge? What about modal aspects like the necessity of a proposition? These questions can be made more accessible by thinking about intuitions in terms of scaffolded or freestanding judgments.

Again taking the Gettier intuition about knowledge, what makes this intuition, even though not universal, so astonishingly stable among Western philosophers? I argue that this is due to the close match between the content of the intuition (i.e. "She doesn't know!") and the rules that one learns about how to successfully use the concept of

knowledge in our cultural niche (i.e.: "Only ascribe knowledge if a person is justified in the right way to believe a proposition!").¹⁴ So in the context of Western philosophy, the intuitive judgment can be regarded as a scaffolded and thus reliable judgment. It is reliable because it is embedded in our conventional, everyday use of the word "knowledge".¹⁵ But what about knowledge in general, i.e., outside the context of Western culture? In that case, the content of the intuition, due to its personal character, would not match the context-free, abstract use of the concept of knowledge. The judgment would be a freestanding judgment and thus an unreliable source of evidence for making general claims about knowledge. This would perfectly fit the idea of intuitions as individually-acquired concepts and also explain findings from experimental philosophy, which indicate that intuitions are highly variable among different cultures (Weinberg et al. 2008). One could now argue that, even if I am correct about conceptual intuitions like those in Gettier cases, there are basic intuitions that are reliable. A candidate for such an intuition is presented by Bealer in the form of rational intuitions:

By contrast, when we have a rational intuition—say, if P then not not P —it presents itself as necessary: it does not seem to us that things could be otherwise; it must be that if P then not not P . (I am unsure how exactly to analyze what is meant by saying that a rational intuition presents itself as necessary. Perhaps something like this: necessarily, if x intuits that P , it seems to x that P and also that necessarily P [...].) (1997)

The reliability of such a basic intuition can also be accommodated in the terminology of scaffolded and freestanding judgments. Due to the close match between our intuition and the way

¹⁴ Surely this is a very simplified and rough description of concept acquisition. Further details should be empirically investigated, but due to limited space, and for and the purposes of my argument, this must suffice.

¹⁵ The scaffold here would be the proper use of a word or concept in its respective culture or context. Further, notice that it is also possible to have several types of scaffolding at the same time, like conceptual expertise (i.e. cases in which a person has a significant amount of background knowledge about special concept) plus the above-mentioned cultural scaffolding. For a defence of conceptual expertise, see Williamson (2011).

in which we learned to describe the world, in which it never is the case that p while simultaneously not p , we can regard that intuition as a scaffolded judgment. Concerning the intuition about the necessity of this intuited content, however, the personal character of intuitions again does not warrant the generalization. Statements about the modal status of the claim are perhaps secured by correctly applying the laws of logic (like in the above mention example of the principle of contradiction), but not by my personal intuition (Alexander 2012; Pust 2014). But even if this is true and thus if such basic intuitions are always reliable, it still needs to be shown by general optimists, concerning the reliability of intuitions, how this extends to more complex phenomena like those often discussed in the intuition debate (Cappelen 2012). I take the above-discussed cases of Gettier-intuitions and Bealer's rational intuitions as evidence that we should at least doubt that most intuitions that are taken as reliable sources of evidence are sufficiently scaffolded. Until this is shown I would advise that we stay skeptical and regard those intuitions as Unreliable Freestanding Intuitions (UFIT).

UFIT =_{DF} Many intuitions that are treated as reliable sources of evidence in philosophical theorizing lack the right scaffolding and must thus be regarded as freestanding intuitions, which makes them epistemically unreliable.

4 Conclusion

In this commentary I have tried to show that the connections between introspection and intuitions are so profound that the debates about the two phenomena can inform each other substantially, and in particular how ideas from the introspection debate can help to clarify open questions in the intuition debate (SFIT). I have taken the idea of scaffolded and freestanding judgments from the introspection debate and applied it to that about intuitions. In so doing, I have tried to show that the wide-ranging skepticism about introspection also concerns intuitions, since many intuitions are investigated by

introspecting on one's phenomenology of certainty that typically accompanies intuitions, as well as introspection itself (IPCV). Bayne's introduction of the scaffolded versus freestanding judgments idea suggests that a global pessimism towards introspection is not warranted by the arguments that are raised by proponents of such a position. I hope to have shown that the same is true in the case of intuitions, which can also be reliable if they are embedded in the right context, or if concerning the basic structures of our experience. The question for further discussion has now become how big the scope of both scaffolded introspective and scaffolded intuitive judgments actually is. Is it possible to develop clear-cut criteria for when a content is sufficiently scaffolded? Must one draw further distinctions and introduce different kinds, or at least a gradual concept, of scaffolding? So far, applied to often very abstract epistemic targets in philosophy, my predictions for the scope of scaffolded judgments in the on-going debates are not very optimistic. I would advise that without further argumentation for the scaffolding of abstract intuitions they are best regarded as freestanding judgments (UFIT). I agree with Sosa when he says, about the skeptical challenges to intuitions: "If that sort of consideration is a serious indictment of intuition, therefore, it seems no less serious when applied to introspection [...]" (1998). The only difference might be that I hold this to be bad news for proponents of the widespread use of both phenomena, rather than a convincing defence of their general reliability.

Acknowledgements

I would like to thank Tim Bayne for his inspiring target article, as well as two anonymous reviewers for their very helpful suggestions and critical remarks. I would also like to thank Thomas Metzinger and Jennifer Windt for the opportunity to contribute to this collection.

Introspection and Intuition

A Reply to Maximilian H. Engel

Tim Bayne

This paper is a response to Maximilian H. Engel's commentary on my target paper, in which I provided a critical examination of pessimism accounts of the trustworthiness of introspection. Engel's focuses on the distinction that I drew between two kinds of introspective judgments, scaffolded judgments and freestanding judgments, and suggests that this distinction might fruitfully illuminate the epistemology of intuitive judgments. I present some doubts about whether the distinction can be transferred to intuition in this way, and also sketch a more fundamental contrast between introspective judgments and intuitive judgments.

1 Introduction

Let me begin by thanking Maximilian H. Engel for his commentary. I take the heart of his paper to consist in the suggestion that the distinction between freestanding and scaffolded judgments which Maja Spener and I ([Bayne & Spener 2010](#)) developed in connection with introspection can be usefully applied to the epistemology of intuition. I will start by revisiting the freestanding/scaffolded distinction, before turning to Engel's proposal.

The epistemology of introspection is that it is not flat but contains peaks of epistemic security alongside troughs of epistemic insecurity. Any attempt to understand the epistemology of

introspection needs to take this landscape into account, for although our pretheoretical views concerning the epistemology of introspection are not sacrosanct they do form a useful constraint on theorizing about introspection. Any account of introspection should explain why some introspective judgments strike us as highly secure whereas others seem to be insecure.

This is where the distinction between scaffolded and freestanding judgments comes in. Both types of judgments have as their intentional objects current conscious states that one takes oneself to be in. (The notion could also be applied to judgements concerning the states

that one is not in.) An introspective judgment is scaffolded when the subject is disposed to make a first-order judgment whose content bears a rough correspondence to that of the introspective judgment. For example, the judgment that one is experiencing a red light in front of one is scaffolded by the disposition to judge that there is a red light in front of one, whereas there is no such first-order disposition corresponding to the introspective judgment that one is merely imagining or thinking about a red light. Experiences that are the intentional objects of scaffolded judgments are themselves employed in world-directed first-order judgments, whereas that is not the case where free-standing judgments are concerned. Contrary to what Engel suggests, there is no commitment here to the idea that only scaffolded judgments are epistemically trustworthy. The idea, rather, is that scaffolded judgments have a certain kind of first-person warrant that free-standing judgments tend to lack.

2 From introspection to intuition?

Engel argues that the distinction between scaffolded and free-standing judgments can also be applied to the kinds of judgments deployed in debates about philosophical intuitions, and also suggests that most such judgments—or at least, those which are of central philosophical interest—are best regarded as free-standing, and thus lack the kind of warrant that we might want for them.

Although I welcome Engel's attempt to extend the distinction between scaffolded and free-standing judgments beyond the domain of introspection, I am not convinced that it does much to illuminate the epistemology of intuition. The first issue that needs to be addressed is the fact that intuitive judgments don't form a single, well-behaved class. One kind of intuitive judgment that is of philosophical interest concerns the modal structure of the world, as when one judges that it is necessarily true that $2+2=4$ or that it is only contingently true that Aristotle was a philosopher. But as far as I can tell, Engel is not concerned with intuitive judgments of this kind, but with what we might call intuitions of concept ap-

plication. Such judgments are concerned with the question of whether a certain concept (such as <knowledge>) ought to be applied to a certain state of affairs.

In explaining how the contrast between scaffolded and free-standing judgments might apply to intuitive judgments Engel writes:

Again taking the intuition about knowledge, what makes this intuition, even though not universal, so astonishingly stable among Western philosophers? I argue that this is due to the close match between the content of the intuition (i.e. “she doesn't know!”) and the rules one learns to use [regarding] the concept of knowledge in our cultural niche (i.e.: “Only ascribe knowledge if a person is appropriately justified in believing a proposition!”). So in the context of Western philosophy, the intuitive judgment can be regarded as a scaffolded and thus reliable judgment. ([this collection](#), p. 6)

It is certainly true that an individual's use of a concept is scaffolded by the practices of the culture in which they are embedded. As Kant pointed out, we learn how to apply concepts by noting how they are applied by those around us. Kant (A134/B174) described examples as the “*Gängelwagen* of thought”, where a *Gängelwagen* is a walking frame or go-kart that is harnessed to an infant in order to help it learn to walk. But although this form of support is indeed a kind of scaffolding, it differs in important ways from the kind of scaffolding that I had in mind. In the sense of the term that Spener and I had in mind, a scaffolded judgment is a judgment that is underpinned by a disposition to make a first-order judgment whose content roughly corresponds to the content of the scaffolded judgments. As far as I can see, intuitive judgments are not scaffolded in this sense, in part because intuitive judgments are already “first-order”. So, although I would certainly agree that the possession of such concepts as <knowledge> is supported by one's cultural niche, it doesn't follow that the intuitive judgments about when it is and isn't appropriate to apply this concept are scaffolded.

3 Intuitive disagreement

In closing, let me mention an important background issue concerning which Engel and I appear to have different views. Engel, I take it, holds that the disagreement in intuitive judgments regarding concept application should be regarded as epistemically troublesome in much the way that disagreement about introspective judgment is regarded as epistemically troublesome. The idea is that in both cases there are objective facts of the matter, and the existence of widespread disagreement indicates that significant numbers of individuals are systematically mistaken about what those facts are.

Although I am inclined to accept this diagnosis when it comes to many introspective disagreements, I do not find it particularly plausible when it comes to disagreements concerning intuitions of concept application. Here's why. Suppose that Weinberg and his collaborators are right when they suggest that low-socioeconomic status individuals are disposed to apply the concept <knowledge> in contexts where high-socioeconomic status (SES) individuals are disposed to withhold it (Weinberg et al. 2001). Would it follow (as Engel seems to assume) that at least one of these groups is mistaken about a matter of objective fact? I don't think so. It seems to me more plausible to assume that low-SES subjects and high-SES subjects simply have different concepts (or "conceptions", if you prefer) of knowledge, and each of them is applying its own concept correctly. The two concepts are similar enough to be both associated with the single word "knowledge", but there is no case for regarding one of these concepts as superior to the other, or for thinking that only one of them truly captures the essence of knowledge. They are simply different concepts.

If this is right, then apparent disagreement between the judgments of low-SES subjects and high-SES subjects about whether or not S knows that P is not substantive in the way in which most introspective disagreement appears to be. Moreover, it seems to me that something similar should be said concerning many (if not all) disputes about the application of other central philosophical concepts. (One needs to

take the possibility of performance errors into account here, but such problems will typically be minimized in philosophical contexts.) But I wouldn't want to commit myself to this account of *all* intuitive disputes. In particular, it seems to me that introspective disputes concerning modal matters are likely to be substantive in a way in which disagreements about intuitions regarding concept application are not.

4 Conclusion

In his commentary Engel suggests that the contrast between scaffolded and freestanding judgments that Spener and I applied to introspection might also be usefully applied to intuition. Although I welcome Engel's attempt to extend the distinction between scaffolded and freestanding judgments beyond its original sphere of application, I have suggested that such a move might not be quite as straightforward as Engel takes it to be, for there don't appear to be any first-order judgments that might scaffold intuitive judgments in the way that first-order perceptual judgments scaffold certain kinds of introspective judgments. But although I cannot see how the distinction between scaffolded and freestanding judgments might apply to intuition, I certainly share Engel's conviction that "comparing and contrasting" the epistemology of introspection with that of intuition is a fruitful exercise, for both domains pose the puzzle of how we might reconcile individual certainty and apparent self-evidence with intersubjective disagreement.

Meaning, Context, and Background

Christian Beyer

It is widely held that (truth-conditional) meaning is context-dependent. According to John Searle's radical version of contextualism, the very notion of meaning "is only applicable relative to a set of [...] background assumptions" (Searle 1978, p. 207), or background know-how. In earlier work, I have developed a (moderately externalist) "neo-Husserlian" account of the context-dependence of meaning and intentional content, based on Husserl's semantics of indexicals. Starting from this semantics, which strongly resembles today's mainstream semantics (section 2) I describe the (radical) contextualist challenge that mainstream semantics and pragmatics face in view of the (re-)discovery of what Searle calls the background of meaning (section 3). Following this, and drawing upon both my own neo-Husserlian account and ideas from Emma Borg, Gareth Evans and Timothy Williamson, I sketch a strategy for meeting this challenge (section 4) and draw a social-epistemological picture that allows us to characterize meaning and content in a way that takes account of contextualist insights yet makes it necessary to tone down Searle's "hypothesis of the Background" (section 5).

1 Introduction

"Meaning" is a popular term in philosophical slogans. Meaning is said to be normative; not to be in the head. The notion of meaning is (nevertheless) said to be the key to the notion of intentional content, to only be applicable relative to a set of background assumptions, and meaning is said to be context-dependent. These slogans are not unrelated, and all of them have a reading, I suppose, in which they are true. Here I shall mainly focus on the last two slogans, regarding background and context. My main question will be twofold:

1. In which sense, and to which extent, can the meaning of assertive utterances be said to be context-dependent?

2. Does this context-dependence have an impact on the validity of Searle's Background Hypothesis, which states that the intentional experiences expressed by assertive utterances, and bearing their respective meaning, and the mental acts of grasping this meaning, both require a non-intentional background on the part of the speaker/hearer, relative to which the truth-conditional content and the satisfaction conditions of the relevant experience are determined?

The upshot will be that (1) whilst there may be expressions lacking the context-sensitivity that many expressions (namely, the indexicals) possess in virtue of their conventional linguistic

meaning, there is a sense (to be explained in terms of the background) in which context-dependence is ubiquitous; but that (2) this context-dependence does not prevent competent language users who lack the sort of individual background in terms of which this particular context-dependence can be defined (the “consumers”) from grasping the literal truth-conditional meaning (the semantic content) which an assertive utterance expresses on a given occasion.

2 Three levels of meaning

An early proponent of the view that meaning is context-dependent is Husserl. His thought on meaning, as manifested in his first major work [Logical Investigations](#), starts out from the problem of what it is for a linguistic expression, as used by a speaker or (scientific) author, to function as a meaningful unit.¹

Husserl’s approach is to study the units of *consciousness* that the respective speaker deliberately presents herself as having—that she “intimates” or “gives voice to”—when expressing the meaning in question. This is what Searle refers to as the condition of sincerity of the relevant speech act ([Searle 1983](#), pp. 9-10). These units of consciousness Husserl labels INTENTIONAL EXPERIENCES or ACTS, since they always represent something—thus exhibiting what Brentano called intentionality. They are “about”, or “as of,” something. For instance, if you claim “One of my goals is to defend contextualism,” you give voice to a judgment or belief-state to the effect that defending contextualism is among your goals. This judgment is intentional, in that it represents a state of affairs, namely your having a particular goal; it is “about” that state of affairs, even if the latter does not exist (i.e., obtain) because you do not have that goal. Now it is the content of this judgment (which may be empty or unfulfilled, i.e., made in the absence of a corresponding intuition, such as a corresponding perception) that a hearer has to know in order to understand your utterance, i.e., to grasp its literal meaning. Thus, the (unfulfilled) judgment functions as the “meaning-

bestowing” or “meaning conferring act” ([Husserl 2001](#), p. 192) regarding the sentence uttered. This act is given voice to, or intimated, “in the narrow sense” ([Husserl 2001](#), p. 189)—it is the condition of sincerity of the speech act. However, in the present example (“One of my goals is to defend contextualism”) the speaker also deliberately presents herself as someone who wants to defend contextualism; after all, she explicitly ascribes that intention to herself. This latter act (the intention in question) is given voice to “in the broader sense” only ([Husserl 2001](#), p. 189), as it fails to be the meaning-bestowing act regarding the sentence uttered and thus to be given voice to in the narrow sense. In other words, the speaker intentionally presents herself as performing or undergoing that act, but if the hearer does not recognize that intention he does not *thereby* fail to grasp the literal truth-conditional meaning of the utterance. Again, if you assert “This is a blooming tree,” you give voice, in the narrow sense, to a demonstrative judgment; but you also present yourself as perceiving (or having perceived) something as a blooming tree, where the act of perception is given voice to in the broader sense. This perceptual act verifies the unfulfilled judgment by intuitively “fulfilling” it ([Husserl 2001](#), p. 192). Since the meaning-bestowing act finds its aim, so to speak, in this intuitive fulfilment, Husserl also refers to it as the corresponding “meaning intention” ([Husserl 2001](#), p. 192). Since any meaning intention aims at its intuitive fulfilment, every meaningful utterance can in principle be made to give voice (in the broader sense) to such an act of fulfilment, provided its literal meaning is not evidently inconsistent. In sections 3 and 4 I shall argue that only the group of speakers capable of both making and understanding such epistemic implicatures (the “producers”) must meet the requirements of Searle’s [Background Hypothesis](#). One does not have to meet these requirements in order to express, or correctly ascribe, a meaning intention and thus grasp the literal truth-conditional meaning of an (assertive) utterance.

The “original function” of linguistic expressions is their communicative use in giving voice to meaning-bestowing acts, or meaning intentions ([Husserl 2001](#), p. 189). However, this “indicating (*anzeigende*)” function is not essen-

¹ For the following presentation of Husserl’s theory of meaning cf. Beyer & Weichold 2011, p. 406.

tial to their functioning as meaningful units, as they can also be employed “in [the] solitary life [of the soul] (*im einsamen Seelenleben*),” thanks to meaning-bestowing acts not actually given voice to but experienced all the same (Husserl 2001, pp. 190-191). But these acts and the meanings they bear are constrained by semantic factors concerning the linguistic expressions employed, with these factors being determined by linguistic conventions regarding the relationship between their meaning and the features of non-linguistic reality they serve to represent:

[...] it pertains to the *usual* [i.e., conventional; CB] sense of these classes of expressions, that they owe their determinate meaning to the occasion [...] [T]heir [respective] meaning is oriented in each case to the individual instance, though the manner of this orientation is a matter of usage.² (Husserl 2001, p. 221)

Husserl’s theory of meaning strongly resembles the mainstream view in philosophy of language attacked by Searle and other contextualists. In the following passage Searle gives a concise summary of that view:

Sentences have literal meanings. The literal meaning of a sentence is entirely determined by the meanings of its component words (or morphemes) and the syntactical rules according to which these elements are combined. [...] The literal meaning of a sentence needs to be sharply distinguished from what a speaker means by the sentence when he utters it to perform a speech act [...]. For example, in uttering a sentence a speaker may mean something different from what the sentence means, as in the case of metaphor; or he may even mean the opposite of what the sentence

means, as in the case of irony; or he may mean what the sentence means but mean something more as well, as in the case of conversational implications and indirect speech acts. [...] For sentences in the indicative, the meaning of the sentence determines a set of truth conditions [...] Sometimes the meaning of a sentence is such that its truth conditions will vary systematically with the contexts of its literal utterance. Thus the sentence ‘I am hungry’ might be uttered by one person on one occasion to make a true statement and yet be uttered by another person, or by the same person on another occasion, to make a false statement. [...] It is important to notice however that the notion of the meaning of a sentence is absolutely context free. Even in the case of indexical sentences the meaning does not change from context to context; rather the constant meaning is such that it determines a set of truth conditions only relative to a context of utterance.³ (Searle 1978, pp. 207-208)

To bring out the relevant semantic factors, consider what Husserl calls “essentially occasional expressions,” i.e., systematically context-sensitive, or indexical, expressions such as “I,” “here,” “now,” “I am here now.”⁴ In his pioneering discussion of these expressions in the first *Logical Investigation*, paragraph 26, Husserl introduces the semantic distinction between, on the one hand, an expression’s *general meaning-function* (i.e., the linguistic meaning of the expression, roughly corresponding to what Kaplan calls “character”) and, on the other hand, the propositional, or sub-propositional,⁵ content – the “*respective meaning*” – expressed in a given context of utterance (Husserl 2001, p. 218). If, for example, you and I both say “I,” then our two

2 The German original runs: “Es gehört zur *usuellen* Bedeutung dieser Klassen von Ausdrücken, ihre Bedeutungsbestimmtheit erst der Gelegenheit zu verdanken [...] [Sie orientieren] ihre jeweilige Bedeutung erst nach dem Einzelfall, während doch die Weise, in der sie dies tun, eine usuell ist.” (Hua XIX/1, pp. 91f.) So Husserl does not subscribe to a Humpty-Dumpty view of meaning, according to which the meaning of an expression in the mouth of a speaker is solely determined by what the speaker wants the expression to mean on the respective occasion; cf. Beyer 2000, pp. 78-79.

3 For an overview of more recent developments in semantics and pragmatics, cf. Lepore & Smith 2006, and the entries in Barber & Stainton 2010.

4 Unlike mainstream semantics, Husserl considers such expressions to be ubiquitous in empirical thought and speech; cf. Husserl 2001, p. 7. The approach to meaning I shall sketch below supports this contention.

5 A sub-propositional content is a non-propositional content (or respective meaning) that is a subpart of a propositional content. Singular and general terms may be used to express sub-propositional contents.

utterances share the same general-meaning function but express different respective meanings, with different referents. Again, if you and I both assert “I have blood type A,” our utterances share the same general meaning-function but express different respective meanings, with different truth conditions. These respective meanings, or truth-conditional contents, are often referred to as *propositions* expressed by the utterance of a sentence.

Husserl regards the general meaning-function as fixed by common usage (Husserl 2001, p. 221). The *respective* meaning determines the expression’s reference, or truth condition, in the sense that two expressions sharing that meaning are thus bound to refer to the same object(s), or to represent the same state of affairs, if any. Husserl construes “respective meanings” as two-factored, with the general meaning function plus the relevant context of utterance (if any) determining the meaning in question. Thus we have two levels of meaning⁶ being expressed when a meaning intention is given voice to:

General meaning-function (conventional linguistic meaning, “character”) =_{DF} The general meaning-function of an expression is a function yielding a respective meaning for a use of that expression in a given utterance context; where the assignment of this meaning-function to the relevant expression is generally a matter of (implicit or explicit) linguistic convention.

*Respective meaning ([sub-]propositional content, semantic content)*⁷ =_{DF} The respective meaning of an expression as used

in a given utterance context is a function yielding a reference or extension for that expression as used in that context, given particular circumstances of evaluation (see below).

In the case of indexical expressions, the respective meaning, alias semantic content, is a function of both the context of utterance and the general meaning-function of the expression used, which differs from the respective meaning; in all other cases, the two levels can be said to coincide.

Indexicality =_{DF} An expression is used as an indexical if and only if it is used in such a way that its respective meaning is dependent on both the utterance context (see below) and its general meaning-function, such that it may acquire different referents or extensions in different utterance contexts in virtue of its general meaning-function.

The level of respective meaning is subject to what Husserl calls “pure grammar,” which is the study of what distinguishes sense (i.e., respective meaning) from nonsense.⁸ On this view, semantic content displays something like formal, syntactic structure. This idea helps to explain the compositionality of meaning, which in turn explains how speakers and hearers, or interpreters, are able to grasp the meaning of an infinite number of sentences, many of which they have never heard before, on the basis of a finite vocabulary and a finite set of linguistic rules or conventions.

It is at the level of *respective* meaning that the bearers of truth-value (that is, of truth and falsity, respectively) are located—i.e., propositions. In modern semantics, truth-value ascriptions are relativized to what Kaplan calls *circumstances of evaluation*, consisting of possible worlds and, according to Kaplan, also times, on occasion. To illustrate one of the theoretical merits of this relativization to possible worlds, consider an utterance of mine of the sentence

⁶ The corresponding idea of different levels (*Stufen*) of understanding, which include the grasping of both character, content, and implicatures, is borrowed from Künne, who is also to be credited for pointing out the close similarity between Kaplan’s character/content distinction and Husserl’s distinction between general meaning-function and respective meaning; cf. Künne 1982. In Beyer 2000, I worked out the consequences of this distinction for Husserl’s semantics and theory of intentional content (“noematic sense”) in detail, arguing that the latter is to be rationally reconstructed as a moderate version of externalism, and that it can be fruitfully compared to Evans’ (radically externalist) neo-Fregean conception of sense, among others. That Husserl’s view can be read this way lends support to Dagfinn Føllesdal’s so-called Fregean interpretation of Husserl’s notion of noema (cf. Føllesdal 1969).

⁷ Note that “semantic content” is used by some authors to refer to conventional linguistic meaning rather than respective meaning (which Kaplan calls “content”).

⁸ Husserl’s investigations into pure grammar, especially his notion of a syntactic meaning category, had an important impact on modern linguistics (due mainly to Ajdukiewicz 1935).

(S0) I exist.

If we make the relativization in question, we can say two things: first, for every context of utterance it holds that the respective proposition expressed in an utterance of this sentence is true in the possible world of that context, so that the *sentence* can be said to be *a priori* or *logically true* (Kaplan 1989). Second, the *proposition* expressed in a particular utterance of S0, the respective meaning, is only *contingently true* – after all, the speaker need not exist: there are, in other words, possible worlds in which the proposition in question is false. Note that:

Context of utterance =_{DF} The utterance context consists of the possible world in which the utterance is (assumed to be) performed, the speaker, the addressee, the time and the place of utterance *and/or* all other entities that (according the general meaning-function of the expressions uttered) have to be identified in order to evaluate the utterance in terms of truth, falsity, or reference, relative to given circumstances of evaluation.

Or thus goes the rather common definition of “utterance context” I have used in earlier writings (e.g., Beyer 2001, pp. 278-279).

It is generally agreed upon, in mainstream semantics, that the levels of meaning mentioned so far – character and respective semantic content – do not exhaust what is communicated in speech. As Husserl puts it, there are mental states given voice to “in the broader sense,” and their contents are candidates for what the speaker non-literally means or suggests, which Grice calls “implicature.” At the same time, these contents are further candidates for what the hearer grasps when understanding, or successfully interpreting, the utterance.

This has been standardly regarded as a third level of meaning that is not the subject matter of formal semantics but rather of pragmatics: the study of the use of language for purposes of action other than the expression of literal meaning.

What is implicated (suggested, indirectly communicated) =_{DF} By using an expression in an utterance context, a speaker implicates the intentional contents of the mental acts she gives voice to in the broader sense. These contents can be made out on the basis of the respective meaning of the expression in that context by applying certain conversational maxims (cf. Maibauer 2010).

3 A contextualist challenge

This, then, is more or less the received opinion, which has been challenged by philosophers on the basis of ideas that partly go back to Husserl—in particular the notion of *background*. Thus, in his 1978 essay on “*Literal Meaning*” Searle claims that:

[...] for a large number of cases the notion of the literal meaning of a sentence only has application relative to a set of background assumptions, and furthermore these background assumptions are not all and could not all be realized in the semantic structure of the sentence in the way that presuppositions and indexically dependent elements of the sentence’s truth conditions are realized in the semantic structure of the sentence. (Searle 1978, p. 210)

On this view, the role of context is not simply that of fixing the reference of indexical expressions in a semantically well-regulated manner. There is contextual content determination everywhere, and correspondingly there is semantic underdetermination all over the place. There is no propositional meaning content attached to a sentence independently of context; and (some authors would add) *context* itself is not a well-defined notion: there is no neat list of semantically fixed context-factors and context-sensitive expressions. There is a huge and confusing background of assumptions, or know-how, that we bring to a given linguistic utterance, without which the utterance would fail to express any semantic content, and to thereby

determine truth conditions; and there is no hope of constructing a formal theory of this background (or “context”) and the way it determines truth-conditional content. Thus runs Searle’s radical contextualist challenge to mainstream semantics and pragmatics.

To motivate contextualism (so conceived) about meaning and content, consider a situation in which an object is hidden in a box. All we know about that object is that it is the only object in that box. Unlike us, the speaker knows which kind of object is in the box. She does not know that we do not know this; she intends to refer to a particular object of that kind, the one she takes to be in the box, or to one of its aspects (dependent features). She utters the sentence

(S1) This is red.

to make a statement about the object or aspect, without implying or suggesting anything else. What statement does she make? What is the respective meaning expressed in this utterance? What does the speaker say? According to radical contextualism, this depends on a wide variety of factors, not encoded in the linguistic meaning of the sentence uttered.

For a bird to be red (in the normal case), it should have most of the surface of its body red, though not its beak, legs, eyes, and of course its inner organs. Furthermore, the red color should be the bird’s natural color, since we normally regard a bird as being ‘really’ red even if it is painted white all over. A kitchen table, on the other hand, is red even if it is only painted red, and even if its ‘natural’ color underneath the paint is, say, white. Moreover, for a table to be red only its upper surface needs to be red, but not necessarily its legs and its bottom surface. Similarly, a red apple, as Quine pointed out, needs to be red only on the outside, but a red hat needs to be red only in its external upper surface, a red crystal is red both inside and outside, and a red watermelon is red only inside. [...] In short, what counts

for one type of thing to be red is not what counts for another. (Lahav 1989, p. 264)

So, in which way does the relevant meaning of S1 (“This is red”) depend on context? I want to consider three options.

1. *Speaker intentions*: Are the referential intentions of the speaker, such as their intention to refer to a particular *bird* by “this,” part of the relevant context? One problem with this answer is that it prevents us from adopting a conception of context according to which shared knowledge of context is what (in addition to shared knowledge of conventional linguistic meaning) enables both speaker and hearer to grasp one and the same respective meaning in cases of successful communication. After all, context, thus understood, is supposed to help the hearer make out the speaker’s referential intentions, among other things. So the present answer does not help—provided we conceive of context in a communication-theoretical way—as a means, so to speak, that in accordance with the relevant linguistic meaning enables the hearer to determine the respective meaning expressed.⁹
2. *Object referred to*: Is the relevant context simply identical to what’s in the box? But the speaker might only be referring to a particular aspect of the object in the box, rather than to the whole object. So we are thrown back to the speaker’s referential intentions—which do not help us, as we saw above.
3. *Background assumptions*: Does the relevant context consist of background assumptions about the object, or kind of object, in the box? Which assumptions, exactly? It seems to be impossible to make a comprehensive list, because every set of assumptions brings with it further assumptions. For example, suppose that the speaker takes an apple to be in the box. *Apples* normally count as red even if their *skin* is not completely red. However, consider a social group who have only encountered two kinds of apples thus far (as far as their colour

⁹ The epistemic availability of this means may require further means, to be found in a wider context itself not necessarily predelineated semantically.

is concerned): apples whose skin is completely red and apples whose skin is completely green; imagine that their apples instantaneously turn red when ripe. These people probably wouldn't classify an almost-ripe apple of the kind we know as "red." In fact, they wouldn't know what to say, because they have always assumed that there are only two kinds of apple-colour, and because this background assumption determines the meaning they conventionally associate with S1 as applied to apples. So shall we regard the assumption that there are grades of apple-redness corresponding to their ripeness as part of the context of our assertive uses of the sentence "this [the speaker refers to an apple] is red"? But how many grades are relevant? What if there had been exactly three apple colours? This would probably again lead to a different use, and hence respective meaning, of S1, as applied to apples, and so on and so forth.

Obviously these sorts of examples can easily be multiplied. Is there any way to avoid the following radical contextualist conclusion?

Radical contextualism =_{DF} There is no fixed relation between

- (i) the linguistic or literal meaning of a sentence S;
- (ii) a neatly defined set of context parameters; and
- (iii) the respective meaning and truth condition of S in the context of utterance, such that (iii) is uniquely determined by (i) and (ii).

Rather, the respective meaning is always determined differently, from situation to situation, so that the notion of a conventionally (co-)determined semantic content is untenable.

4 Two kinds of knowledge about truth conditions

The best strategy I can think of to avoid this radical conclusion draws upon a distinction made by Emma Borg. In her 2004 book *Minimal Semantics*, Borg distinguishes between minimal se-

mantic understanding, i.e., knowledge of what she calls "liberal" truth conditions, on the one hand, and knowing how to "verify" (or knowing what would make it the case) that the truth condition *is met*, on the other hand (Borg 2004, p. 238). Thus, the members of the social group who only know (what we would call) completely red-skinned and completely green-skinned apples are unable to know whether the truth condition of the sentence "this [the speaker refers to an apple] is red" is *met* regarding a not fully ripe apple, but they nevertheless *know* the truth condition—namely that the object the speaker wants them to attend to be red—whatever the latter may require in the case at hand. *They have full semantic knowledge but lack background know-how.* However, the latter is only required for "verification," or

1. knowledge of the proposition *p* stated (i.e., knowledge that *p*),

but not for the less demanding

2. knowledge of *which* proposition was stated (i.e., knowledge that *p* is the proposition literally expressed by the speaker).

The latter is sufficient for semantic knowledge regarding the statement.

I like this answer to the contextualist challenge, but I think that it eventually leads to a more moderate version of contextualism, rather than to a full-scale rejection: it leads to a version that makes room for semantic knowledge without background assumptions or know-how, knowledge whose content can indeed be investigated by formal semantics.

Clearly, the advocate of the present answer needs to explain how one can understand a sentence while lacking the kind of background know-how regarding which Searle would claim that in the absence of such capacities the "notion of the meaning of the sentence" has no clear "application" at all (see quotation above). Searle would stress that in the absence of appropriate background assumptions or know-how we have no clear idea of how to understand a sentence like "This (apple) is red;" which mani-

festes itself in the fact that we do not, for instance, know how to follow the corresponding order “Bring me the red apple!” (cf. [Searle 1983](#), p. 147). In the light of Borg’s distinction, this can be described as lack of knowledge about “verification,” but what about the strong intuition that in the absence of such background know-how the sentence fails to express a content that can be evaluated in terms of truth and falsity? To strengthen this intuition, consider Searle’s examples S2–S4 (cf. [Searle 1983](#), Ch. 6):

- (S2) Bill opened the mountain.
- (S3) Bill opened the grass.
- (S4) Bill opened the sun.

These sentences are syntactically well-formed and contain meaningful English expressions; yet they do not express clear semantic content—unless we imagine some background know-how regarding what it means to open a mountain, the grass, or the sun.¹⁰ The mere combination of the literal meaning of the verb “opened” with the literal meanings of other English expressions in accordance with the English syntax does not seem to be enough to produce a clear truth-evaluable content, despite the fact that “to open” does not look like an indexical that yields as reference a unique behavioural relation (or type of action) referred to as “opening,” for a neatly defined type of context—in the way that “I” always yields the speaker of the utterance context as its referent. Borg would disagree; she says about an analogous example by Searle (“John cut the sun”):

If the competent language user understands all the parts of the sentence (she knows the property denoted by the term ‘cut’, she grasps the meaning of the referring term ‘John’ and she understands the meaning of the definite description ‘the sun’) and she understands this construction of parts, then she knows that the utterance of this sentence is true just in case

[...] John stands in the cutting relation to the sun. Now clearly any world which satisfies this condition is going to be pretty unusual (and there may be some vague cases [...]) but there will be, it seems, some pretty clear cases on either side of the divide. For instance, any world where John’s actions do not have any effect on the physical status of the sun is clearly going to be a world where the truth-condition is not satisfied. While any world where John’s actions do result in some kind of severing of the physical unity of the mass of the sun is a world where the truth-condition is satisfied. ([Borg 2004](#), p. 236)

This reply to Searle is unconvincing for at least two reasons.

First: To begin with, Borg here equates semantic knowledge concerning the verb phrase “cut” with knowledge of the property it denotes (see the first brackets in the quotation). But arguably this phrase does not denote any property in isolation; it only does so in the context of a *sentence* (by the “context principle”).¹¹ And Searle’s parallel point about “opened” is that this verb phrase denotes quite *different* properties in S2–S4, respectively, without being ambiguous. That the verb is unambiguous in these cases becomes intuitively plausible if we apply the “conjunction reduction” test (cf. [Searle 1992](#), pp. 178–179). Instead of asserting the conjunction of S2–S4 we can just as well say: “Bill opened the mountain, the grass, and the sun” and perhaps add: “he used a secret universal device for the task recently developed by NASA.” This may be a weird example, but its

¹¹ Cf. [Beyer 1997](#), p. 341, where I raise the same point in order to criticize one of Searle’s arguments for the Background Hypothesis. As for the precise content of the context principle, Robert Stainton distinguishes between three readings:

“The first [is] merely methodological, a claim about how to find out what particular words mean: To find word meanings, look at what they contribute to sentences. The second reading [is] metasegmental, a claim about why words have the meanings they do: words only have meaning because of how they affect sentence meanings. The third reading of the Principle is interpretational/psychological. [...] [T]he idea underlying it is that the only things we are psychologically able to understand are whole sentences.” ([Stainton 2010](#), pp. 88–89). In the present context, a consequence of the *metasegmental* reading is intended which follows from the conjunction of that reading and the assumption that the meaning of a predicate (like “... cut ...”) denotes a property or relation, if anything.

¹⁰ Another option might be to admit category mistakes as semantic contents. (I wish to express my thanks to Adriana Pavic for reminding me of this option.)

weirdness does not seem to be due to the ambiguity of “opened.” Rather, unlike the imagined NASA devisors we simply have no background know-how that would enable us to assign truth conditions to this sentence.

Borg would probably reject the context principle (thus paying a high price for her view) and answer that there may be vague cases in which we do not know whether the opening relation obtains or not, but that “there will be [...] some pretty clear cases on either side of the divide” (Borg 2004, p. 236); after all, in the preceding quotation she makes a parallel claim about the example “John cut the sun.” But this answer is, again, unconvincing (as is Borg’s parallel claim). One might just as well argue that both S5 and S6 describe the same relation, the opening relation, as obtaining between different objects.

(S5) Bill opened his hand.

(S6) Bill opened the door.

But opening a hand is an intentional bodily movement, while opening a door is a more advanced or complex action that merely *involves* such bodily movements. These are different kinds of behavioural relation. Of course, clear examples of the obtaining of both of these relations may have something in common, but this common feature does not seem to constitute a common *type of action*. And what (if anything) is the verb phrase in S5 and S6 supposed to denote, if not a type of action?

Nor is the verb phrase in this pair of sentences ambiguous. This is made plausible by the conjunction reduction test: it is perfectly fine to abbreviate the conjunction of S5 and S6 as follows: “Bill opened the hand and the door.”

The (to my mind) false impression that the unambiguous verb phrase in S2–S4 denotes the same behavioural relation or feature as in, say, S6, merely comes from the fact that we tend to think of *established* uses of “*a* opened *b*” sentences (or “*a* cut *b*” sentences) when trying to construct an interpretation for cases like S2–S4 that we do not really understand. But there is no such use in these cases (see the next paragraph but one).

Second: Moreover, Borg’s claim that “any world where John’s actions do result in some kind of severing of the physical unity of the mass of the sun is a world where the truth-condition [of ‘John cut the sun’] is satisfied” is simply false. If John causes an explosion whose effect is that the physical unity of the mass of the sun is severed (such that it breaks into, say, two halves),¹² he does not thereby *cut* the sun. I suppose that any attempt to secure a minimal truth condition for S4 (and S2–S3, for that matter) is doomed to failure. In order to have at least a slight chance of getting off the ground, any such attempt will have to mention something that can be done using sharp-edged tools (or devices simulating such tools),¹³ and it seems impossible to define (let alone imagine) a procedure of this type that could in principle be applied to the sun.

To anticipate the alternative approach I am going to take, in cases like S2–S4 there is no established sentence-use because there is no appropriate background know-how to be found in the relevant social group (including its late members), hence no group of (current or former) “producers” (see below), and hence no relation conventionally denoted by the verb phrase that could enter the respective truth condition. Therefore, these sentences have “literal meaning” (as Searle puts it) but lack semantic content. Literal meaning is not usage (in the current sense), nor does it require a particular usage—unlike respective meaning.

On similar grounds (to return to the last example about S1), if in the envisaged social group there is no background know-how regarding certain apples that *we* would readily classify as “red,” against that background, the sentence S1 has no clear application to such apples in the language use of that group, and it *does not have the same truth condition* as in ours. An in-

¹² A reviewer claims that “to sever” means to cut. Even if the corresponding interpretation of “severing” were admissible, it could not be the one intended by Borg. Have a look at the preceding quotation. If you replace “severing” by “cutting” there, you obtain: “While any world where John’s actions do result in some kind of cutting of the physical unity of the mass of the sun is a world where the truth-condition [of ‘John cut the sun’] is satisfied.” If this sentence is meaningful at all, it expresses a triviality that does nothing to support Borg’s view.

¹³ See the entry on “cut” in the Oxford Advanced Learner’s Dictionary of Current English.

interpretation problem occurs. I am attracted by an interpretation-theoretical principle proposed by Timothy Williamson, probably inspired by Gareth Evans, which Williamson calls the principle of knowledge maximization (as opposed to the principle of *truth* maximization to be found in traditional hermeneutics, and endorsed by Donald Davidson):

The shift from conventions of truthfulness to conventions of knowledgeableness also has repercussions in the methodology of interpretation. The appropriate principle of charity will give high marks to interpretations on which speakers tend to assert what they know, rather than to those on which they tend to assert what is true [...]. (Williamson 2000, p. 267)

The right charitable injunction for an assignment of reference is to maximize knowledge, not to minimize ignorance. (Williamson 2007, p. 265)

According to the principle of knowledge maximization, an interpretation is correct to the extent that it maximizes “the number of knowledgeable judgements, both verbalized and un-verbalized, the speaker comes out at making” (McGlynn 2012, p. 392). To motivate this principle, although in a somewhat modified version, imagine that in the above example about the box there are in fact two objects in the box—a red ball and a yellow apple—but that we know that the speaker does not know about the ball, which was already hidden in the box before we put the apple into the box while the lightning was such as to make the apple look red.¹⁴ The speaker, who observed how we put the apple into the box, mistakenly believes it to be red and exclaims: S1 (“this is red”). No doubt, if this utterance has any truth condition, it involves an apple rather than a ball, and the utterance is false. A suitably modified version of

the principle of knowledge maximization yields this result as the correct interpretation, while the principle of truth maximization fails to do so. After all, the speaker would only give voice to a true belief here if her statement concerned the *ball* rather than the apple. However, this belief would not qualify as knowledge, in the described situation, and by assumption the speaker lacks any other knowledge regarding that ball. By contrast, the speaker possesses some knowledge about the apple, which is in fact yellow. In Evans’ terms, the speaker has opened a mental dossier (a dynamic system of beliefs) about the apple, which contains quite a number of (correct) information about it, even though the addition of the belief that the apple is red does not enlarge that body of knowledge. Thus, the speaker ought to be interpreted as giving voice to that false belief, Davidson and traditional hermeneutics notwithstanding. This interpretation takes into account more relevant knowledge on the part of the speaker than the other.

The principle of knowledge maximization needs to be modified in terms of, or supplemented by, a more traditional theory of justification in order to yield this result. To see this, let us first consider another example, inspired by Husserl (cf. Husserl 1987, p. 212), which I have used in earlier writings to motivate my “neo-Husserlian,” moderately externalist reconstruction of his view on respective meaning and intentional content.

Let’s assume that at a time t_1 Ed points at a certain table in the seminar room where he has just been lecturing and exclaims:

[(S7)] This table wobbles.

One of the students is prepared to take Ed to the caretaker, to make sure that the table gets repaired immediately. The way from the seminar room to the caretaker’s office is rather complicated. But they manage to find it. The caretaker asks Ed to take him to the seminar room with the wobbling table. The student has other things to do. So Ed has to take the care-

¹⁴ Following the realism inherent to ordinary language use, I assume that the everyday world of experience involves objects displaying real colours. It may be possible to eliminate real colours, but such attempts at revisionary metaphysics should have no impact on the study of the actual use of language, unless they lead to a change of language use, which has not happened yet in the case of colour words.

taker to that room by himself. Finally, they arrive at a seminar room that Ed falsely believes to be the room with the wobbling table. At t_2 Ed points at a certain table, which he regards as that wobbling table, and once again declares [S7]. The caretaker investigates the table and contradicts Ed—who reacts somewhat irritatedly. (Beyer 2001, pp. 284–285)

It is unclear which referent (table 1 or table 2) the interpreter is supposed to assign to the demonstrative term “this” according to the (unmodified) principle of knowledge maximization. After all, both of these assignments would lead to an ascription of knowledge to the speaker: knowledge about table 1 (to the effect that it wobbles) and table 2 (to the effect that it is a table he takes to be wobbling), respectively.

To decide the issue, the interpreter needs to take a closer look at the speaker’s epistemic motivation for making the judgment given voice to in her utterance of S7 at t_2 —he needs to consider the experience(s) with recourse to which the speaker can *justify* her claim to knowledge. If the judgment is motivated by a perception the speaker is having, thus qualifying as an *observational* judgment, it will be about the object of that perception: that object is perceived as thus-and-so and for this reason (on this ground) judged to be thus-and-so. This is what happens at t_1 : the speaker perceives table 1 as wobbling and is sincerely giving voice (in the narrow sense) to an accordingly motivated judgment to the effect that it wobbles. However, at t_2 the epistemic situation is different. The speaker’s judgment is motivated by a *memory of table 1* rather than by her current perception of table 2. It is this memory that rationalizes her judgment, and could be self-ascribed by the speaker when justifying her judgment. Therefore, the speaker gives voice, in the narrow sense, to a judgment about table 1, namely that it wobbles. I have elsewhere called this epistemically-determined truth condition the utterance’s *internal truth condition*.¹⁵ According to

the neo-Husserlian approach, respective utterance meaning determines the *internal* truth condition.

So in order to yield interpretations that adequately reflect the meaning intentions actually given voice to by the speaker, and thus the respective meanings of their utterances, the principle of knowledge maximization needs to be supplemented by (or reformulated in terms of) a more traditional theory of justification, drawing upon notions like *observation*, *memory* and *testimony* (referring to sources of justification). Note that the present approach to reference supports a version of the context principle: it is only in the context of a judgment that a referent can be assigned to a mental act of reference given voice to by a singular term.

Let us finally return to the example about the two objects in the box. In this example the speaker gives voice to a judgment about the yellow apple rather than the red ball in her utterance of S1, because she (falsely) remembers that ball as being red, having opened, on an earlier occasion, a mental dossier about it containing the (incorrect) information that the ball is red, while she neither remembers nor perceives, nor has heard about the ball that also happens to be in the box. Thus, the judgment given voice to can only be motivated by, and justified with recourse to, that memory—even if it does not yield knowledge in the case at hand. And that memory concerns the apple rather than the ball, because it belongs to the speaker’s body of information about the apple. Thus, on a version of the principle of knowledge maximization modified in accordance with the foregoing neo-Husserlian approach to reference assignment, the utterance in question concerns the apple, if anything.

Now by the principle of knowledge maximization (in both versions), if there is no back-

ternal truth-condition is the state of affairs represented by the (intentional content of the) judgement the speaker should give voice to, given (a) the linguistic meaning [i.e., the general meaning-function] of the employed sentence and (b) the external context.” The external context is the actual (observable) context of utterance, which on the neo-Husserlian approach may differ from the phenomenologically relevant (“internal”) context, which is determined by the motivational structure of experience with recourse to which the speaker could justify the judgment given voice to. In the present example, the internal context involves table 1.

¹⁵ Cf. Beyer 2001, p. 289: “The internal truth-condition of an assertion is the state of affairs represented by the (intentional content of the) judgement actually given voice to in that assertion. Whereas the ex-

ground that enables members of a social group to express knowledge by a sentence like S1 in a situation where we would readily apply that sentence—on the basis of our own knowledge *and* background know-how—, then the following conclusion recommends itself: in the language use of this social group the sentence lacks the determinate truth-evaluable meaning it expresses in our own language use, in a given context. (Contrast what Borg says about “John cut the sun;” see the above quotation from [Borg 2004](#), p. 236.)

This speaks in favour of contextualism. However, it does not speak in favour of a radical version of contextualism, which would not allow for a notion of minimal semantic knowledge that can indeed be possessed in the absence of personal background know-how—a version that thus ignores the above-described difference between two types of knowledge regarding truth conditions. In what follows, I shall sketch a more moderate version of contextualism that does take this difference into account.

5 Towards a moderate contextualism about meaning

It is plausible to assume that all that is required for semantic knowledge, conceived as knowledge *which* truth condition has been stated, is that the following two conditions be met. First, a sufficient number of current or former (late) members of the *speech community* to which the speaker belongs possess appropriate background know-how. Second, the speaker stands in an appropriate social relation to these members (a relation that would enable the speaker to express communal knowledge by a true sentence whose content she may be unable to “verify” herself).

These members are experts; they are capable of “verifying” or “falsifying” the semantic content of the sentence in question, as opposed to merely grasping it. Other members of their social group participate in their knowledge thanks to intersubjective processes of information transfer. The main idea behind this approach is an adaptation of Evans’ distinction between what he calls name-producers and mere name-consumers, which is used to substantiate

the above distinction between two kinds of knowledge regarding a sentence’s truth condition.¹⁶ This strategy leads to a social-epistemological conception of the background of meaning and to a version of contextualism that preserves basic insights of anti-contextualists like Borg. Evans writes:

Let us consider an ordinary proper-name-using practice, in which the name ‘NN’ is used to refer to the person x. The distinctive mark of any such practice is the existence of a core group of speakers who have been introduced to the practice via their acquaintance with x. They have on some occasion been told, or anyway have come to learn, a truth which they could then express as ‘This is NN’, where ‘This’ makes a demonstrative reference to x. Once a speaker has learned such a truth, the capacity to re-identify persons over time enables him to recognize later occasions on which the judgement ‘This is NN’ may be made, and hence in connection with which the name ‘NN’ may be used. [...] Members of this core group, whom I shall call ‘producers’ [...], do more than merely use the name to refer to x; they have dealings with x from time to time, and use the name in those dealings – they know x, and further, they know x as NN. [...] [T]he expression does not become a name for x unless it has a certain currency among those who know x – only then can we say that x is known as NN. [...] Perhaps in the early stages of its existence all the participants in the name-using practice will be producers, but this is unlikely to remain so for

¹⁶ As Evans acknowledges, this distinction is inspired by Putnam’s notion of a “linguistic division of labour” (see [Putnam 1975](#), pp. 145–146); cf. [Evans 1982](#), p. 377. I should stress that on the view proposed in this contribution, the producers do not grasp the respective meaning of relevant expressions more “fully” than the mere consumers. Rather, they help sustain the common practice necessary for those expressions to be usable (by both producers and mere consumers) to express a respective meaning (a truth-conditional “semantic content”). I should also stress that I take the producer/consumer distinction to be universally applicable, and not just in the case of rigid designators, and that on my view the capacities of the producers (unlike the capacities of what Putnam calls “experts”) need not include scientific knowledge. (Thanks to Adriana Pavic for pressing me on these points.)

long. Others, who are not acquainted with x , can be introduced into the practice, either by helpful explanations of the form ‘NN is the φ ’, or just by hearing sentences in which the name is used. I shall call these members ‘consumers’, since on the whole they are not able to inject new information into the practice, but must rely upon the information-gathering transactions of the producers. [...] Let us now consider the last phase of a practice of a name-using practice, when all the participants are consumers. [...]. Later consumers manifest the intention to be participating in this practice, and, using a name which, in the practice, refers to Livingstone, themselves refer to Livingstone. Thus the practice is maintained with a constant reference, perhaps for very long periods of time. (Evans 1982, pp. 376-393)

is satisfied; they know how to follow a corresponding order, and so on.

The rest of the speech community merely knows the truth condition and can gain and transfer information an utterance of the sentence bears without themselves being in the know—that is, without having the original knowledge only the producers have in their possession. They may acquire and transfer knowledge (sometimes) by testimony, thanks to the existence of a community-wide practice of sentence-usage sustained by intersubjective processes of information transfer, in a way yet to be understood in more detail.

Eventually, mere consumers “must rely upon the information-gathering transactions of the producers,” to use Evans’ formulation. Mere consumers have semantic knowledge, but they lack more substantive knowledge. Semantics is concerned with the content of their semantic knowledge. Mere consumers need a background of what Searle calls *social practices*, including social practices of language use. However, they lack the producers’ individual or personal background know-how and thus their substantive knowledge regarding truth conditions, which requires such know-how (i.e., the knowledge of how to “verify” those conditions).

What kind of individual background do the producers need in order to be able to make possible social practices of language use that allow all members of their speech community to express and grasp semantic contents determining particular truth conditions? In his 1978 paper, which some regard as the constitutive document of contextualism, Searle stresses the importance of background assumptions, such as the assumption that there is a field of gravitation or that things offer resistance to pressure, which is usually taken for granted, quite unreflectedly, when we speak about middle-sized everyday objects such as apples and boxes. This may at first sound like the requirement of what might be called background *knowledge*, consisting of intentional states, i.e., certain epistemically distinguished beliefs. However, especially in his later writings, Searle stresses the non-intentional character of the background, characterizing it as consisting of non-intentional capacities

If we adapt Evans’ distinction between two types of name-users for present purposes, we can say that in a given community there have to be, or have to have been (see the last three sentences of the quotation), people “in the know” regarding (what we use to call) the red colour of apples, or regarding a particular practice of opening mountains, grass, or the sun, in order for the sentences S2–S4 to be candidates, in virtue of their literal meaning, for the expression of knowledge available to us through these sentences.¹⁷ There have to be (current or late) “producers” in order for these sentences to express a semantic content determining truth conditions, thus displaying a clear, interpretable respective meaning in that linguistic community—and this requires that the sentences have a community-wide usage upheld by recourse to (current or late) producers. They know (or knew) how to “verify” the respective meaning of assertive utterances of the sentence, in the relevant usage; i.e., they know which fact (if any) would make it the case that the truth condition

¹⁷ The point is not that we cannot describe uncommon practices (such as using a metal saw) for actions like opening a can, say. Rather, the point is that there have to be common practices, known to the producers, in order for a sentence like “Bill opened the can” to be usable to express a respective meaning representing any practice in the first place. (Thanks again to Adriana Pavic for helping me to make this clear.)

—which I have referred to above as background *know-how*, and which would include the ability to perform social practices. Searle has formulated a thesis about the relation between intentionality, on the one hand, and background know-how on the other, a thesis he calls the “hypothesis of the Background”:

Another way to state [the hypothesis of the Background] is to say that all representation, whether in language, thought, or experience, only succeeds given a set of nonrepresentational capacities. In my technical jargon, intentional states only determine conditions of satisfaction relative to a set of capacities that are not themselves intentional. (Searle 1992, p. 175)

Later in the same book chapter he explains:

The actual content [sc. of an intentional state] is insufficient to determine the conditions of satisfaction. [...] Even if you spell out all contents of the mind as a set of conscious rules, thoughts, beliefs, etc., you still require a set of Background capacities for their interpretation. (Searle 1992, pp. 189-190)

This addition to the formulation in the penultimate quotation is, I think, false—or even absurd. The respective meaning of an utterance is the intentional content of the mental state given voice to in the narrow sense, which means that intentional content is precisely what determines the truth condition (or, more generally, the conditions of satisfaction). Indeed, Searle seems to agree:

[...] I want to capture our ordinary intuition that the man who has the belief that Sally cut the cake has a belief with exactly the same propositional content as the literal assertion ‘Sally cut the cake.’ (Searle 1992, p. 184)

I take it to be a definitional truth that intentional content provides the answer to Wittgenstein’s question “What makes my representation

of him a representation of *him?*”. A conception of intentional content must spell out this answer. It makes no sense to conceive intentional content along the lines of Searle’s addition in the penultimate quotation, just as it makes no sense (*pace* Searle) to say of semantic content, properly construed, that it is not self-applying, or that it needs to be interpreted against a non-representational background in order to determine reference or satisfaction conditions.

In the following passage Searle commits himself to radical contextualism:

An utterance of [the sentence ‘Sally gave John the key, and he opened the door’] would normally convey that first Sally gave John the key, and later he opened the door, and that he opened the door with the key. There is much discussion about the mechanisms by which this additional content is conveyed, given that it is not encoded in the literal meaning of the sentence. The suggestion, surely correct, is that sentence meaning, at least to a certain extent, underdetermines what the speaker says when he utters the sentence. Now, the claim I’m making is: sentence meaning radically underdetermines the content of what is said. (Searle 1992, p. 181)

Thus, Searle explains, nothing in the literal meaning of the sentence referred to excludes crazy interpretations like: “John opened the door with the key by swallowing both door and key, and moving the key into the lock by way of the peristaltic contraction of his gut.” (Searle 1992, p. 182) Note that we are dealing with a claim about linguistic meaning here, not about semantic content—properly construed as *representational* content, uniquely determining satisfaction conditions.

From the viewpoint of the social-epistemological picture of semantic content sketched above, the Background Hypothesis should be restricted to the *producers* of sentences figuring in linguistic representation. On this picture, only the producers’ intentionality requires background know-how regarding the application of

those sentences. Mere consumers merely need an appropriate background of *social practices*. If the advocate of this picture did not restrict the Background Hypothesis to the producers, he would be committed to the view that mere consumers can give voice, in the narrow sense, to intentional states in which they cannot be, due to lack of background know-how. This would mean that only the producers can be *sincere* in their assertive utterances of sentences regarding which they are producers. But this seems wrong. It is possible for mere consumers to deliberately express knowledge by testimony. Hence, the (unrestricted) hypothesis of the Background ought to be rejected, on the present view. Meaning-intentions (meaning-bestowing acts) do not generally require a non-intentional background relative to which their (truth-conditional) content and satisfaction conditions are determined; while their intuitive fulfilments (the corresponding “verifications”), if any, do. For instance, it is impossible to *perceive* something as an elm without being able to distinguish elms from other sorts of trees. This of course means in turn that one ought to reject the present picture if one accepts the Background Hypothesis (in unrestricted form). In order to decide the issue, more needs to be said to explain this hypothesis. I cannot decide the issue here. But it may be helpful in this regard to end by saying a bit more about the content of Searle’s Background Hypothesis.

In *The Rediscovery of the Mind* Searle plausibly contends that *mental representation*, i.e., underived, original intentionality is realized just in case a given mental state “is at least potentially conscious” (Searle 1992, p. 132). We find similar claims in Husserl.¹⁸ Due to the “as-

pectual shape” of intentional states (the fact that they have perspectival, intentional content) there are no “deep unconscious mental intentional phenomena” (Searle 1992, p. 173), such as reflectively inaccessible belief states. There is an important sort of background elements whose distinctive mark is that they are *capacities to be in intentional states*; that is, they are dispositions to have (actually or potentially) conscious representations, such as occurrent beliefs. The general assumption that things offer resistance to pressure is a case in point. We normally do not form a belief to this effect but are nevertheless committed to it by the way we behave towards things (cf. Searle 1992, p. 185).

One may call these capacities for (at least potentially) conscious representation “background assumptions” or “network beliefs” if one likes, but according to Searle one must keep in mind that these capacities fail to be intentional states: “the Network of unconscious intentionality is part of the Background” (Searle 1992, p. 188) and “the Background is not itself intentional” (Searle 1992, p. 196). If Searle is right about this, then many elements of the so-called “web of belief” are part of the non-intentional background.

This view has far-reaching consequences for the theory of intentionality. For, if Husserl is basically right about the structure of consciousness (as I believe he is), then conscious states must be embedded in a holistic structure, which Husserl calls the “intentional horizon,” whose future elements are predelineated (at least in part) by the intentional content of the respective state of consciousness. For example, if you consciously see something whose front side you

consciousness iff they are both intentional objects of a dispositional higher-order belief of the sort “I am now having such-and-such experiences” that would be actualized by one and the same higher-order judgment (where the temporal demonstrative specifically refers to the moment of (internal) time at which both of these experiences occur). (2) Two diachronous intentional experiences belong to the same stream of consciousness iff both of them are intentional objects of a dispositional higher-order belief of the sort “I just (or earlier) had such-and-such experiences” that would be actualized by one and the same higher-order judgment. This approach fits in well with Husserl’s contention that “[i]ntentionality is what [...] justifies designating the whole stream of [experiences] as the stream of consciousness and as the unity of *one* consciousness” (Husserl 1982, p. 199). It also fits in well with a view on which Husserl conceives of consciousness as “pre-reflective self-awareness;” cf. Beyer 2011.

¹⁸ Husserl has a dispositionalist higher-order judgment view of consciousness, according to which conscious experiences are “essentially capable of being perceived in reflection,” such that “they are there already as a ‘background’ when they are not reflected on and thus of essential necessity are ‘ready to be perceived’” (Husserl 1982, p. 99; also cf. p. 80, where Husserl cites as an example a case in which “we are reflecting on a conviction which is alive right now (perhaps stating: I am convinced that ...)”). (Compare Searle 1992, p. 156: “This idea, that all unconscious intentional states are in principle accessible to consciousness, I call the connection principle [...].”) In Beyer 2006, Chs. 1-2, I defend a dispositionalist higher-order judgment view of intentional consciousness and argue that it explains the unity of consciousness (1) at a time as well as (2) across time, as follows: (1) Two simultaneous intentional experiences belong to the same stream of con-

are visually confronted by *as a house*, then you will anticipate¹⁹ visual appearances of a back side and an inside, respectively, as future experiences you would undergo if you walked inside or walked around the object while observing it. But is the corresponding set of anticipations really an *intentional* structure? Searle's arguments regarding the background cast doubt on this, given his view that consciousness (or what is consciously accessible) is the only occurrent reality of intentionality. After all, it is plausible to equate (a large subset of) the set of anticipations determining the respective intentional horizon with a relevant part of what Searle calls the "Network," given that they cannot be described properly as occurrent beliefs or conscious judgments, but rather as mere dispositions to form higher-order beliefs. For, as Husserl explains, the anticipations in question concern the way the represented object would present itself to consciousness in possible worlds compatible with what is currently experienced, and they also concern the way this object relates to other objects in the world—thus constituting the core of one's current *world* horizon, which core Husserl calls the "external horizon" (Husserl 1973, p. 32) of the experience (see below). It is only when these anticipations are intuitively fulfilled, in the sense that relevant conscious episodes of (what seem like) *verification* (such as perceptual verification) occur, motivating corresponding acts of judgment, that there will be entries into the relevant mental dossier associated with the object in question. As Husserl puts it (referring to mental dossiers associated with proper names as "individual notions"):

I see an *object without an 'historic' horizon* [footnote: without a horizon of acquaintance and knowledge], and now it gets one. I have experienced the object multifariously, I have made 'multifarious' judgements about it and have gained multifarious [pieces of] knowledge about it, at various times, all of which I have connec-

ted. Thanks to this connection I now possess a 'notion' of the object, an individual notion [...] [W]hat is posited in memory under a certain sense gains an epistemic enrichment of sense, i.e., the *x* of the sense is determined further in an empirical way.²⁰ (Husserl 2005, p. 358; my translation)

The "historic" horizon and the objects of the relevant anticipations constitute the "internal horizon" (Husserl 1973, p. 32) of the experience. They all belong to the same "*x* of the sense" (also referred to by Husserl as the "determinable *X*"), i.e., they share a sense of identity (of represented object) through time. Other past and anticipated experiences bring it about that one's "'notion' of the object" is *networked* with other notions of objects. They constitute the external horizon of the experience.

If the anticipations in question were part of a non-intentional background, then it would be wrong, of course, to describe them as being directed at objects; as a consequence, the Husserlian conception of intentional horizon just sketched would break down. To avoid this consequence, Searle's Background conception needs to be altered, such that the background may indeed contain intentional elements, albeit in a derived sense.

This can be fleshed out as follows. The primary bearers of intentionality are (at least potentially) conscious units, such as judgments and the experiences that motivate them. It is true that respective meaning and intentional content only function against a background the elements of which lack this primary form of intentionality. However, this background contains some elements that possess a *derived* form of intentionality, so that it is misleading to describe it as completely non-intentional. In particular,

²⁰ The German original runs: „Ich sehe einen *Gegenstand ohne einen „historischen“ Horizont* [Fn.: ohne Bekanntheithorizont und Wissen-shorizont], und nun bekommt er ihn. Ich habe den Gegenstand vielfältig erfahren, „vielfältige“ Urteile habe ich über ihn gefällt, vielfältige Kenntnis von ihm in verschiedenen Zeiten gewonnen und habe sie verknüpft. Nun habe ich durch diese Verknüpfung einen „Begriff“ von dem Gegenstand, einen Eigenbegriff [...]. [D]as in [der Erinnerung] mit einem gewissen Sinn Gesetzte erfährt eine erkennt-nismäßige Sinnbereicherung, das heißt, das *x* des Sinnes bestimmt sich näher erfahrungsmäßig.“ (Husserl 2005, p. 358).

¹⁹ For the close connection between anticipation and (internal) horizon, cf. Husserl 1973, para. 8. For an insightful interpretation of Husserl's notion of horizon, cf. Smith & McIntyre 1982, pp. 227–265.

it contains mental capacities or dispositions to form beliefs about the further course of experience which Husserl (in 1973, para. 8) calls “anticipations.” Some of the experiences thus anticipated correlate with an internal horizon. Their occurrence may lead to entries being made in a mental dossier, which are empirical beliefs (informational states) to which a “referent” (an object they are about) can be assigned in a principled way, in accordance with the modified principle of knowledge maximization. Here is an example of such a principle of reference assignment, which I have proposed in earlier work.²¹

The logical subject x of [...] a belief of the form a is F [...] whose acquisition goes together with the opening of a mental dossier about x is identical with the logical subject y of the judgement *initiating* that belief (or x would be identical with y , if x and y existed). (Beyer 2001, p. 287)

“Logical subject” here refers to the object the relevant belief is about (such as table 1 in the case of the persisting belief actualized by the judgment given voice to at t_2 in the above example about the wobbling table); and the judgment initiating that belief is understood to have its logical subject assigned in accordance with the modified principle of knowledge maximization, as explained at the end of section 3, above.

I conclude, first, that the background of meaning and intentional content may be looked upon as being at least in part itself intentional, albeit in a derived sense, but that, second, the applicability of the Background Hypothesis still needs to be restricted, as far as the part of the background (co-)determining truth-conditional content is concerned, to what I have called the producers.

6 Conclusion

In summary, I have distinguished three levels of meaning, the first of which (general meaning-function) is a matter of linguistic convention, while the second level (respective meaning) is

truth-conditional and partly dependent on the first, purely semantic level, but also dependent on the reference or extension determined by the intentional state actually given voice to. This intentional state has its intentional object (the reference of the corresponding utterance) fixed epistemically, in accordance with the modified principle of knowledge maximization. Furthermore, this epistemic reference-fixing depends on the informational states (or dossiers) of the producers only. Only the producers need to possess the kind of background that Searle wrongly takes to be required for all speakers or hearers capable of giving voice to or grasping the respective meaning in question, the grasping of which then serves as the basis for accessing the third, purely pragmatic level of meaning (namely, what is implicated).

Acknowledgements

Earlier versions of this paper were presented to audiences in Göttingen and Erfurt, whom I thank for helpful discussion. For helpful comments and suggestions I would like to thank the editors and three anonymous reviewers. I am particularly grateful to Adriana Pavic for her detailed comments and suggestions.

Grasping Meaning

A Commentary on Christian Beyer

Anita Pacholik-Żuromska

Christian Beyer, referring to a combination of Husserl's and Searle's theses, proposes an account of meaning that is context-dependent and that expresses not only propositional content but also the intentional state of the speaker. However, he tries to weaken Searle's Background Hypothesis, which should be restricted only to the speaker. Thus he excludes from the relation of intentional directedness the third element (called either the hearer, interpreter, or consumer). I will argue that if avoiding radical contextualism is right, it cannot be implemented at the cost of the Background Hypothesis and the triadic relation of intentionality.

1 Introduction

Since the linguistic turn the main problems considered by philosophers of mind and language are the questions of how words connect with the world, what relations exist between words and objects, what makes utterances true or false, and how we can extrapolate propositional content from internal mental states on external reality. These are particular questions that stem from the general issue of meaning. Our target article is concerned with the question of grasping the meaning and intention that stands behind expressions in the process of producing and interpreting assertive utterances. Its author argues for the thesis that meaning is context-de-

pendent, but in order to properly grasp the meaning of utterances one does not need to have knowledge-how, characterized by John Searle in the form of so-called "Background". Instead, the author proposes a neo-Husserlian conception that allows the reading of intentions standing behind assertions, without reference to factors coming from external context—although this is not an internalistic standpoint. However, taking this position he excludes from the relation of intentionality its third element, namely the hearer (interpreter), depriving him of some kind of responsibility for knowledge about factors determining the truthfulness of asser-

tions. He believes that for the hearer to understand literal meaning knowledge-how is not necessary.

This commentary presents four objections against Beyer's arguments about understanding the meaning of sentences and one separate criticism of his approach to the problem of intentionality. At the beginning I shall reconstruct the thesis and arguments of the author. In the following sections the theses of Beyer will be considered in the light of the general question: what does it mean for meaning to be context-dependent? Here the issue of the differences between contextual and literal meaning will be discussed with reference to Searle's Background Hypothesis. The line of the argumentation will rest on four objections to Beyer's claim about the restriction of the Hypothesis, and will focus on: (1) the problem of indexicals; (2) the distinction between literal and contextual meaning; (3) semantic and social externalism; and (4) understanding as epistemic triangle. The last part of the commentary will be concerned with intentionality considered as a triadic relation strongly connected with the model of understanding. This assumption should lead to an answer to the question of why we cannot reduce the requirements of the Background Hypothesis to producers only.

Even at this early stage, according to Beyer's account, we might ask whether, if the interpreter of the article in question was to misunderstand the article, who has made the mistake—the speaker (producer, author) or the hearer (consumer, reader)? This is another open question that shall accompany this commentary.

2 *Précis of Meaning, Context, and Background*

Arguing for a version of meaning that is context dependent, yet still accessible to every competent language user, Beyer combines two standpoints toward the relation between meaning and intentionality in the work of Edmund Husserl and John Searle. Linking the theses of both philosophers, he assumes that:

1. The meaning of assertive utterances is context dependent.
2. Assertive utterances express not only propositional content but also an intentional state.
3. Searle's Background Hypothesis about the requirement of non-intentional background on the part of the speaker and hearer for recognizing intentional states expressed by assertive utterances as well as for grasping the respective meaning of the utterances could be relevant to an understanding of the context-dependency of assertive utterances, but only in a restricted form.

Beyer's main thesis can be summarized as follows:

The speaker uttering a sentence intentionally presents herself as performing or undergoing an act, but if the hearer does not recognize that intention, she does not thereby fail to grasp the literal truth-conditional meaning of an utterance. Hence, only the group of speakers (utterance producers) must meet the requirements of Searle's Background Hypothesis.

In other words, according to Beyer, context dependence does not prevent competent language users who lack the correct background from grasping the literal truth-conditional meaning of an utterance.

Beyer gives brilliant examples, which justify this main claim. The first group contains indexicals like "I", "here", and "now", which share the same general meaning function—which I generally prefer to call "sense" or "concept"—but which have different respective meanings, that is, a different extension. Take an example, in which Subject 1 asserts: "I have blood type A", and Subject 2 also asserts: "I have blood type A". Both utterances have the same general meaning-function, but express different truth-conditional contents—or propositions. Using an alternative philosophical terminology, they have the same intension but different extension, which results in the famous conclusion that intension does not determine extension (Putnam 1975). However, according to Hilary Putnam's Twin Earth Thought Experiment, even natural kinds "have an indexical unnoticed component" (1975, p. 152). This forces the con-

clusion that every sentence is somehow context dependent, including those containing concepts of natural kinds.

To the second group of examples belong sentences without established uses, such as have been proposed by Searle: “Bill opened the mountain”; “Sally opened the grass”; “Sam opened the sun”. As Searle claims, in the case of such sentences we have no clear idea what they mean, or else we fail to find a proper way of understanding the sentences because we lack the necessary background capacities and social practices.

We know how to open doors, books, eyes, wounds and walls; and the differences in the Network and in the Background of practices produce different understandings of the same verb. Furthermore, we simply have no common practices of opening mountains, grass, or suns. It would be easy to invent a Background, i.e., to imagine a practice, that would give a clear sense to the idea of opening mountains, grass, and suns, but we have no such common Background at present. (Searle 1983, p. 147)

However, Beyer claims that even if we do not have the background we can still grasp the literal meaning of such sentences. We lack knowledge about **verification**—here Beyer agrees with Emma Borg (2004)—i.e., **knowledge-how**, but we can still understand the sentence.

Another example given by Beyer concerns situations where the speaker utters a sentence that the hearer repeats, while referring to another object than that referred to by the speaker. In other words, the hearer mistakenly takes for entitlement¹ an uttered claim about an object, which he thinks is the right referent—for example, when saying “This is red”, the sentence refers to a ball in a box, which the hearer does not know about because he has seen only a

red apple being put into the box. Beyer claims that, according to the principle of knowledge maximization formulated by Timothy Williamson, the speaker should be regarded still as possessing some knowledge about the apple, even if he has a false belief about that object, because even a false judgment in certain circumstances can count as knowledgeable. However, Beyer proposes a modification of this principle, which should, according to him, be “supplemented by a more traditional theory of justification, drawing upon notions of observation, memory and testimony” (Beyer this collection). From the examples given above Beyer infers that contextualism is the right account for this phenomenon, but only in a form that allows minimal semantic knowledge concerning the literal meaning, which can be possessed even in the absence of Background.

3 What does it mean for meaning to be context-dependent?

Epistemic or semantic contextualism has been created as an answer to a sceptical challenge against knowledge in the sense of *episteme*—defined as justified, true belief. It is claimed in this conception that the satisfaction conditions for “x knows that p”—i.e., the truth-conditions of sentences—on whose basis we ascribe knowledge to a subject, depend on the context in which they are uttered, i.e., on epistemic standards obtaining in these contexts (cf. Palczewski 2013, p. 197). “Contextualists speak of the semantic value of knowledge ascriptions as somehow shifting with context [...] The parameter that shifts with the context may be the threshold of justification, the standard of epistemic position, the set of epistemic alternatives” (Preyer & Peter 2005, p. 3).

In contrast to contextualist meaning, for literal truth-conditional meaning we have to look to semantic content. As Searle claims, it is a meaning with “zero context”, determined by the meaning of its semantic components and syntactic rules of composition. However, “for a large class of sentences there is no such thing as the zero or null context for the interpretation of sentences, and that as far as

¹ The *terminus technicus* “entitlement” plays an important role in the philosophy of Robert Brandom, built on the inferential role of the semantic. In Brandom’s account, understanding relies on the participation of subjects in a language game of giving and asking for reasons, where entitlement can be defined as “giving a reason” for repeating the judgment as being true about the object it concerns. I thank Daniel Żuromski for pointing this out.

our semantic competence is concerned we understand the meaning of such sentences only against a set of background assumptions about the contexts in which the sentence could be appropriately uttered” (Searle 1978, p. 207).

The distinction between literal and contextual meaning is clear for Beyer. Literal meaning is not usage. It is a subject of the semantics but not pragmatics. One can grasp the literal meaning of the sentence “The snow is white”, adding to it that this sentence is true only if the snow is white. But when a speaker utters the sentence “The snow is white”, the hearer needs not only to understand the literal meaning, because otherwise he could simply ask “So what?” The hearer needs also to interpret the statement, inferring what kind of linguistic function this sentence fulfils. The hearer needs to understand why (or for what purpose) this statement has been uttered by the speaker. In other words, to grasp the proper meaning he needs to establish what pragmatic and epistemic consequences it has. Thus, the pragmatic consequence is investigated by checking what else the utterance communicates, and what the sentence pragmatically implies. But meaning as usage is not only a matter of implicatures or presuppositions. The epistemic consequences concern the setting of conditions in which the sentence can be truly uttered—that is, the background. To understand an utterance expressing some kind of intentional state, both speaker and hearer have to dispose the background, i.e., knowledge-how. In fact, this is a passive form of knowledge, which depends on physical and social determinants, on which a subject has a little influence and in which she is deeply rooted. Such utterances are evidence of propositional attitudes with certain representational content. In other words, a subject uttering a sentence also expresses (using the terms of folk psychology) his attitude toward its content. However, according to Searle, propositional attitudes are not intentional states, understood as a relation of being directed (or of taking an attitude, i.e., belief) toward a judgment in a logical sense, expressed in the form of a sentence (utterance). “There is indeed a relation ascribed when one ascribes an Intentional to a person, but is not a relation between

a person and a proposition, rather it is a relation of representation between the Intentional state and the thing represented by it. In other words, proposition is rather a content of a statement than its object” (Searle 1983, p. 19).

Searle’s standpoint does not convince Beyer, who claims that to express or correctly ascribe a meaning intention and, consequently, to grasp the literal truth (the conditional meaning of an assertive utterance) one does not need to meet the requirements of Searle’s Background Hypothesis—according to which a subject needs to dispose a set of nonrepresentational capacities to correctly interpret the meaning of utterances. These requirements must be fulfilled only by sentences-producers, who can be regarded as “experts”—however, not necessarily in a scientific sense.

4 Meaning and intentionality

As Beyer claims, if the hearer does not recognize an intention accompanying an utterance, she does not fail to grasp the literal truth-conditional meaning of an utterance. Arguing for this thesis, Beyer gives examples of sentences that do not have an established use or that share the same general meaning function but have different respective meanings. But here are some objections:

The first question concerns indexicals: could we really grasp the literal meaning of the indexical “I” if we could not dispose a background of self-identification? In other words, what would be the distinctive features of context that allow the right ascription of beliefs, if subjects A and B utter the same content, and in the same context? It might be, for example, a capacity to identify themselves as subjects of a certain state, which is a capacity belonging to the unintentional background. If we do not dispose a concept of an individual subject, but only of collectivity, self-identification would be disturbed. In that case, could we still grasp the literal meaning of a sentence like “I do x”? Such self-identification depends on many factors—physical, like a completely unintentional sense of proprioception or homeostasis, and social, based on norms and rules. The case of physical

factors determining the ability to self-identify shows that the Background Hypothesis cannot be reformulated such that the Background must contain intentional elements. As [Searle](#) writes:

On the conception I am presenting, the Background is rather the set of practices, skills, habits, and stances that enable Intentional contents to work in the various ways that they do, and it is in that sense that the Background functions causally by providing a set of enabling conditions for the operation of Intentional states. (1983, p. 158)

Intentional elements would not help our grasping of the meaning if they referred to subjective intentions, which, as Beyer admits, are fully accessible only from first-person perspective. Beyer also doubts whether it is possible to make a comprehensive list of assumptions about a hidden object. But Searle's Background Hypothesis was created precisely to avoid such a regress.

The second question concerns the distinction between literal and contextual meaning. Namely we can raise the doubt: if a hearer does not grasp the contextual meaning, i.e., the truth-conditional meaning, then might she only grasp the sense of the utterance, and not its meaning? If we change terminology, and call general meaning function "sense" or "concept", then we could use Frege's theory of sense and meaning (intension and extension) and say that a subject who grasps only conventional linguistic meaning but not respective meaning grasps *de facto* not the meaning of a sentence but its sense. According to Frege's theory of intension/extension of a sentence, one cannot know a sentence's meaning if one does not know its truth-conditions, because the meaning of a sentence is its truth-value ([Frege 1948](#)). Further, if we turned to were Frege as interpreted by Michael Dummett, we could say that a subject who does not know the truth-conditions of some sentence does not understand this sentence, because, according to [Dummett](#), a theory of meaning should be a theory of understanding ([1993](#)).

The third objection can be formulated as follows: if, according to Beyer, only a producer carries the burden of the requirements of the Background Hypothesis, and if she was a false expert, is there a method (also accessible to a hearer who does not have to know the background) for the identification of false experts by a non-expert? This is a version of Putnam's externalism, which says that external factors, which determine the content of our beliefs could be experts, who for example tell us how to properly use the names "elm" and "beech" (cf. [Putnam 1975](#), p. 145). But what if these experts just pretend to be professionals, or simply have a gap in their education?

If only producers should carry the burden of the requirements of the Background Hypothesis, consumers would have limited access to methods enabling the identification of the satisfaction conditions of an uttered sentence. Hence consumers, grasping only literal meaning, would have to believe everything they heard. As was said, intentionality should not be regarded as a feature of an individual mind. Intentionality is a relation between minds and the world. It is a social phenomenon, developed and practiced through interactions with other minds (cf. [Tomassello & Rakoczy 2003](#)). Hence there must be a theory that can explain how both speaker and hearer have a potentially equal chance of understanding a sentence (of grasping its truth-conditional content). Such a model of understanding has been proposed by Christopher Peacocke. Peacocke claims that the thinker can only judge the content that she recognizes (cf. [Peacocke 1992](#), p. 51). Recognition is possible only if the person knows the truth-conditions of the grasped content. According to Peacocke, the basic concepts are individuated by the fact that, in certain circumstances, our beliefs containing these concepts will be true. These beliefs constitute the knowledge of the subject. Peacocke builds his theory on the assumption that components of the propositional content are concepts individuated by their possession conditions, which fix the semantic value of concepts.

The determination theory for a given concept (together with the world in empir-

ical cases) assigns semantic values in such a way that the belief-forming practices mentioned in the concept's possession condition are correct. That is, in the case of belief formation, the practices result in true beliefs, and in the case of principles of inference, they result in truth-preserving inferences, when semantic values are assigned in accordance with the determination theory. (Peacocke 1992, p. 19)

In fact, in such an account, Peacocke's theory of knowledge is a theory of social solidarity, where knowledge is not a privilege and subjects are considered not as monads or individual minds but as creating a new interpersonal subjectivity—i.e., a social sphere. On the basis of Peacocke's model of gaining knowledge, which contains the triadic relation: concepts, the possession condition of concepts, (conditions in which the use of concept is valid), and through semantic value (fixed on the basis of determination theory), this solidarity is possible, because according to this model everyone can verify or falsify judgments of others. I support this account. The so-called "theory of social solidarity" assumes that both speaker and hearer must share the Background in order to have an access to conditions of justification of utterances.

From the third objection follows the next question: if only a producer needs to dispose a background, then what would be an indicator of the proper usage of a sentence? How could a consumer conclude that a producer understands the uttered sentence (that is, is a competent language user)?

As I have suggested, the consumer also has to utilise certain methods to conclude whether the producer understands the uttered sentence. This tool of verification should be the world, as in Donald Davidson's model of epistemic triangulation. In Davidson's theory, meaning is dispositional. He claims that asymmetry, which happens between a speaker and interpreter's knowledge about a word's meaning, is the same kind of asymmetry between the first- second-person perspectives. This means that knowledge about meaning has to be inferential—hence it is to be identified by an interpreter on the basis of

the speaker's behaviour. To understand the behaviour of an agent, the interpreter has to have a hypothesis about her intention, and then check this hypothesis with respect to the external conditions of the world. In this way, he can verify or falsify his interpretation. If it is wrong, then he must change it and form another hypothesis. Interpretation should be undertaken according to a principle of charity, which means that if the hypothesis fails, then it is the probably the interpreter who is wrong and not the sender—here is the place for experts—the interpreter has to assume that the sender acts rationally, but he has tools to prove it (Davidson 1980).

But in the context of the Background Hypothesis we do not even need to refer to Davidson's theory to show the necessity of an external validation indicator. Searle's original account is good enough:

If my beliefs turn out to be wrong, it is my beliefs and not the world which is at fault, as is shown by the fact that I can correct the situation simply by changing my beliefs. It is the responsibility of the belief, so to speak, to match the world, and where the match fails I repair the situation by changing the belief. But if I fail to carry out my intentions or if my desires are unfulfilled I cannot in that way correct the situation by simply changing the intention or desire. In these cases it is, so to speak, the fault of the world if it fails to match the intention or the desire, and I cannot fix things up by saying it was a mistaken intention or desire in a way that I can fix things up by saying it was a mistaken belief. Beliefs like statements can be true or false, and we might say they have the 'mind-to-world' direction of fit. Desires and intentions, on the other hand, cannot be true or false, but can be complied with, fulfilled, or carried out, and we might say that they have the 'world-to-mind' direction of fit. (Searle 1983, p. 8)

As I have emphasized, since Background and Intentionality are strongly connected it is im-

possible to weaken the Background or add intentional elements to it, because then the mechanism of intentional directedness preserving the external and relational character of propositional attitudes will fall. Nevertheless, Beyer rightly begins his considerations with a comparison of the conception of intentionality from Husserl and Searle. What they have common is the antipsychological thesis that intentionality can be expressed in language. Their idea was to separate intentionality from psychological explanations, which is possible when we consider propositional attitudes as reported in sentences containing the I-clause and the that-clause, thus expressing a relation between an attitude and a judgement in a logical sense. In general, anti-psychologists claim that intentionality is a binary relation between mental acts and the world: the contents of mental acts refer to objects, which exist outside of these acts, while the relation of intentionality is represented in sentences. The relational approach to intentionality affects how we think of mental functions and products, such as judging, believing, doubting, and so on, which are themselves relational.

As Beyer underlines, the problem of meaning intention (termed thus by Husserl) concerns the partly subjective nature of experienced content—a factor that creates the content of the proposition associated with the modality of the state and allows the subject to grasp the content of the experienced state. He refers to Franz Brentano, according to whom every conscious mental act is intentional. In other words, consciousness is intentional because it is always a consciousness of something. Consciousness cannot exist without an intentional act of directedness toward itself. This means that characteristic of mental phenomena is their intentionality or the “mental inexistence of an object [and that] every mental phenomenon includes something as object within itself” (Brentano 1973). So, for example, if I hear a sound, I also grasp the phenomenon of hearing. On the other hand, the content of a mental state is characterized as that which can be expressed in an objectively-verifiable judgment, due to the specific nature of the content which allows the subject to move from first-order beliefs to second-order beliefs

that arise when she ascribes to herself a propositional attitude. This switch can be seen as a change in the form of language: from object language referring to the external world to—and here are two possibilities—either metalanguage, in which the subject reports that she has a belief about having a belief, or to subjective language, in which the subject reports having an attitude with a certain content. In the case of metalanguage, this has to do with issues of semantic externalism, like inheriting truthfulness by second-order beliefs.

Meaning exists only where there is a distinction between intentional content and the form of its externalization, and to ask for the meaning is to ask for an Intentional content that goes with the form of externalization. (Searle 1983, p. 28)

Since propositional attitudes are mental states with propositional content, to interpret them correctly one has to dispose a background of physical and social determinants of the content of the sentences expressing the propositional attitude. This is why a proper theory of intentional directedness should treat both speaker and hearer equally. Speaker and hearer cannot be separated. They are so strongly connected that they should be considered holistically as a single intentional structure or one structure of intentional directedness. Only then arises social intersubjectivity, which does not consist only of individual minds but also of interactions between minds and world as in Davidson's model of triangulation. This relation works for both sides. And the constitution of an individual self is an effect of switching between individual and social minds and between the beliefs of these two kinds: social and individual. It happens for example when an individual mind joins a group and meets regularities different to her own (cf. Tomasello et al. 2005). This means that sometimes, for some reason, it is useful for her to change her beliefs or even her belief-system. She must do this on the basis of her own inferences, so she has to have a reason to do it. Done in any other way she would have problems with understanding this new beliefs.

Hence the triadic model of intentional reference contains a structure that simulates relations of understanding between sender, interpreter, and the world. Subjects never live a solitary life, as is claimed by Husserl. That is why the case of intentionality does not concern a solitary mind. This standpoint gives a straightforward route to contemporary theories of enactive cognition, where a subject is embedded in an environment and, to gain knowledge, has to act and interact with the world of objects and other subjects. This point of view, however, leaves little room for epistemological internalism and thus for the Cartesian mind. Followers of theories of enactivism would say that the content of a subject's mental states is deeply rooted in the body's interactions with the environment—because the whole of cognition is.

That is why when one investigates the content of mental states one needs to refer to both the situation and the situated cognizer taken together as a single, unified system (Wilson 2002). Such enactive theories will be a kind of new version of active externalism, which assumes that “the content-fixing properties in the environment are active properties within a sensorimotor loop realized in the very present” (Metzinger 2004, p. 115). This standpoint, however controversial in the light of classic externalism, has much in common with proponents of this view. So, for example, diachronic externalism holds that the causal story, namely all facts in the past that have had an influence on the thinker, together with an environment, are important determinants of the content of a thinker's propositional attitudes. In contrast to this, synchronic externalism holds also that the content of propositional attitudes is determined by the current environment of the thinker and his disposition to respond to it. On the other hand, social externalism holds that the content of thoughts is determined in part by the social environment of a thinker, and especially by how others in our linguistic communities use words. These “others” could be experts, who establish the scientific names of objects, such as, for example, trees. This version of social externalism could prove fruitful when we consider Searle's Background Theory, but it creates trouble for

Beyer. As I have argued above, in the third objection, externalism is the right approach but it is possible only under the condition of the equal treatment of both participants of the communication process, namely the speaker and hearer, and only when they have access to the background.

5 Conclusion

To conclude, the idea of neo-Husserlian approach to meaning combined with Searle's Background Hypothesis seems to be promising. However, there are several questions that need to be answered. The main problem seems to be the postulated restriction of the hypothesis by adding intentional elements and an abolition of its requirements for a hearer. It would be then a new hypothesis, and rather more Husserlian than Searlian. These requirements may impair the triadic relation of intentional reference, which has to remain triadic if we do not want to come back to idea of a Cartesian mind.

I have raised four objections to Beyer's claim about the restriction of the Hypothesis, concerning the problem of indexicals, the distinction between literal and contextual meaning, semantic and social externalism, and understanding as an epistemic triangle. In the first objection about the use of indexical “I” we have asked whether we could really grasp the literal meaning of the indexical “I” if we didn't have a background of self-identification. I have argued that in the proper use of the pronoun “I” we need a special, non-intentional background. The second objection concerned the problem of whether a hearer, who does not grasp the contextual meaning, grasps only the sense of utterance but not its literal meaning. Answering this question, I claimed that in some approaches—such as, for example, the Dummettian version of Frege's sense and meaning—a subject who does not know the truth-conditions of some sentence does not understand the sentence. The third and fourth objection concerned the restricted role of the hearer in the act of communication. I raised a doubt about whether it is possible to identify false experts and to recognize incompetent language users if the hearer (interpreter)

lacks a non-intentional background. I claimed that to do this, the relation of intentionality must contain three elements: speaker, hearer, and world, where both hearer and speaker have equal access to the background. The relation of intentionality has been considered to be strongly connected with the model of understanding, where speaker and hearer make one unified structure of intentional directness. In such an account, the requirements of the Background Hypothesis cannot be restricted solely to producers, as Beyer would have it.

Self-identification, Intersubjectivity, and the Background of Intentionality

A Reply to Anita Pacholik-Żuromska

Christian Beyer

Two suggestions by Pacholik-Żuromska, concerning the background of “I”-references and the intersubjective dimension of intentionality, respectively, are taken up and related to Husserl’s theory of intentionality. Moreover, a number of misunderstandings of my view are corrected, Searle’s “regress argument” for the Background Hypothesis is criticized, and a distinction between two functions of the background of intentionality is drawn in order to clarify my view.

1 Introduction

Pacholik-Żuromska takes issue with both my proposal to tone down Searle’s Background Hypothesis in terms of the distinction between producers and mere consumers and my claim that part of the background of intentionality is itself intentional (albeit in a derived sense). In her introduction she kindly raises the question “who has made the mistake—the speaker (producer, author) or the hearer (consumer, reader),” provided that “the interpreter of the

article [...] was to misunderstand the article” ([Pacholik-Żuromska this collection](#), pp. 2–6). I answer that in case of doubt it is the author of the target article, of course, who has made the mistake. As the formulation of her question shows, Pacholik-Żuromska has indeed misunderstood a central distinction, i.e., that between producer and mere consumer. However, before I take the opportunity to correct this and other misunderstandings, I would like to comment on

two ideas and suggestions by Pacholik-Žuromska that I find interesting and well worth pursuing further.

2 The background of self-identification

The first suggestion concerns our ability to “grasp the literal meaning of the indexical ‘I’” (Pacholik-Žuromska [this collection](#), p. 4) Pacholik-Žuromska contends that this may require, on the part of both speaker and hearer, “a capacity to identify themselves as subjects of a certain state, which is a capacity belonging to the unintentional background.” (Pacholik-Žuromska [this collection](#), p. 4) I agree that (1) the same sort of capacity is in play with both speaker and hearer, and that (2) this capacity belongs to the background. I reject the claim, though, that this capacity is non-intentional. Let me explain.

Ad (1): In *The Thought* Gottlob Frege contends that only the speaker herself can grasp the proposition expressed by the sentence “I have been wounded,” as used in a soliloquy, and that the hearer therefore has to grasp a different proposition, provided by the utterance context, in order to understand a corresponding sentential utterance, such as the proposition expressed by “She who is speaking to you at this moment has been wounded” (Frege 1956, p. 298). This flies in the face of the Husserlian conception of linguistic communication from which I start out in my article, which requires that the hearer ascribes the right meaning-bestowing act to the speaker in a case of successful communication; which means, in the case at hand, that he ascribes to the speaker what Pacholik-Žuromska aptly calls a self-identification (rather than an act of speaking to the hearer, as Frege has it). In fact, this is precisely the way Husserl himself describes what happens in the case of the correct interpretation of “I”-utterances:

Es ist klar: Wer ‘ich’ sagt, nennt sich nicht nur selbst, sondern er ist sich dieser Selbstnennung auch als solcher bewußt, und dieses Bewußtsein gehört wesentlich mit zum Bedeutungskonstituierenden des Wor-

tes ‘ich’. Das aktuelle Sich-selbst-Meinen fungiert [...] so, daß darin sein Gegenstand als Gegenstand eines Selbstmeinens gemeint [...] ist. [...] Der Hörende versteht es, sofern es ihm Anzeige für dieses ganze Bewußtseinsgebilde ist, also der Redende für ihn als jemand dasteht, der sich selbst, und zwar als ‘ich’ nennt, d.i. sich als Gegenstand seiner als Selbsterfassung erkannten Selbsterfassung nennt.¹ (Husserl 1984, p. 813)

Thus, if the speaker asserts “I have been wounded,” she presents herself as someone who refers to herself *as* referring to herself (or as meaning herself/having herself in mind/thinking of herself), in order to state about herself that she has been wounded; and the hearer understands this assertion if he takes the speaker to refer to herself as referring to herself and to assert about herself that she has been wounded. I regard this metarepresentational view of the meaning-bestowing acts underlying the assertive use of “I”-sentences as quite plausible. After all, if someone claims, say, “I have a broken leg,” then she *eo ipso* knows that she *refers to herself* by “I;” she could instantly add: “I am speaking of *myself*.” (Contrast this to a case in which a speaker unknowingly looks at herself in a mirror and exclaims “She has a broken leg.” See Beyer 2006, pp. 33 ff.) Incidentally, this view fits in well with a dispositionalist higher-order judgment theory of consciousness, which implies that (thanks to an underlying, “pre-reflective” structure of inner time-consciousness) “I”-awareness disposes its subject to judge that she herself is thinking of herself (see Beyer 2006, pp. 33 ff.).² If a mental disposition such as this is actualized (which is not re-

1 The English translation is as follows: “Clearly, if someone says ‘I’, he does not only refer to himself, but he is also aware of this referring to himself as such, and this awareness builds an essential part of what constitutes the meaning of the word ‘I’. The current act of meaning oneself is functioning [...] in such a way that in the course of it its [intentional] object is [...] being meant *as* the object of an act of meaning oneself. [...] The hearer understands it, if he takes it as an indication for the whole structure of consciousness just described, that is to say, if the speaker is regarded by him as someone who refers to himself precisely as ‘I’, i.e., as someone who refers to himself as the object of his recognition of himself recognized as a recognition of himself” (My translation.)

quired for self-identification), then the resulting (“reflective”) “I”-judgment is based upon, and epistemically motivated by, a (“pre-predicative”) act of referring to oneself *as* referring to oneself.

Ad (2): In order for the hearer to ascribe such a meaning-bestowing act of self-identification to the speaker, he does not, of course, have to actualize his own capacity for self-identification, in the sense of actually thinking of himself as thinking of himself. But in the absence of this *capacity* he would be unable to ascribe such an act to the speaker, at least if we follow Husserl and Edith Stein and conceive of third-person act ascriptions as based on empathy, where the ascriber mentally simulates the cognitive situation of the target person (see [Beyer 2006](#), ch. 3). So I agree with Pacholik-Żuromska that an element of the background (notably, the capacity for self-identification) is required for the ability to understand “I”-utterances. However, I deny that this capacity is completely non-intentional. It is precisely a mental disposition that is actualized (if it gets actualized) in *intentional* consciousness, namely in pre-predicative acts of referring to oneself *as* oneself—acts which may, but need not, give rise to corresponding “self-reflective” higher-order judgments.

3 The intersubjective dimension of intentionality

Another interesting suggestion made by Pacholik-Żuromska concerns the relationship between intentionality and intersubjectivity. She claims that “[i]ntentionality is a relation between minds and the world” ([Pacholik-Żuromska this collection](#), p. 5), thus subscribing to an externalist conception of intentionality (which I share), and goes on to characterize it as “a social phenomenon, developed and practiced through interactions with other minds” ([Pacholik-Żuromska this collection](#), p. 5). [Pacholik-Żuromska](#) refers to Tomasello, Rakoczy, and Davidson in this connection, but (her ascription to Husserl of the thesis that

subjects can “live a solitary life” notwithstanding, which I regard as a misreading; [this collection](#), p. 8) she could also have referred to Husserl here. In the second volume of his *Ideas Pertaining to a Pure Phenomenology and to a Phenomenological Philosophy (Ideas II)*, Husserl presents a detailed analysis of the intersubjective, reciprocal constitution of intentional objects that belong to a “communicative environment” and are thus immediately perceivable as valuable heating material, for example:

Kohle z.B. sehe ich als Heizmaterial; ich erkenne es und erkenne es als dienlich und dienend zum Heizen, als dazu geeignet und dazu bestimmt Wärme zu erzeugen. [...] Ich kann [den brennbaren Gegenstand] als Brennmaterial benutzen, [...] er ist mir wert mit Beziehung darauf, daß ich Erwärmung eines Raumes und dadurch angenehme Wärmeempfindungen für mich und andere erzeugen kann. [...] [A]uch andere fassen ihn so auf, und er erhält einen intersubjektiven Nutzwert, ist im sozialen Verbande geschätzt und schätzenswert als so Dienliches, als den Menschen Nützlichendes usw. So wird er nun unmittelbar ‘angesehen’ [...].³ ([Husserl 1952](#), p. 187)

Notice that near the end of this passage from § 50 of *Ideas II* Husserl observes how intersubjective agreement in the form of reciprocally shared emotional valuations, and accordingly motivated evaluations (evaluative judgments), add a social dimension to the constitution of the environment. In this way, the personal environment of an individual subject acquires the significance of a social environment equipped with

3 The English translation is as follows: “I see coal as heating material; I recognize it and recognize it as useful and as used for heating, as appropriate for and as destined to produce warmth. [...] I can use [a combustible object] as fuel; it has value for me as a possible source of heat. That is, it has value for me with respect to the fact that with it I can produce the heating of a room and thereby pleasant sensations of warmth for myself and others. [...] Others also apprehend it in the same way, and it acquires an intersubjective use-value and in a social context is appreciated and is valuable as serving such and such a purpose, as useful to man, etc. That is how it is first ‘looked upon’ in its immediacy.” ([Husserl 1989](#), pp. 196f.)

2 This may also fit in with the Brentanian conception of consciousness that Pacholik-Żuromska alludes to in section 4.

common objects possessing intersubjectively shared values—in the case at hand: shared use-values, to be perceived immediately (e.g., as a piece of heating material). In the following section, §51, entitled “The person in personal associations,” Husserl generalizes these observations. He claims that the social environment is relative to persons who are able to “communicate” with one another, i.e., to “determine one another” by performing actions with the intention of motivating the other to display “certain personal modes of behavior” on his grasping that very communicative intention (Husserl 1989, p. 202). If an attempted piece of communication such as this, also called a “social act” (Husserl 1989, p. 204), is successful, then certain “relations of mutual understanding (Beziehungen des Einverständnisses)” are formed (Husserl 1989, p. 202):

[A]uf die Rede folgt Antwort, auf die theoretische, wertende, praktische Zumutung, die der Eine dem Anderen macht, folgt die gleichsam antwortende Rückwendung, die Zustimmung (das Einverstanden) oder Ablehnung (das Nicht-einverstanden), ev. ein Gegenvorschlag usw. In diesen Beziehungen des Einverständnisses ist [...] eine einheitliche Beziehung derselben zur gemeinsamen Umwelt hergestellt.⁴ (Husserl 1952, pp. 192-193)

A few lines later, Husserl even claims that relations of mutual understanding help determine the common surrounding *world* for a group of persons; the world as constituted this way is called a “communicative environment.” On his view, the world of experience is partly structured by the outcomes of communicative acts. If it is structured this way, then there will be meaningful environmental “stimuli,” or solicitations (to use a more recent terminology), which motivate a given subject to display personal behaviour that consists in his reacting upon such environmental stimuli;

where the notion of motivation is to be understood as follows:

[W]ie komme ich darauf, was hat mich dazu gebracht? Daß man so fragen kann, charakterisiert alle Motivation überhaupt.⁵ (Husserl 1952, p. 222)

I regard this Husserlian conception of the structures underlying our being-in-the-world as highly plausible. So Pacholik-Żuromska kicks at an open door when she stresses the importance of (what is nowadays called) embedded cognition and dynamic mind-world interaction for an adequate conception of intentionality.⁶

4 Some corrections and clarifications

Finally, some corrections. I begin with two misunderstandings that I find easily comprehensible.

First, my use of the term “producer” may be misleading, as it differs from the ordinary use of the term. Not every producer of an utterance, in the ordinary sense, is a producer in the technical sense that Evans and I associate with the term. To take up the example that Evans gives in the long quotation cited at the beginning of section 5 of my article, if someone uses the name “Livingston” today to refer to (say) an 18th century politician, then she will be a mere consumer of that name, because she could not “have been introduced to the [name-using] practice via [her] acquaintance with” Livingston, to put it in Evans’ terms (1982, pp. 376–393). This holds true even if she is the *speaker* of an utterance in which the name “Livingston” is used this way. I do not think that the producer/consumer distinction leads to a problematic

⁵ The English translation is as follows: “How did I hit upon that, what brought me to it? That questions like these can be raised characterizes all motivation in general.” (Husserl 1989, p. 234; in part my translation)

⁶ Pacholik-Żuromska also refers to Davidson’s notion of triangulation in this connection. For a Husserl- and Føllesdal-inspired critique of Davidson’s recourse to causal concepts in this context, see Beyer 2006, pp. 88–99. In the last paragraph of section 4 she draws a distinction between diachronic externalism—a position she ascribes to Davidson—, synchronic and social externalism, claiming that the latter “creates trouble for Beyer” (Pacholik-Żuromska this collection, p. 8). In the light of both the foregoing considerations and her misreading of my view on Searle’s Background Hypothesis (see section 4), I regard this claim as false.

⁴ The English translation is as follows: “[S]peaking elicits response; the theoretical, valuing, or practical appeal, addressed by one to the other, elicits, as it were, a response coming back, assent (agreement) or refusal (disagreement) and perhaps a counterproposal, etc. In these relations of mutual understanding, there is produced [...] a unitary relation of [persons] to a common surrounding world.” (Husserl 1989, pp. 203-204)

two-tier society of linguistic insiders and outsiders, as Pacholik-Żuromska seems to believe. It merely reflects the way proper names and other expressions acquire a particular usage, as a matter of fact. Actually, Pacholik-Żuromska herself draws upon a very similar distinction (but see footnote 16 in the target article, [Beyer this collection](#)) when she talks about experts. Of course, in principle anyone may become an expert regarding the application of any term—although it is difficult, to say the least, to become a producer regarding a proper name whose bearer has passed away a long time ago (see above). If this latter remark is correct (as I think it is), then it is not the case that in general “everyone can verify or falsify judgments of others,” as [Pacholik-Żuromska \(this collection, p. 6\)](#) wants to claim following Peacocke. In some cases (such as the case of proper names whose bearers have passed away) some people—the mere consumers—are in an epistemically underprivileged position.

Since Pacholik-Żuromska mistakenly equates what I call producers with speakers and mere consumers with hearers, she misreads my proposal to tone down Searle’s Background Hypothesis in such a way that only the producers with regard to a given set of sentences need “background know-how regarding the application of those sentences” (as I put it in section 5 in the target article, [Beyer this collection](#)), and her relevant arguments are besides the point—even if they contain interesting ideas (see sections 1 and 2 above). I do not claim that the Background Hypothesis “should be restricted only to the speaker,” as [Pacholik-Żuromska \(this collection, p. 1\)](#) puts it in her abstract. I contend that it should be restricted to the producers.

This brings me to a second misunderstanding that also concerns my view on the Background Hypothesis. In some places (like the last paragraph of section 4 in the target article; [Beyer this collection](#)) I carelessly put my view in such a way that it invites the following interpretation, which Pacholik-Żuromska takes for granted: only the producers need any background know-how. However, this is, again, a misreading, as becomes clear when one looks at

more careful formulations of my view, such as the one quoted in the preceding paragraph or the following formulations from section 5: “Meaning-intentions [...] do not generally require a non-intentional background *relative to which their (truth-conditional) content and satisfaction conditions are determined*,” ([Beyer this collection, p. 15](#); emphasis added) “the applicability of the Background Hypothesis [...] needs to be restricted, *as far as the part of the background (co-)determining truth-conditional content is concerned, to what I have called the producers*.” ([Beyer this collection, p. 17](#); emphasis added) What Pacholik-Żuromska does not notice, and what I should have made clearer, is that I distinguish between two different functions of the background:

- On the one hand, some of its elements (such as personal acquaintance with a name-bearer, or with a practice like opening a can) help to determine a particular truth-condition for a sentence-use and its underlying meaning-bestowing act—here I claim that only the producers need a corresponding background.
- On the other hand, the existence of what Searle calls the Network is an enabling condition for intentional consciousness.

Regarding the latter, I argue near the end of my article that it is misleading to characterize the part of the Network that constitutes “the set of anticipations determining” ([Beyer this collection, p. 16](#)) what Husserl refers to as the “intentional horizon” of a conscious intentional state as completely non-intentional, because they are mental dispositions to form occurrent higher-order beliefs. In order to save Husserl’s notion of intentional yet unconscious horizon anticipations, which I regard as an indispensable contribution to the theory of intentionality, I propose that we (re)formulate Searle’s background conception in such a way that “the background may indeed contain intentional elements, albeit in a derived sense” ([Beyer this collection, p. 17](#)), notably in the sense of mental dispositions to form higher-order beliefs. The only argument I find in Pacholik-Żuromska’s commentary that may at

first sight be taken to speak against the admission of such intentional background-elements is the regress argument she refers to in section 4 of her commentary. She points out that the Background Hypothesis is supposed to avoid a regress of assumptions such as the one I describe in section 3 in the target article (under the heading “Background assumptions”) in order to motivate Searle’s radical contextualism. But, quite apart from the fact that I do not claim that *all* elements of the background are intentional in the relevant sense, I find Searle’s corresponding argument for the Background Hypothesis confused. He claims that “[t]he actual content is insufficient to determine the conditions of satisfaction,” and that “[e]ven if you spell out all the contents of the mind as a set of conscious rules, thoughts, beliefs, etc., you still need a set of Background capacities for their interpretation.” (Searle 1992, pp. 189–190) To repeat a point I make in section 5 of my article, this is an absurd view (cf. Beyer 1997, p. 346). Neither intentional content (“actual content”) nor respective meaning can be interpreted (or “applied”) at all—only (utterances of) linguistic *expressions*, including *formulations* of rules, can be interpreted, and the result of this interpretation will be (the ascription of) a meaning-bestowing act which displays an intentional content that uniquely determines the conditions of satisfaction.

Here are some further corrections and clarifications.

I do not take the case of indexicals like “I,” “here” and “now” to show that “literal truth-conditional meaning” can be grasped even in the absence of “the correct background.” Unlike “sentences without established use” (as Pacholik-Żuromska aptly calls them; [this collection](#), pp. 2–3), these examples have no bearing on the truth of the version of the Background Hypothesis for which I argue. They can be captured by any standard semantics that distinguishes between general meaning-function (character) and respective meaning (content).

I do not give any example in which “the speaker utters a sentence that the hearer re-

peats, while referring to another object” ([Pacholik-Żuromska this collection](#), p. 3) than the one the speaker refers to. In the example about the yellow apple and the red ball in the box, the speaker refers to the apple in order to (wrongly) state that it is red, and the hearer may figure this out by applying a suitably modified version of Williamson’s principle of knowledge maximization (rather than Davidson’s principle of truth maximization). Nor do I claim that any “false judgment in certain circumstances can count as knowledgeable.” ([Pacholik-Żuromska this collection](#), p. 3) Rather, the unmodified version of Williamson’s principle is not applicable in the case at hand.

Furthermore, epistemic contextualism does not only (often) purport to answer sceptical challenges to *justified-true-belief* accounts of knowledge, but also to other accounts such as reliabilist theories of knowledge that make recourse to the notion of the ability to exclude relevant alternatives. I do not distinguish between “literal truth-conditional meaning” and “contextual respective meaning,” as Pacholik-Żuromska claims in section 3. In the case of indexicals, literal meaning is not to be confused with linguistic meaning in the sense of general meaning-function (character). The relevant distinction is that between literal and figurative meaning; unlike “meaning as usage,” figurative (or non-literal) meaning is a case of (what is expressed by) implicature.

It is misleading to assert that “according to Searle, propositional attitudes are not intentional states” ([Pacholik-Żuromska this collection](#), p. 4). It is true, however, that (like Husserl) Searle does not conceive of them “as a relation of being directed [...] towards a judgment in a logical sense” ([Pacholik-Żuromska this collection](#), p. 4), i.e., towards a proposition. Propositional contents are to be distinguished from the satisfaction conditions they determine (which Husserl refers to as states of affairs).

I do not claim that “if the hearer does not recognize an intention accompanying an utterance, she does not fail to grasp the literal truth-conditional meaning.” ([Pacholik-Żuromska this collection](#), p. 4) Grasping that mean-

ing requires, on the part of the hearer, to ascribe the intention to express a meaning-bestowing act to the speaker.

I distinguish (following Borg) between knowing a sentence's truth-condition, on the one hand, and being able to decide whether this truth-condition is satisfied, on the other. Mere consumers *do* know the truth-condition of a sentence when they understand it, but they are unable to decide (in an epistemically responsible way) whether it is met. *Pace Pacholik-Żuromska*, this does not mean that they "have to believe everything they [hear]." ([this collection](#), p. 5) Nothing in the notion of a mere consumer implies that he must regard a given speaker as infallible (and sincere), even if this speaker is in fact a producer; and nothing in the notion of a producer implies that producers are infallible (and always truthful). Nor does this mean that producers grasp truth-conditional content more "fully" than mere consumers (see footnote 16 of my target article; [Beyer this collection](#)).

On my conception of a producer, there can be no producer who is "a false expert." It is possible, though, on my view, to be a producer without being a scientific expert on whatever it is that constitutes the extension, reference, or truth-condition of the relevant expression (again, see footnote 16 of my target article; [Beyer this collection](#)).

Pacholik-Żuromska raises an excellent question when she asks what, on my view, "would be an indicator of the proper usage of a sentence." ([this collection](#), p. 6) However, it does not speak against a particular approach to meaning that this problem arises in its framework. It arises in any framework.

Husserl took over the idea of intentionality from Brentano, but he does not share Brentano's view that consciousness is always intentional. According to Husserl, there is also non-intentional consciousness, such as pain. Without intentionality, there would be no stream of consciousness, and hence no consciousness. But not every single element of the stream of consciousness is itself intentional. As usual, I find myself in agreement with Husserl here.

5 Conclusion

Despite some serious misunderstandings, for which I am prepared to take responsibility at least in part, *Pacholik-Żuromska* presents some promising ideas. In particular, she highlights the significance of the background of self-identification and the intersubjective dimension of intentionality. In addition, her commentary has helped me to see the need to explicitly distinguish between two functions of the background: its reference-determining role on the one hand, and its enabling role in connection with the functioning of the intentional horizon on the other.

The Puzzle of Perceptual Precision

Ned Block

This paper argues for a failure of correspondence between perceptual representation and what it is like to perceive. If what it is like to perceive is grounded in perceptual representation, then, using considerations of veridical representation, we can show that inattentive peripheral perception is less representationally precise than attentive foveal perception. However, there is empirical evidence to the contrary. The conclusion is that perceptual representation cannot ground what it is like to perceive.

1 Introduction

Attention increases acuity, allowing the perceiver to see details that would otherwise be missed. In addition, for items that the perceiver does actually see, attention changes their appearance, increasing, for example, the appearances of contrast, (differences between light and dark), speed of a moving object, spatial frequency (a measure of how closely spaced light and dark areas are) and the size of a gap—as in Figure 4. But when attention makes something appear bigger or faster, does it work like a magnifying glass, trading off a gain in information at the cost of making something appear bigger or faster than it is? Or does attentive perception portray the item more as it really is? Or are both percepts veridical—or are both non-veridical? Similar issues arise with regard to inhomogeneities in the visual field. Vision in the

lower visual field is about 65% more sensitive to contrast (and orientation discrimination, texture segmentation, gap size, speed, spatial frequency) than vision equidistant from fixation in the upper visual field. (See Figure 1 for examples of low and high contrast.) In addition, there is a great deal of noise in perceptual systems. Percepts involving the same area of the visual field and the same degree of attention will typically differ in visual response from occasion to occasion. So on different occasions, one can see the same object or event in the same conditions, with the same degree of attention, and from the same vantage point and it will look different in size or speed or contrast because of random factors.

What is the consequence of these facts for the veridicality of perception? One viewpoint

Figure 1: Six levels of contrast. The Wikipedia caption reads “Different levels of contrast - original image top left - less contrast to the left (50%, 75%), more to the right (25%, 50%, 75%)”. I take this to mean that the mid-left photo has 50% less contrast than the upper left, the lower left photo as 75% less contrast than the upper left, etc. These percentages are differences from photoshop, not absolute measures of contrast of the sort to be discussed later in the paper. Percent contrast in the sense to be discussed is the difference between the luminance of the lightest and darkest parts divided by the sum of these luminances. These images come from the Wikipedia entry on contrast. According to Wikipedia, “Permission is granted to copy, distribute and/or modify this document under the terms of the GNU Free Documentation License, Version 1.2 or any later version published by the Free Software Foundation; with no Invariant Sections, no Front-Cover Texts, and no Back-Cover Texts. A copy of the license is included in the section entitled *GNU Free Documentation License*.”

says that perception is mostly slightly mistaken. We usually see length, speed and contrast non-veridically but the extent of error is small enough not to be problematic. However, this viewpoint cannot be right since it is only in virtue of a history of veridical representation both in our own lives and in the past of our species that our perceptual representations even have representational contents (Burge 2010). Without such a history of veridical representation it is not clear that perceptual representation really makes sense.

An alternative way of thinking about the issue is that perception is sufficiently imprecise in its representational content for all these varying percepts to be veridical. If a person is said to be 5 feet to 6 feet tall on one occasion and 6 feet to 7 feet tall on another, both are veridical if the person is 6 feet tall. One could put this by saying that perceptual representation is “intervallic”. The intervals however would have to be pretty large given the size of these effects—notably the 65% difference between lower and upper visual field just mentioned. And it is hard to square such large differences with the phenomenology of foveal vision. Hold a piece of lined paper in front of you. You seem to see the difference between the white space and the lines fairly precisely. “Irrelevant!,” you may retort, “Those differences in the visual field affect only peripheral perception; attentive foveal perception is much more precise than inattentive peripheral vision.” And this resolution seems to be reflected in our phenomenological judgments: move the piece of lined paper out to 30° away from the line of sight. Doesn’t your visual impression of the contrast between the lines and spaces seem, well, less precise? Surprisingly there is evidence that unattended and peripheral perception of some properties (notably contrast) are about as precisely represented in attentive foveal vision as in inattentive vision and vision in the near periphery (up to a 30° angle from the line of sight). The upshot is that the phenomenology of perception may mislead us with regard to the precision of the representational content of perception.

One might suppose that help will come from bodily action. Goodale & Murphy

presented 5 rectangular blocks to subjects at various positions in the visual field ranging from 5° to 70° away from the line of sight (1997). They compared accuracy of perceptual discrimination of one block from another with accuracy of grip via a device that measured the aperture between thumb and forefinger as subjects reached out to pick up one of the blocks. Grip accuracy is roughly the same at 5° as at 70°. The fine details of action are controlled by a largely distinct system from the system that underlies conscious vision. So what this result dramatically illustrates is that the precision of bodily action is unlikely to cast any light on the precision of perceptual phenomenology.

This is the puzzle of the title. I argue that the disconnect may be real and that perceptual phenomenology may mislead about perceptual representation. Perceptual phenomenology may not be grounded in the representational content of perception. Further, there may be no “phenomenal content”, that is no representational content that emerges from the phenomenology of perception.¹

This is a very long paper so it might be useful to know what parts to focus on. You can see the basic lines of the dialectic from reading sections 1-3. Sections 4-7 concern the experimental data concerning attention and can be skimmed without losing the thread. The argument resumes with 8-10. 11 can be skipped without loss of continuity. 12 covers some of the results that the argument is based on. 13 can be skipped. 14 is the conclusion.

2 Background

This section describes some assumptions and terminology. A simple percept consists of a representation of an environmental property and a singular element that picks out an individual item (Burge 2010). The representational content is the condition of veridicality and is satisfied only if the referent of the singular element has

¹ Direct realists reject representational contents, holding instead that the phenomenology of perception is grounded in what properties one is directly aware of. They face a parallel set of issues with regard to the question of how precise the properties are that one is directly aware of.

the property represented by the property-representation. The precision of a representation—in my terminology—is a matter of the range of values attributed. For example, consider two visual representations of the height of a person, one representing the person as between 5'6" and 6' tall, the other representing the person as between 5'8" and 5'10" tall. The latter has a narrower precision. Precision in the sense used here is not a matter of indeterminacy of borders but rather the size of the range.²

The claim that the precision of a representation is wide is a form of the claim that perception is “intervalic”. There are other measures of perception that are easily confused with precision. One of them is acuity—also known as spatial resolution. Acuity is the ability to resolve elements of stimuli. Common measures in the case of vision are the extent to which the subject can distinguish one dot from two dots, detect a gap between two figures, determine whether a rotating figure is rotating clockwise rather than counter-clockwise, ascertain whether two line segments are co-linear, distinguish a dotted from a solid line or detect which side of a Landolt Square a gap is on. (See Figure 4 for an example of a Landolt Square.)

These and other items of terminology are gathered together in a glossary at the end of the article. Of course other quite different definitions of ‘precision’ and ‘acuity’ are just as legitimate as these. Note in particular that I am not using the notion of precision as the inverse of variance or the notion of precision associated with the predictive coding literature.

Representationists (also known as representationalists and intentionalists) think that what it is like to have a perceptual experience—that is, the phenomenology of perceptual experience—is grounded in the representational content of the perception. (Not that representationists have used the notion of grounding, but I believe that it captures what they have meant.) Representationism is sometimes framed as an identity thesis (e.g., Pautz

2010; Tye 2009): what it is for an experience to have a certain phenomenal character = for it to have a certain representational content. But the identity formulation is inadequate because the phenomenology is supposed to be based in the representational content and not the other way around. Identity is symmetrical. The grounding characterization of representationism avoids this problem since grounding is asymmetrical. To say that perceptual representation grounds perceptual phenomenology is to say that it is in virtue of the representational content of a percept that it has the phenomenology it has. And *in virtue of* is asymmetrical. (See Fine 2012 on the concept of ground and my 2014a for further discussion of grounding in philosophy of mind.)

Representationism is often framed in terms of supervenience: no difference in the phenomenology of perception without a difference in its representational content. But supervenience does not capture a key motivation behind representationism: that the representational content of perception is the source of the phenomenology of perception, that it is in virtue of the representational content of the perception that it has the phenomenology it has. A supervenience formulation would entail that a difference in the precision of phenomenology requires a difference in representational content. However, on a supervenience formulation of representationism it would be a further question whether the phenomenology of perception could increase in precision without a commensurate increase—or even with a decrease—in precision of its representational content. On the grounding characterization, any change or difference in phenomenological precision is dependent on a commensurate change or difference in representational precision.

The grounding formulation of representationism rules out some but not all kinds of multiple realization. Suppose that red₇₈₂ is an example of the most fine-grained color we can experience. And suppose that the representationist theory of the experience as of red₇₈₂ is that this experience is grounded in representation of red₇₈₂. Different experiences as of red₇₈₂ can be realized by different representational states so

² As Tim Williamson noted when some of this material was presented at Oxford, the fuzziness of the borders is vagueness rather than imprecision. Ryan Perkins & Tim Bayne argue against representationism using considerations of vagueness (2013).

long as they all involve the representation of red₇₈₂.

The grounding characterization captures a representation-first view and excludes phenomenology-first doctrines that are often portrayed as representationist. Phenomenology-first views suppose that phenomenology grounds at least some kinds of representational contents (Hill 2009; Kriegel 2011, 2013; Shoemaker 2007). And it also excludes versions of representationism that treat both the phenomenology and representational content of perception as grounded in something else (Chalmers 2006; Siegel 2013). That is a plus for the grounding characterization—distinguishing between fundamentally different points of view. Although I won't talk about this much here, I think the considerations I will be raising will cast doubt on views that phenomenology grounds any kind of representational content.³

The reader may feel that both peripheral and unattended perception are odd and unimportant phenomena that cannot be the test of any theory of perception. However, peripheral unattended perception is ubiquitous. The fovea is the high density center of the retina. If you hold your hand at arm's length, your foveal perception encompasses about double the width of your thumb. Much of perception at any fixation occurs outside that area and a similar point applies to attention. However, even if you think that both peripheral and unattended perception are atypical, you should recognize that atypical cases often are a window into the nature of a phenomenon. The experiment in which a beam of light goes through two slits was crucial in demonstrating a wave aspect of light (Feynman 1988).

³ Some of the philosophers who call themselves “representationists”, for example Michael Tye (2009), have endorsed “object-involving” representational contents. Suppose I am looking at a tomato and having an experience that represents the tomato as being red₇₈₂. You are looking at an exactly similar tomato in identical circumstances and also having an experience that represents it as having red₇₈₂. According to Tye, we are having phenomenally different experiences in virtue of looking at different tomatoes. As Burge has noted in an article on direct realism (2005), there are object-involving phenomenal types (of the sort Tye is talking about), but there are also non-object-involving phenomenal types. Representationism as discussed here is concerned with the latter types. I mentioned in footnote 1 that the same issues about precision arise for direct realism—and the same applies to Tye's view.

3 The inhomogeneous visual field

Although this article is mainly about differences in perception wrought by differences in attention, it will be helpful to start with a discussion of similar issues that arise independently of attention because of the massive inhomogeneities in the visual field. I will discuss the perception of contrast. The visual system is much more sensitive to differences in luminance than to luminance itself and contrast is a matter of luminance differences. (Luminance is a measure of the light reflected from a surface.) Contrast can be defined in a number of different ways, all ways of capturing the average difference in luminance between the light and dark parts of an array. The four patches in Figure 2 have roughly equal apparent contrasts if one is fixating the cross though there is substantial variation among persons in comparative sensitivities in the visual field. But the top patch has a 30% contrast and the bottom patch has a 15% contrast. (To fixate the cross is to point your eyes at it.) Vision in the lower visual field (the South) has about 65% better sensitivity than vision in the upper visual field on average along the “vertical meridian” (the vertical line through the fixation point) for points of equal eccentricity. And sensitivity is better along the horizontal meridian than the vertical meridian, that is East and West have higher sensitivity than points of equal eccentricity in the North and South. This sensitivity advantage is about 63%. Marisa Carrasco suggests that the advantage of the horizontal over vertical meridians probably has to do with the presence of more relevant information on the horizontal meridian (Carrasco et al. 2001). These differences in sensitivity manifest themselves phenomenologically in differences among patches required for equal apparent contrasts. It takes a 30% contrast patch in the North to phenomenologically match a 10% contrast patch in the East at the equal eccentricity depicted in Figure 2. Performance asymmetries along these lines have been observed for gap size, spatial frequency (roughly density of stripes), orientation discrimination, texture segmentation, letter recognition and motion perception. Performance asymmetries of this sort have been shown in comparisons between an on-screen stimulus and a stimulus from the recent

Figure 2: If you fixate (i.e., point your eyes at) the plus sign, these four different patches should look roughly equal in contrast at normal reading distance (roughly 15 inches away). The one above the horizontal meridian has twice the contrast of the one below the meridian (30% vs 15%). The two patches on the horizontal meridian have 10% contrast. It takes a 30% patch in the North to match the 10% patch equidistant from the plus sign in the East. Much of the work of investigating this phenomenon comes from Marisa Carrasco’s lab. See [Cameron et al. \(2002\)](#) and [Carrasco et al. \(2001\)](#). Note that there is a large degree of variation from person to person so the patches may not look exactly the same in contrast to you. (The patches are called “Gabor patches” or sometimes just gabors.) Thanks to Jared Abrams for making this figure for me. @copyright Ned Block

past in visual short term memory for 1-3 seconds, albeit at a slightly lower level ([Montaser-Kouhsari & Carrasco 2009](#)). These differences are thought to be due to anatomical asymmetries ([Abrams et al. 2012](#)).

I will assume that the percepts of North and East have the same contrast phenomenologies when seen (simultaneously) in peripheral vision. Of course the fact that they don’t look different

does not prove that they look the same. And their looking the same does not prove that the phenomenology of each of the two patches is the same— as we know from the phenomenal Sorites problem ([Morrison 2013](#)). However, the fact that they look the same is *evidence* that they are the same phenomenologically and we would need a reason to resist that conclusion. Similar issues will be taken up later in section 8 and 10.

I take it as obvious that the North and East patches are determinately different in apparent contrast when sequentially foveated and attended. The fact that the percepts are sequential makes it unlikely that we are misled about the determinate difference by any analog of the “beats” one hears when guitar strings vibrate at slightly different pitches. (I will return to this issue in section 10.)

North and East look the same in peripheral vision and different in foveal vision. How could this be explained in terms of representational content? The only representational explanation I can think of would be based on the idea that the content of foveal representation of contrast is more precise than the content of peripheral representation of contrast. However, as I will explain below, there is evidence that the representation of contrast in the fovea is the same in precision as the representation of contrast in the periphery. So the burden is on the representationist to explain the difference between foveal and peripheral experience of contrast without appeal to a difference in representational precision. I will now turn to a much longer version of the argument which does not have the form of a burden of proof argument but which makes use of the notion of phenomenal precision.

I claim that when you fixate on and attend to the cross, both your perception of the North patch and your perception of the East patch normally veridically represent the contrasts of those patches despite the fact that one sees them only in peripheral vision. Many details cannot be seen in peripheral vision but what can be seen is seen veridically in normal circumstances. Of course the comparisons are illusory: patches that are different in contrast look the same. But the issue I am raising is whether the individual percepts of single patches are illusory. One reason to think there is no illusion is that the same kind of differences in perception caused by spatial inhomogeneities in the visual field occur in all percepts due to *temporal* inhomogeneities—that is, random noise in the visual system that differs from percept to percept. Any two percepts of the same items at the same point in the visual field with

the same degree of attention are likely to differ in apparent contrast (and other properties) due to these random factors. It is hard to see a rationale for supposing that spatial inhomogeneities engender illusion while claiming the opposite for temporal inhomogeneities. And claiming that both engender illusion would make most perception illusory.

This is where my appeal to Tyler Burge’s recent book comes in (2010). As Burge notes, we can explain the operation of constancy mechanisms in perception only by appeal to their function in veridically representing the distal environment. And that function precludes perception being mostly non-veridical.⁴

I will say more by way of justification of the veridicality claim later but for now let us accept that claim and think about the consequences for representationism. Note that the veridicality assumption is meant to apply to non-categorical perception of properties that admit of degrees and is not meant to apply to categorical perception. Afraz et al. (2010) showed that gender neutral faces are more likely to look male in some areas of the visual field and female in others. The veridical percept in this case would represent the gender-neutral faces as androgynous so both of the percepts described are non-veridical. Many varying mag-

4 The popular “predictive coding” framework (Clark 2013; Hohwy 2013) is a kind of Bayesian approach that is sometimes thought to provide a revolutionary alternative to the view of perception as constitutively involving veridical conditions. Of course all of vision science involves a background of Bayesian probabilistic processes. And prediction in the visual system is ubiquitous and important. But these approaches do not undermine the veridicality of perception. A recent review of Jakob Hohwy’s 2013 book on predictive coding (Wilkinson 2014) singles out the predictive coding explanation of binocular rivalry as the parade case, claiming that the predictive coding framework “provides a very satisfying account of binocular rivalry.” Clark (2013, pp. 184-185) also emphasizes the supposed explanation of binocular rivalry. Binocular rivalry is a surprising visual phenomenon in which different stimuli are presented at the same time to the two eyes, e.g., a face to one eye and a house to the other. What the subject sees however is an alternation between a face filling the whole visual field, then a house, then a face, etc. It is widely agreed in vision science that the rough outline of the binocular rivalry phenomenon is explained by a combination of reciprocal inhibition and adaptation: the competing interpretations reciprocally inhibit one another, and when one is in the ascendancy, adaptation weakens it until the other takes over. Hohwy and his colleagues more or less concede this (Hohwy et al. 2008) saying that the predictive coding framework explains why we have reciprocal inhibition and adaptation in the first place. But to the extent that this reflects what is good about the predictive coding framework, it is not a revolutionary alternative to standard vision science but rather an evolutionary gloss on it.

nitudes such as size and contrast are not perceived categorically in this way so there is no corresponding “reality check” for such magnitudes. (Some magnitudes such as orientation may mix categorical and non-categorical perception.)

A percept that attributes a property to an item is veridical only if the item has the attributed property. However, the veridical percepts of North and East (when fixating the cross) attribute the same contrast property since they look the same in contrast. Let us ask what the content of the (veridical) percepts of North and East are when one is fixating the cross and they look the same in contrast. That is, what contrast would the percepts of North and East attribute to those patches? Since East is a 10% patch and North is a 30% patch, and both are veridical, it follows that the percepts have to attribute the same contrast to them (since they look the same). What attributions would be the same and also veridical? The patches would have to be represented as having a range of contrasts between 10% and 30% at a minimum. That is, the minimal imprecision in the representation is 20%, the imprecision of a representation of 10%-30% contrast (including the endpoints).

Now let us ask what the contrast-content is when we fixate (and attend to) the East patch, the 10% patch. If the precision is the same as in peripheral perception (i.e., 20%), the percept could have a content of 10% plus or minus 10%, i.e., 0% to 20%. (A 0% contrast patch would be invisible, so presumably imprecision ranges should be weighted towards higher absolute values of the magnitude perceived. Variability in perceptual response increases with the absolute value of the magnitude perceived—one form of the Weber-Fechner Law. This is a complication that I will mainly ignore.) And for similar reasons, if the precision is the same in foveal as in peripheral perception, the contrast content of the percept of the North patch when one fixates it would be 20%-40%.

The representational precision is 20% but what about the phenomenal precision? Can we make sense of this idea? As with all that is phenomenal, no definition is possible. The best that

we can do is indicate a phenomenon that the reader has to experience for him or herself. One type of example exploits the difference between an object close up and the same object at a distance. An object may look to have the same properties at both distances but with different precisions. An object may look crimson close up but merely red (and not any particular shade) at a distance.

If the phenomenology of perception is grounded in its representational content and if there is such a thing as phenomenal precision, an increase in phenomenal precision depends on a corresponding increase in representational precision. Representational precision can be indexed numerically—a representational content of the length of something as 1 inch—2 inches (i.e., between 1 and 2 inches) is more precise than a representational content of it as 1 inch—3 inches. According to representationism, phenomenal precision is just the phenomenology of the precision of representational content. We experience a percept with representational content of 1 inch-2 inches as having more (i.e., narrower, smaller range) precision—as being more phenomenally determinate—than we experience a percept with representational content 1 inch—3 inches.⁵

Note that I am not saying that we can always ask whether a certain item of phenomenology is more precise or less precise than a certain representational content (though I think there are some cases where this does make sense). What I am saying is that a representationist has to hold that a difference in phenomenal precision is grounded in a difference—of the appropriate sign and magnitude—of representational precision.

Here is the application of these ideas about precision: Foveate North and East in turn (i.e., serially). I claim that they look determinately different. According to what I mean by looking determinately different, for items to look determinately different, their phenomenolo-

⁵ For a direct realist, phenomenal precision is just the precision of the properties we are directly aware of. We can be directly aware of properties with different precisions, for example, crimson, or alternatively red. Similarly we can be directly aware of a 10%-20% contrast property and also a 10%-30% contrast property and the difference constitutes a phenomenal precision difference.

gies cannot be almost completely overlapping. Why is lack of almost complete overlap important? The representational contents of perception can be very imprecise even though discrimination is fine grained. One might represent one patch as 10%-30% in contrast and another patch as 10.5%-30.5% and as noted by [Jeremy Goodman \(2013\)](#) that would in principle allow for discrimination between them. If the phenomenal precision of these percepts is also very wide, then the phenomenologies of these percepts would not be determinately different from one another—given what I mean by these terms.

Don't get me wrong: I do think that items can look different on the basis of different but overlapping contents. For example, if one is foveating a patch and simultaneously sees a patch of the same contrast in peripheral vision, the two will look different in contrast. Each of the two percepts can be veridical (even though the comparative percept is not). And being veridical and being of the same contrast, the intervallic contents have to overlap.

You may be skeptical about whether there is such a thing as phenomenal precision and whether there is such a thing as phenomenal overlap. But a representationist should not be skeptical. If one's visual experience represents one length as between 1 inch and 2 inches and a second as between 1 inch and 3 inches, then it is hard to see how a representationist could deny that the phenomenal character that is grounded in the first is more precise than the phenomenal character that is grounded in the second. And if one patch is represented as 10%-30% in contrast and another patch as 10.5%-30.5% the representationist would need a good reason to claim that the phenomenologies did not almost completely overlap. Given that representationism would seem to be committed to phenomenal precision and phenomenal overlap, it would seem legitimate to assume them in an argument against representationism.

North and East look the same when fixating the cross and determinately different when fixating (and attending) to each in turn. What does this fact tell us about representational and phenomenal precisions? The phenomenal preci-

sion of perception of contrast must be narrower (i.e., smaller range, greater precision) in foveal vision than in peripheral vision—in order to explain why North and East look the same in respect of contrast in peripheral vision but determinately different in foveal vision. Even if we cannot make sense of an absolute value of phenomenal precision at least we can make sense of differences in it. We might think of this as a phenomenal precision principle:

If two things look the same in peripheral vision and determinately different in foveal vision, then the phenomenal precision of foveal vision is narrower (smaller range) than that of peripheral vision.

At least for one of the foveal percepts, and why would one have narrower precision but not the other? And so according to the representationist, representational precision must be narrower in foveal than in peripheral vision as well—otherwise there would be a difference in phenomenal precision that was not grounded in a difference in representational precision. (The peripheral perceptions are simultaneous and the foveal perceptions are serial. The inhomogeneities described here hold both for simultaneous and serial presentations, albeit at a slightly reduced level in serial presentations. This has been shown separately for inhomogeneities in the visual field ([Montaser-Kouhsari & Carrasco 2009](#)) and for the attentional effects to be discussed later ([Rolfs et al. 2013](#))).

Note that as far as the doctrine of supervenience of phenomenology on representation is concerned, North and East could look the same but still be represented differently. The grounding formulation says: With qualifications to be mentioned: different representational contents require different phenomenologies; supervenience speaks to the converse only. Qualifications: there may be different representational parameters, only one of which is the ground of the relevant phenomenology. So there could be multiple representational realizations of a single type of phenomenal state where the representational differences reflect differences in the parameters that are irrelevant to grounding. And:

phenomenology might be grounded in representational content even though the grain of phenomenology is coarser than that of representational content. So there might be differences in fine-grained representational content that do not make a phenomenal difference.

No one would object to the idea that pure dispositions like fragility or solubility could be grounded in different molecular structures in the case of different substances. And physicalists about phenomenology have held that the underlying basis of a common phenomenology might be one physical state in humans and another in robots. However, I have argued that the grounding framework reveals that physicalists should not acknowledge this kind of multiple realizability (2014a). Applied to this case, the idea is that a representationist account should give us a representationist answer to the question of what it is in virtue of which the phenomenology of the peripheral percepts of North and East are the same. Phenomenal sameness requires representational sameness as a ground. And that representational sameness in this case has to be a precision range of 10%-30% or more.

Of course the notions of phenomenal precision and almost complete overlap of phenomenologies are obscure. The methodological situation we are in is that we have a well-developed science of perception but very little science of the phenomenology of perception. One response—very common until recently—is to avoid issues of phenomenology like the plague. But the time may be ripe to try to leverage the science of perception to get some insight into the phenomenology of perception. And that project cannot help but start with some vague intuitive notions.

Here is where we are: foveal percepts of the contrasts of North and East are determinately different in phenomenology but peripheral percepts of them are the same in phenomenology so the phenomenal precision of North and East, each seen foveally is narrower than the phenomenal precision of North and East seen peripherally. If representationism is to avoid a difference in phenomenal precision that is not based in a corresponding and commensurate dif-

ference (of the right direction) in representational precision, then representational precision has to be narrower in foveal than peripheral perception. That is, the representationist should hold that peripheral perception is less representationally precise than foveal perception.

Here comes the punch line: Robert Hess & David Field (1993) compared the discrimination of the locations and contrasts of patches of different contrasts. They presented triples of patches in which the middle patches could differ from the flankers in (1) locations and (2) contrasts. They asked subjects two questions concerning each triple: whether the middle patch differed from the flanker patches in location and contrast. What they found was that discrimination of locations falls off greatly in the periphery but discrimination of contrasts does not. They conclude (pp. 2664, 2666), “... we show that for normal periphery, elevated spatial uncertainty is not associated with elevated levels of contrast uncertainty at any spatial scale... A change in positional error of a factor of 14... from the fovea to the periphery has an associated contrast error that does not significantly increase over the same range of eccentricities.” The graphs are striking: position error increases greatly with peripherality of the stimuli but contrast error is a flat line. See Figure 3 for one of the figures that illustrates this fact. As far as I can tell, this result is widely accepted. Even a critical reply (Levi & Klein 1996) says “Their results (discussed below) show that position discrimination is selectively degraded in the periphery, while contrast discrimination is not affected.” Levi and Klein dispute the alleged explanation of the result, not the result.

Note that I am taking the fact that contrast discrimination does not diminish in peripheral vision to be evidence that representational precision does not decrease in peripheral vision. Hess & Field (1993) describe a model of the result in terms of constant “uncertainty” for contrast across the visual field but increasing uncertainty for location. Their concern is whether the subjects’ visual representations produce locational errors as a result of “undersampling”. They argue that undersampling should affect contrast errors too.

And because it does not, they conclude that the explanation is “uncalibrated neural disarray”: “We propose that, for reasons as yet unknown, the periphery, unlike the fovea, has not undergone sufficient self-calibration to resolve all of its innate anatomical neuronal disorder...” (p. 2669). But we don’t have to buy into neural disarray to accept the observation that contrast uncertainty does not decrease in the periphery.

We feel that foveal attended perception is “crisp”, i.e., high in precision but for some properties—contrast and probably gap size, spatial frequency (stripe density) and speed—there is some reason to think that foveal and peripheral perception are equally precise. The resolution is that some properties—e.g., location—really are represented more imprecisely in the periphery than in the fovea (by a factor of 14). (And some properties seem to be represented *more* precisely in the periphery, e.g., flicker rate for some spatial frequencies; Strasburger et al. 2011). So we can’t think of peripheral perception as imprecise in regard to all properties we can see. And for the properties that do not decline in precision in the periphery, the representational point of view doesn’t seem to work very well.

Acuity is lower in the periphery than in foveal vision. Anton-Erxleben & Carrasco (2013) describe five mechanisms that jointly explain the decrease in acuity with eccentricity. Cone density and the density of the retinal ganglion cells that process cone signals decrease with eccentricity. In addition, average receptive fields are larger in the periphery. (The receptive field of a neuron is the area of space that a neuron responds to. See glossary.) So the elements of a grid will not be visible in the periphery if they are too finely spaced (i.e., if the spatial frequency is too high). To compensate for this, Hess & Field used only very coarse grids in the periphery. So what the result suggests is that contrast uncertainty does not increase in the periphery—for grids that one can actually see in the periphery.

But why do the behavioral results reflect on representational precision rather than phenomenal precision? The anatomical asymmetries

that are the probable basis of the inhomogeneities discussed here are bound to affect unconscious perception in the same way as conscious perception.

The Hess & Field result shows a kind of homogeneity in the visual field in regard to contrast but as I have emphasized in regard to the phenomenon of Figure 2, the visual field is inhomogeneous in regard to contrast. How are these compatible? The inhomogeneities in Figure 1 reflect contrast sensitivity whereas the homogeneity showed by Hess & Field reflect contrast precision.

Here is the argument summarized:

1. The peripheral percepts of North and East, being the same in contrast phenomenology, are the same in contrast-representational contents—if phenomenology is grounded in representation.
2. The peripheral percepts of North and East are both veridical; that is, North and East have the properties attributed to them in peripheral perception.
3. Given veridicality and the difference between North and East in actual contrast, the representational contents of the peripheral percepts must be rather imprecise. Since North is 30% and East is 10%, and since the content characterizes both, the peripheral representational contrast-content has a precision range of at least 10%-30%.
4. Foveal percepts of North and East—one at a time—are determinately different in phenomenology.
5. The phenomenal precision principle: If two things look the same in peripheral vision and determinately different in foveal vision, then the phenomenal precision of foveal vision is narrower (smaller range) than that of peripheral vision.
6. So the phenomenal precision of the foveal percepts of North and East must be narrower than that of the peripheral percepts of these patches.
7. Representationism requires that a difference in phenomenal precision be grounded in a commensurate difference in representational precision.

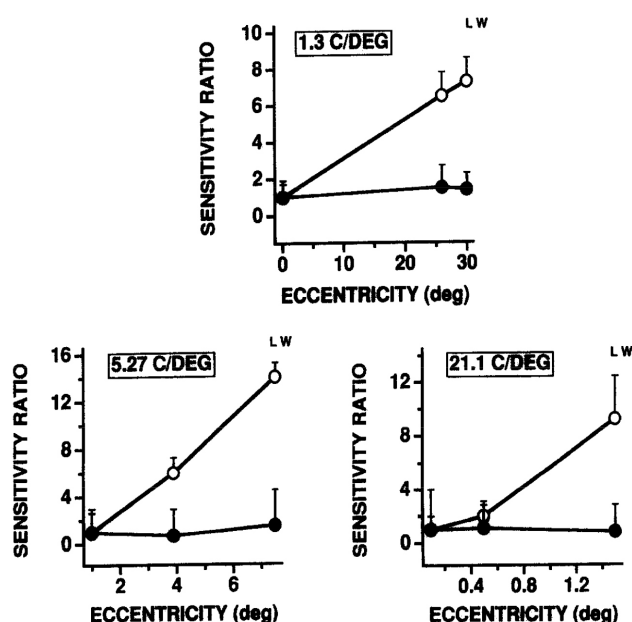

Figure 3: This is one of four graphs from (Hess & Field 1993) showing the comparison between the sensitivity to contrast as compared with the sensitivity to location. The Y-axis represents foveal sensitivity divided by peripheral sensitivity so a value of more than 1 represents greater foveal sensitivity. The solid dots represent contrast sensitivity whereas the open circles represent location sensitivity. The top graph shows sensitivity up to 30 degrees from the line of sight for a very coarse grid of 1.3 cycles per degree. The bottom two graphs show sensitivity for finer grids but at much lower eccentricities. (Coarse grids are visible in the periphery but fine grids would look like a uniform gray surface in the periphery.) Foveal discrimination thresholds are given an arbitrary value of 1. (This is referred to in the article as the values being “normalized”.) What this figure and the other 3 figures show is that contrast sensitivity for grids that are coarse enough to see is the same in the periphery as in the fovea but location sensitivity is much worse in the periphery. Reprinted with permission of *Vision Research*.

8. So representationism requires that the foveal representational precision be narrower than the peripheral representational precision. However the experimental facts suggest maybe not.⁶

⁶ This argument can be stated in direct realist terms but it would require an analog of the veridical/illusory distinction in direct realist terms. See Block (2010) and footnote 14.

9. Conclusion: there is some reason to think that the phenomenology of perception is not grounded in its representational content.
10. The same argument applies to views that hold that there is a kind of “phenomenological representational content” that emanates from the phenomenology of perception (Bayne 2014; Chalmers 2004; Horgan & Tienson 2002). If there were such a thing, it would have to be precise enough to properly reflect phenomenology but imprecise enough to handle the veridicality considerations raised here. And the argument presented here suggests that can’t happen.

The premise that I think needs the most justification is 4. Do we really have enough of a grip on what it is for percepts to be determinately different in phenomenology to justify the idea that the foveal percepts do not have almost completely overlapping phenomenal characters?

Given the problem with 4, I should remind the reader that I started with an argument that did not appeal to phenomenal precision. North and East look the same in peripheral vision and determinately different in foveal vision. How could this be explained in terms of representational content without appealing to a difference in representational precision between fovea and periphery? This argument has the usual problem of a burden of proof argument but it has the advantage of avoiding the obscurity of phenomenal precision.

Another more introspective route to the same conclusion derives from the point mentioned at the beginning that it is natural to feel that the phenomenology of seeing the contrast between lines and spaces foveally differs in precision from seeing the same lines peripherally. The foveal percept seems more “crisp” than the peripheral percept. If this intuitive judgment is correct, there is a discrepancy between the precision of phenomenology and the precision of representational content.

I think this argument gives the reader a pretty good idea of the dialectic of the paper though the paper is more concerned with the issue of change in precision due to differences in attention than with peripherality.

Worth Boone has argued against my point of view using two-point thresholds of tactile discrimination (2013).⁷ As I will explain, I think some of the issues he raises actually support my conclusion.

Boone noted that there are large differences in representational determinacy (precision in my terminology) between tactile acuity as measured by two-point thresholds at various points on the body but that—contrary to what I have said—the precision of the phenomenology matches the precision of the representational content.

First, what are two-point thresholds? “Subjective” two-point thresholds are based on one or two sharp points (e.g., pencil points) being placed at constant separations at various body parts, with subjects reporting whether it feels like there are two points or one point. Objective two-point thresholds are measured by stimulating the skin with either one or two sharp points and observing to what extent the subjects are able to discriminate between these stimuli. Objective thresholds are based on whether there actually are two rather than one point whereas subjective thresholds are based simply on the judgments themselves, independently of their accuracy. The subjective method shows extremely high variability within a single subject on the same body part for a variety of reasons. The objective method has a number of paradoxical features that I won’t go into but if you are interested you can read a short article dramatically titled “The Two-Point Threshold: Not a Measure of Tactile Spatial Resolution” (Craig & Johnson 2000).

However, a recent review (Tong et al. 2013) suggests better measures of tactile acuity that confirm Boone’s point that tactile acuity varies enormously from one part of the skin to another. A glance at a graph in the Tong, et. al. paper reveals that acuity on the tip of the finger is about 5 times that of the palm and about 20 times the acuity on the forearm.

We can ask: is the phenomenology of these perceptions as imprecise as the representational content? Boone says yes but he is judging the

phenomenology of two-point perception. That method is doubly illicit, first because it is unclear that two point discrimination is a measure of anything tactile. Second, the two point judgments may simply reflect the representational contents rather than or in addition to the phenomenology, contaminating the verdict on the very point at issue. If you ask someone how determinate their phenomenology of a two point stimulus is, they may simply be reporting how sure they are they are perceiving two points rather than one. The latter is suggested by considerations of representational “transparency” or “diaphanousness” of experience (Stoljar 2004)⁸. As Thomas Metzinger puts it, we “look through” the experience to its object (2003, p. 173). If so, the phenomenology of judging one vs two may be contaminating the judgment of the precision of the percept.

So I will ask again: Do the differences in phenomenological precision between fingertip and palm and between fingertip and forearm perception differ by factors of 5 and 20? The question is not well formed: we cannot ask about either phenomenological or representational precision without specifying what is being represented.

To get a better question, let us focus on the perception of location. Representational locational imprecision does vary with location on the body. The explanation of the variation is that the number and spatial distribution of sensory receptors that feed into a single sensory neuron (i.e., the receptive field of the sensory neuron) varies widely over the body.⁹ Is there a matching change in the phenomenal precision with regard to location? If there were a massive decrease in representational precision of location from fingertip to forearm without a corresponding decrease in phenomenal precision, we would have a violation of grounding (of a different kind from those already discussed). I suggest you put a single pencil point on your finger tip

⁸ G. E. Moore (1903) famously said “... the moment we try to fix our attention upon consciousness and to see what, distinctly, it is, it seems to vanish: it seems as if we had before us a mere emptiness. When we try to introspect the sensation of blue, all we can see is the blue; the other element is as if it were diaphanous ...”

⁹ For an amusing account of the facts surrounding these issues see Ramachandran & Hirstein (1998).

⁷ I used Figure 2 in a talk at Pittsburgh where Boone was in the audience on November 2, 2012.

and then on your palm and forearm. (Or if you have a helper, do them simultaneously.) If there is a five-fold or twenty-fold difference in phenomenological precision of location it should be appreciable with any stimulus. My own introspective judgment is that there is little or no difference in precision of representation despite the five-fold difference between the fingertip and palm and 20-fold difference between the fingertip and forearm. I am pretty sure that the percepts are not determinately different. No doubt people differ both in these experiences and in their introspective access to them. And with all difficult phenomenal judgments, contamination by theory is no doubt a major source of variability.

If my judgment is right, we have a case of a difference in representational precision without a corresponding difference in phenomenal precision. In the visual case just mentioned, we have evidence for a difference in phenomenal precision without a corresponding difference in representational precision. Taken together, the cases suggest a considerable disconnect between perceptual phenomenology and perceptual representation.

The conclusion of this section is that there is some reason to think that there is no representational content of perception that either grounds or is grounded by the phenomenology of perception—what it is like to perceive.

The reader may wonder how there could be such a disconnect between the phenomenology of perception and its representational content. I mentioned the fact that grip accuracy is about the same in the far periphery (70° off the line of sight) as it is close to the line of sight (5°) despite the fact that conscious vision is extremely weak in the far periphery. Conscious vision is a distinct system from the system that underlies the fine details of perceptually guided action. Though I am not alleging that the system underlying conscious perception is distinct from the system underlying perceptual representation, the upshot of this paper is that they are partially distinct.

In what follows, I will be arguing that facts about attention motivate a similar argument for a discrepancy between the phenomeno-

logy of perception and its representational content. The reason I went through the argument based on inhomogeneities first is that the issues are straightforward compared with the corresponding issues concerning attention. Attention is a complicated phenomenon about which there is a great deal of disagreement, so the rest of the paper has many twists and turns. The argument form as presented so far will not resume until section 8.

4 Attention affects appearance

William James (1890, p. 404) famously said attention “... is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others.” Except for the exclusion of unconscious attention, most scientists would accept something like that characterization today. Spatial attention is attention directed to a portion of environmental space and is distinct from attention to an individual (e.g., a thing, a surface or a property instance) or to a property.

The mechanisms of attention are fairly well understood. Spatial attention boosts neural activation in circuits that process information from the spatial area that is attended, inhibiting activation in circuits that process information from adjacent areas. Feature-based attention boosts neural activation for attended features, inhibiting neural activation for other features. Object based attention does the analogous task for objects. Feature-based attention refines selectivity for the attended feature whereas spatial attention refines selectivity for the attended area of space (Carrasco 2011; Ling et al. 2014).

The main body of this paper is concerned with the effect of the modulation of spatial attention on phenomenology and representational content. Except when mentioned explicitly, I am talking about spatial attention rather than attention to a property instance or an object. My argument is based on experiments that indicate that attention affects appearance. To begin, at-

tention affects perceptual acuity, one measure of which is whether one can detect whether there is a gap or what side it is on in a Landolt square. (For examples of Landolt squares, see Figure 4.)

Figure 4: Landolt squares, i.e., squares with gaps. The subjects' task in the experiment diagrammed in Figure 4 was to report (via key presses) whether the gap is on the left or on the right. The squares were presented at various locations while the subject was fixating in the middle of the screen. Redrawn from Yeshurun & Carrasco (1999).

Yaffa Yeshurun & Marisa Carrasco (1999) asked subjects to press different keys depending on whether a Landolt square had a gap on the left or the right. The Landolt square could be presented at any of 16 different locations of 3 different eccentricities. In half of the trials, the square was preceded by a green bar presented briefly at the location in which the square would appear. Then after a pause, a Landolt square appeared in the same location as the line, and then a noise “mask” was presented to prevent an ongoing iconic representation of the stimulus. The subject was supposed to press a key indicating which side the gap was on. See Figure 5 for the sequence of presentations. (An icon would introduce an unwanted source of variability since “iconic memory” varies from person to person. A later experiment (Carrasco et al. 2002) obtained similar results without a mask.) The result is that subjects were more accurate and also faster when the cue indicated the location of the square than when there was no cue. Similar results were shown for other acuity tests, e.g., distinguishing a dotted line from a solid line.

This experiment involves “exogenous” attention in which the subject’s attention is automatically attracted by a highly visible change,

e.g., a sudden motion or disappearance of an object. A similar effect has been shown when the subject is told, for example, to attend to the right when a central bar points in that direction. This is a matter of “endogenous” attention. Exogenous spatial attention is sometimes referred to as “transient” or “bottom-up” attention, whereas endogenous spatial attention is “sustained” or “top-down”. Exogenous attention is involuntary whereas endogenous attention is voluntary. Exogenous spatial attention peaks by 120 ms after the cue, whereas endogenous spatial attention requires at least 300 ms to peak and has no known upper temporal limit.

Figure 5: Yeshurun & Carrasco (1999) asked subjects to fixate (point their eyes) at a dot at the center of a screen. Then a cue appeared for 54 ms, then an “inter-stimulus interval”, then a Landolt Square, then a mask. (See the text for the purpose of the mask.) Note that it takes 250 ms for eye movement to a new location, so in this and the other experiments described here the brief presentations of stimuli preclude eye movements to the cued items. I am grateful to Marisa Carrasco for giving me this figure.

Using a similar paradigm and comparing the effects of exogenous and endogenous attention (Montagna et al. 2009), researchers showed that endogenous attention decreased the min-

imum size of a gap that could be detected by about 35% compared to a gap on the opposite side from the cue. That is, subjects could detect much smaller gaps when they attended to the area in which they appeared.

Figure 6: Experiment from [Gobell & Carrasco \(2005\)](#). Procedure described in text. Reproduced with permission from *Psychological Science*.

The conclusion is that attention affects acuity. This is not part of the evidential basis for the argument to come. However there is another effect that is directly relevant to my argument: attention also causes the gap to be perceived as larger. This was shown by a later type of experiment from Carrasco's lab.

The subjects were asked to fixate on the dot that appeared for half a second (upper left in Figure 6). Then the subjects saw a dot on the left or a dot on the right or only at the fixation point in the center of the screen. Then the subjects saw two Landolt squares each of which could have a gap either on the top or the bottom (even though the figure shows the gap on the same side). The subject was then asked to report whether the bigger of the two gaps is on the top or the bottom. If the gap on the left was bigger, the subject was supposed to report the answer using the left pair of keys; *mutatis mutandis* if the right gap is bigger. The subject was told—correctly—that the dot did not predict anything about the size of the gaps. The subjects' instructions focus on the top/bottom

difference whereas what the experiment is really about is the perceived size. The purpose of the dot was to attract the subjects' exogenous (involuntary) attention to one side or the other on some trials. What was being tested is whether attention to, e.g., the left, would cause the perceiver to treat the left gap as bigger. The result was that it does. Subjects did not discriminate between an attended .20° degree gap and an unattended .23° gap. (The gap sizes are measured in degrees of visual angle. If a distance between the eyes and the screen is specified, the degree coding can be changed into inches.)¹⁰ Note that subjects were not asked to judge relative sizes of gaps. In particular they were not asked to judge whether an attended .20° degree gap and an unattended .23° gap “look the same”. Rather, the subjects were asked to make discriminations based on apparent gap size. The result is that they are indiscriminable. And this fact about these experiments has led to disputes about what they really show, as I will explain.

The experiment diagrammed in Figure 5 shows attention increases acuity. This one shows that attention makes gaps look bigger. One of the main mechanisms by which attention improves acuity is that attention shifts and shrinks receptive fields ([Anton-Erxleben & Carrasco 2013](#)). The shifting of receptive fields is probably involved in both the increase in acuity and the larger appearance. Attention to an area of space causes neurons that were not aiming at that area of space to shift towards it. The effect is more neurons covering that area of space. More neurons covering that area increases the acuity of perception of it. And this mechanism is responsible for the increase in apparent size as explained by [Katharina Anton-Erxleben et al. \(2007\)](#). Their explanation depends on the “labeled-line” hypothesis that neurons in the

¹⁰ This effect could be regarded as larger than the result from the Yeshurun and Carrasco paper reported in 5. In that paper, 75% accuracy was achieved by a .20° cued gap as compared with a .22° uncued gap. That difference may be because the 75% accuracy is arbitrary. Or if the difference is real, we could point to the fact that in the Gobell and Carrasco study, the comparison is between an attended square and a square from which attention has been withdrawn, whereas in the Yeshurun and Carrasco study the comparison is between a case in which something is cued and a case in which nothing is cued. Note that there is no need for a mask in this experiment since variations in iconic memory between subjects would be expected to affect equally both the square on the left and on the right.

early visual system are hard wired to code for a certain area of space. So when the receptive fields of neurons shift towards a target the brain treats the size of the target as larger.

5 Is the attentional effect perceptual?

There has been a controversy in the perception literature about whether the kind of effect I have been describing is at least in part genuinely perceptual as opposed to an effect on the decision process involved in generating a report (Schneider & Komlos 2008; Valsecchi et al. 2010).

There probably are effects of attention on aspects of decision, including on conceptualization of a stimulus (Botta et al. 2014). However, I think the case is overwhelming that the attentional effect is at least in part genuinely perceptual. One reason involves “perceptual adaptation” a phenomenon known to Aristotle in the form of the “waterfall illusion”. As Aristotle noted, “...when persons turn away from looking at objects in motion, e.g., rivers, and especially those which flow very rapidly, things really at rest are seen as moving” (1955). Looking at something moving in a direction raises the threshold for seeing motion in that direction, biasing the percept towards motion in the opposite direction.

Perceptual adaptation is involved in the “tilt aftereffect”. If one looks at a left-tilting patch, the neural circuits for the left direction raise their thresholds. This is sometimes described (evocatively but inaccurately—see Anton-Erxleben et al. 2013) as neural fatigue. Then when one looks at a vertical patch, it initially looks tilted to the right. (See Figure 6 of Block 2010). The reason is that the neural circuits for rightward tilt dominate the percept because of the “fatigue” of the leftward tilt neurons. Ling & Carrasco (2006) showed that attending to the adaptor increased the size and duration of a variant of the tilt-aftereffect as if the contrast of the adaptor had itself been raised. Attending to a 70% contrast grating ramped up the tilt after-effect as if the contrast had been raised from 11 to 14% (different magnitudes in different subjects). Ling and Carrasco

directed subjects to attend to gratings for 16 seconds. They found a benefit of attention at first in allowing subjects to distinguish tilts, since attention increases acuity, but then as adaptation increased, discrimination of the adapted tilt was impaired. This kind of adaptation is ubiquitous in perception but does not appear to occur in cognition or decision (Block 2014b). In case anyone thought that the attentional effect was entirely an effect on decision or cognition, this experiment suggests otherwise.

But even apart from the adaptation results, there is strong evidence going back at least to the 1990s from single cell recording in monkeys and in brain imaging for the conclusion that attention increases activity in the neural circuits responsible for the perception of contrast in a manner roughly consonant with an increase in the perception of contrast. Much of this evidence is summarized in sections 4.6 and 4.7 of a review article (Carrasco 2011). My hedge “roughly” stems from debates about the exact effect of attention. There are two kinds of “multiplicative” effects. In “contrast gain” the effect is just as if the contrast of the stimulus has been multiplied by a constant factor. In “response gain” the response is multiplied by a constant factor. The balance of these effects depends on the difference between the size of the target and the size of the “attentional field” (Herrmann et al. 2010). (These ideas are very clearly explained in Chapter 2 of Wu 2014.) A further kind of amplification effect is additive rather than multiplicative: the baseline or “floor” level of activation in the circuit is increased. There is some evidence (Cutrone et al. in press) for increased input baseline as a major part of the attentional effect.

Further, there is plenty of evidence for the conclusion that attention modulates specific cortical circuits depending on what feature is attended. A recent experiment (Emmanouil & Magen 2014; Schoenfeld et al. 2014) compared brain activation when subjects attended to a surface on the basis of its motion and when subjects attended to a surface on the basis of its color. Many of the stimuli involved both color and motion but which feature was task relevant was varied. The result was that motion sensitive

areas of visual cortex were activated first when motion was task relevant and color sensitive areas of visual cortex were activated when color was task relevant. In Carrasco's experiments, subjects' attention is drawn to the specific features that the experiment concerns. In the experiment diagrammed in Figure 6, subjects are directed to report the location of the bigger gap, thereby directing attention to gap size. In the analogous experiment connected with Figure 7, subjects are asked to report the tilt of the patch that is higher in contrast, thereby directing attention to contrast. In experiments concerned with color saturation, subjects are shown stimuli that vary in saturation and asked to report the tilt of the patch that is higher in saturation. Similarly for many other features—speed, spatial frequency, flicker rate, motion coherence, shape, brightness, etc. These instructions can be expected to direct attention to the indicated features with amplification in the circuits that register those features.

Schneider (2011) seems to think that when subjects are asked to report on the side of the larger gap and the gap on the attended side is .20° while the gap on the unattended side is .23°, the subject finds that there is no difference in apparent gap size so the subject just chooses the more salient side. I will discuss salience in the next section, but there is one thing about this charge that raises a distinct issue: that subjects register the increase in apparent size only unconsciously. I now turn to that issue.

6 Is the attentional effect unconscious — like blindsight?

The experiments I have described are “forced choice” experiments in which the subjects must choose between two alternatives. In any perception experiment the issue can be raised of whether the perception is conscious or unconscious, but the issue is often especially troublesome in forced choice experiments with brief stimuli in which subjects make a conscious choice but in which the stimuli are sufficiently evanescent that subjects do not get a really good look at them (Phillips 2011). In addition, the stimuli are presented very briefly, in the ex-

periments described above for 80 ms or less. Many subjects will say that they are never 100% sure of anything. And this can lead to the charge that what is really going on is akin to “blindsight” in which the perception, though genuine, is unconscious (Turatto et al. 2007).

Why are the presentations so brief? Brief presentations preclude eye movements, they preclude significant perceptual adaptation (the “neural fatigue” that causes afterimages), and they preclude certain kinds of strategic responding on the part of subjects. Further, it is known that the effects of exogenous attention peak at around 120 ms after the cue, so to maximize the effects of exogenous attention, brief presentations are required.

Massimo Turatto (2007) showed, using a procedure much like Carrasco's with judgments of perceived speed, that an unattended moving patch was treated as equal in speed to an attended moving patch that was slower by about 10%. However when they asked subjects for subjective judgments of moving stimuli in peripheral vision that really did differ in speed by 10% (without any attentional manipulation), subjects said they saw no difference. Turatto took this as showing that the “just noticeable difference” between the items being distinguished is above the size of the attentional effect so the effect of attention on speed is not conscious. A 10% difference in speed is well above the differences that people can see consciously when they are presented for longer periods, but Turatto argues that for these short presentations the just noticeable difference is larger—that is, it takes a larger difference to be consciously perceived.

There is a difficulty with his experimental procedure though. There are well known problems in asking subjects for same/different judgments. Whether the subjects say ‘same’ or ‘different’ depends not only on their percepts, but also on their decision processes, including how big an apparent difference has to be before they regard it as reflecting reality. These issues are nicely analyzed in (Anton-Erxleben et al. 2010, 2011). When Anton-Erxleben et al. corrected for these deficiencies in another same/different experiment, they found effect sizes that are in

Figure 7: A version of one of the stimuli used in (Carrasco et al. (2004)). Fixate at the dot in the center and move your attention to the left patch without moving your eyes. If you can manage that “covert attention”, the patches should look to have about equal contrast. If you attend to where you are pointing your eyes (the center) you should be able to visually appreciate that the right patch has higher contrast. I am grateful to Marisa Carrasco for supplying this figure.

the vicinity of other paradigms from the Carrasco lab. The effect size is slightly smaller but as they note, that is probably due to inferior sensitivity of the same/different paradigm. (Similar points apply to Kerzel et al. 2010.) One of the conclusions I would draw is that the notion of a “just noticeable difference” in its usual applications is defective because *noticeability is not a perceptual property* but rather the result of an interaction between perception and cognition. I will not go into these issues further here. However, even if Turatto’s methodology is flawed, the issue raised is a good one. How do we know that the effects in Carrasco’s attentional experiments are in fact conscious?

The stimulus in Figure 7 was one of the stimuli used by Carrasco and her colleagues (Carrasco et al. 2004) in the first experiment that demonstrated that attention affects perception by changing the qualities of perception, in this case increasing apparent contrast. The method used was the same as described earlier in connection with Figure 6—in fact this experiment was the model for the experiment of Figure 6. Subjects were asked to report the tilt of the patch that was higher in

contrast after their attention was attracted to one side or the other by a dot as in Gobell & Carrasco (2005). The result was that when the 22% patch was attended it was treated by subjects as the same in contrast as the less attended 28% patch.¹¹ In order to make the judgment, subjects were shown examples of higher and lower contrast. (Contrast is a measure of the difference between light and dark portions of a stimulus.)

As I mentioned, similar experiments have shown that attention increases apparent color saturation, apparent size of a moving pattern, apparent speed, apparent flicker rate, apparent spatial frequency (more about what that is below), apparent motion coherence and apparent time of occurrence—the attended event seems to appear about 40 ms before the unattended event. As I mentioned, the subjects have to take in what parameter the experimenter is talking about—saturation, spatial frequency, gap size, contrast, etc. and then decide which stimulus is greater *with respect to*

¹¹ As mentioned earlier, this methodology tells us that the two were indistinguishable and it is a further step to conclude that they actually look the same.

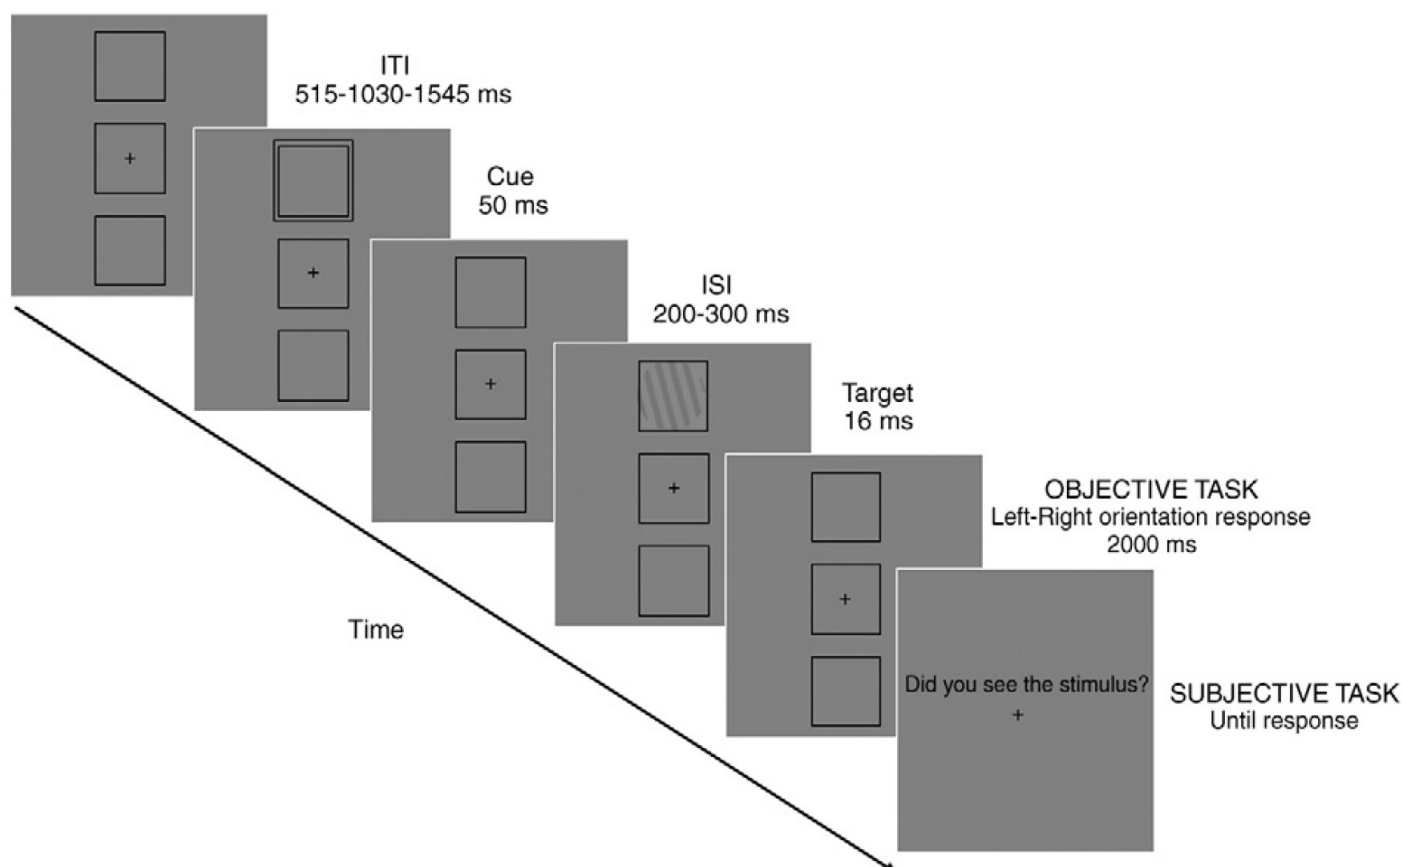

Figure 8: The sequence of events in (Chica et al. 2010) starting from the upper left. ITI = intertrial interval, ISI = interstimulus interval, in this case the period between the offset of the cue and the onset of the stimulus. Reprinted by permission of *NeuroImage*.

that parameter before they can answer the target question about orientation or side that something is on. This is more complex than any certified unconscious perception task that I know of. Further there is positive evidence, summarized in Stanislas Dehaene's recent book on consciousness (2014) that "[m]ulti-step calculations will always require a conscious effort" (p. 95).

What further can be said about whether the effect is conscious? I would be remiss if I did not mention that when you look at a good reproduction of the Carrasco stimuli (Figure 7) you can just see the effect for yourself. (Don't stare for more than a second or two though since adaptation will set in.) It can take a bit of practice to learn to do "covert attention", i.e., to move your attention without moving your eyes though. (In my 2010 paper I included a figure, Figure 2 on p. 32, one of whose purposes was to give the reader practice in covert attention.) Of course you have as much time as you

like to see the effect, whereas in the experiments described you have very little time. Still, what counts for the argument I am making is the effect itself, not its timing. A further difference between just seeing the effect for yourself and the experiments described is that they utilize different types of attention, endogenous for your personal demonstration and exogenous in the experiments described. Endogenous and exogenous attention have been shown to produce roughly comparable effects in Carrasco's experiments, though in some paradigms some exogenous attention is required for endogenous attention to be efficacious (Botta et al. 2014).

I think many people are convinced of the effect because they can just experience for themselves. Not everyone can though as with almost any visual phenomenon. Of course we all know the dangers of relying too heavily on introspective judgments since they are easily manipulated. There is a line of experimentation that addresses part of the issue.

Ana Chica and her colleagues (Chica et al. 2011; Chica et al. 2010) have done a series of experiments that directly address visibility.

The Chica et al. experiment (the 2010 version) presents subjects with tilted patches that are designed to be on the threshold of conscious perception and subjects were explicitly asked whether they saw the target (after making an orientation judgment). Subjects were strongly encouraged to be conservative in saying they saw the target. They were supposed to avoid “false alarms”, i.e., saying there was a target when there was no target, and they saw periodic messages indicating how well they had been doing in avoiding false alarms. In 25% of the trials there was no target.

First subjects saw a fixation point inside the middle of 3 boxes (pictured on the upper left side of Figure 8), then there was a brief cue consisting of a square around one of the boxes. Then the target—a patch oriented either to the right or the left—could appear for 16 ms (even briefer than in Carrasco’s experiments). Next, subjects had to indicate by pressing keys—within 2 seconds—which way the patch was oriented. They had to choose one of the keys whether they saw something or not, i.e., this was a “forced choice” experiment. Then they indicated whether they saw the target or not. The experimenters adopted a procedure—tailored to each subject’s perceptual abilities—to make sure the target was at the threshold of visibility—for that subject. They started each subject with a patch of sufficiently high contrast to see the stimulus. Every 16 trials they lowered the contrast until the subject was not detecting at least 25% of the patches (by the “Did you see the stimulus” test). If the percentage of avowedly seen patches went below 60%, they increased the contrast.

The main result was that the proportion of avowedly seen patches was much higher for “validly cued targets,” i.e., when the cue was on the box that had the patch than when the cue was invalid, i.e., on the box on the opposite side or neutral (when the cue was on the middle box where no target ever appeared). In addition, the reaction time for the cued patches was much shorter than for uncued patches. Chica et al.

also collected brain imaging data that suggested unsurprisingly that the valid cues attracted attention to the cued side, and more interestingly, that when the subjects saw the patch despite invalid cuing (i.e., the cue was on the opposite side), the cue had often failed to attract attention.

This experiment suggests that attention can affect whether a target is consciously visible or not. The subjects were not probed, however, on the issue of whether they actually made their judgments on the basis of the consciously visible tilt. However, when *subjects reported not seeing the target, they were at chance on reporting the tilt. And when subjects reported seeing the tilt, they were substantially above chance.* This is not the profile one sees in blindsight or in unconscious priming where subjects report not seeing the stimulus at all; but more significantly the tight relationship between consciously seeing the stimulus and being able to judge the tilt does suggest that they were reporting the tilt on the basis of the conscious perception.

Chica’s experiments are relevant to the consciousness of Carrasco’s stimuli in another way. Chica’s stimuli were presented very briefly: 16 ms in the experiment just described. Carrasco’s stimuli were presented for longer, up to 100 ms in some experiments. In addition, Chica’s contrasts were very low, as befits stimuli that were supposed to be at the threshold of visibility. The experiment described above does not report contrasts but in other papers with somewhat more complex experiments along the same lines (Botta et al. 2014; Chica et al. 2013), the contrasts required for 50% detection were about 3%; high detection seems to require up to 10% contrast. In Carrasco’s experiments, much higher contrasts are almost always used. I conclude that the reasons against the “blindsight” analogy in Chica’s experiments apply even more strongly to Carrasco’s methodology.

Given the high rates of conscious vision of 16 ms stimulus presentation even at lower contrasts than most of those used in Carrasco’s experiments, I will ignore the issue of brevity of stimulus presentations in the discussion to follow.

Keith Schneider (2011, 2006; Schneider & Komlos 2008) has argued that Carrasco's results are based on salience rather than perceptual variables such as perceived contrast, gap size, flicker rate, spatial frequency, etc. (Recently, Schneider and Jake Beck have written a draft of a paper on this topic. Rather than ascribe any specific view to a paper in draft, I will discuss the issue of salience—stimulated by their remarks—but from my own point of view.) I believe that the Carrasco lab is correct in their experimental and methodological disagreement with Schneider (Anton-Erxleben et al. 2010, 2011), however it would be digressive for me to discuss the issues involved in any detail here. I believe though that it is possible to get some insight without going into those issues.

A crude version of a salience objection treats salience as a “response bias” in the sense of a behavioral disposition to respond (in the basic Carrasco paradigm illustrated in Figure 7) by choosing the attended item. The idea is that when faced with a choice between gaps, the subject is disposed to choose not the gap that looks larger but rather the attended gap. This account is ruled out by a control in many of the Carrasco experiments of asking the subject to report the properties of the smaller gap or the patch that is lower in contrast. The attended side is still boosted in apparent contrast or gap size though the effect can be slightly smaller in magnitude so there is a small effect of “response bias” together with a main effect on perception. Carrasco also showed that choosing the lower contrast patch or smaller gap did not take any extra time, ruling out a version of the behavioral disposition objection that adds on an “inversion of response”.

A more sophisticated salience objection alleges a “decision bias” in the sense of a post-perceptual feature of the cognitive process involved in making a decision of how to respond. All such accounts that I know of are ruled out by the fact, mentioned above, that the effect is substantially perceptual in nature. In addition, Carrasco showed that the effect works for some properties but not others (Fuller & Carrasco 2006). As I have mentioned a number of times, it works for saturation but not hue. Both exper-

iments involved a procedure like that in Figure 6. In the saturation version, subjects were asked to report the tilt of the more “colorful” stimulus, where the stimuli differed in color saturation. In the hue version, subjects were asked to report the tilt of the “more bluish” stimulus, where stimuli differed along a blue/purple continuum. The result: there is an attentional effect on saturation but not hue. A cognitive decision bias should equally affect both saturation and hue. If the subjects are not aware of any difference in hue between the attended and unattended sides, it would seem that the “salience” perspective would say they would choose the attended side. But they don't. Another possibility is that the bias is perceptual in some way, say a matter of perceptual prediction (Hohwy 2013). In either case, the conclusion is that the effect is substantially perceptual and cannot be due simply to any kind of a cognitive decision bias toward choosing attended stimuli.

Whatever understanding of salience the salience objection appeals to, salience must be or be associated with a perceptual property, i.e., a property that is genuinely represented in vision. Some say (Prinz 2012) that the perceptual properties that are involved in vision are limited to a small set whose basic low level representations are products of sensory transduction: shape, spatial relations (including position and size), geometrical motion, texture, brightness, contrast and color. In other words, according to this “lean” theory of perceptual properties, though we speak loosely of seeing something as a face or as a case of causation, in reality seeing-as is limited to a small list of properties that are the output of peripheral sense organs. Others (Block 2014b; Siegel 2010) argue for a more expansive list of genuinely perceptual properties.

How do we know which properties are perceptual? We know that contrast, size, speed, spatial frequency (roughly stripe density), etc. are perceptual properties because they participate in perceptual phenomena, for example in perceptual adaptation and perceptual popout. I mentioned the waterfall illusion in which staring at a moving stimulus makes a stationary item seem to move in the opposite direction. And I'm

sure every reader is familiar with color afterimages. Adaptation is a ubiquitous perceptual phenomenon that can be used to show that size, speed, stripiness, etc. are perceptual properties. Note that I am not trying to *define* the notion of a perceptual property in terms of ...perception. The point rather is that perception is a natural kind and the perceptual nature of a representation is revealed in participating in phenomena in that kind (Block 2014b). By these tests, for example, there is evidence that certain face and facial emotion-related properties are perceptual. Viewers seeing an array of objects including one face can pick out the face very quickly on the basis of “parallel search”, just as they can pick out a red object in a sea of green objects. Similarly there are many adaptation effects for faces and facial expressions.

Is salience a perceptual property in this sense? Attention is important to both cognition and perception, but attention can be perceptual. In order to explain the effect of attention on increasing the duration and magnitude of the tilt after-effect (and the improvement followed by impairment in discrimination) as described earlier, the visual system would have to track or register attention or where or what one is attending to in addition to being affected by attention. As I will explain in the next section, there is an open question of whether the visual system does much by way of tracking attention.

In discussions of salience there is often a conflation between salience as a perceptual property and the genuine perceptual properties that are involved in attracting attention, like high contrast or speed or sudden changes in position. We commonly speak of a saliency map in the sense of the map of locations in the visible environmental layout in terms of whether they are likely to attract attention. The perceptual properties here do not involve salience itself but rather differences with nearby locations in visible feature dimensions (Itti & Koch 2000), for example in visible motion or appearance or disappearance. People also speak of a saliency map in the brain, meaning the increased activations that correspond to attended areas. If salience is supposed to be something other than attention itself, that is If Beck and Schneider are giving

an explanation that is a genuine alternative to Carrasco’s, they have to show that salience is the kind of perceptual property that is registered in the visual system and that can combine in an additive fashion with contrast to affect adaptation as in the tilt after-effect. I know of absolutely no evidence for such a thing.

Many sources of evidence contribute to our knowledge of the fact that attention increases apparent contrast. John Reynolds et al. have shown that attention boosts responses in individual neurons in monkeys (2000). They developed a model of the mechanisms of this and more complex effects involving multiple stimuli (Reynolds & Chelazzi 2004). Many brain-imaging studies have shown similar effects. See sections 4.6 and 4.7 of Carrasco (2011) where much of this work is summarized. At the behavioral level, attention increases sensitivity roughly as if contrast were increased and similarly, attention can mimic the effects of increased contrast on making a stimulus visible (as in the Chica experiment mentioned earlier). And as mentioned earlier, attention increases adaptational effects as if contrast were increased. Every result involving “salience” that I have seen is just a redescription of effects of the sort mentioned.

Here is a way of seeing the emptiness of appeals to salience: As mentioned earlier, at the neural level, there are two main types of response functions by which attention increases the firing rate of neurons, multiplicative and additive. I mentioned a recent paper that compares simulations of neural responses of these sorts to behavioral data in order to ascertain which of the types of amplification are mainly being used by the visual system. Though the multiplicative models work pretty well, one additive model works very well. Thus we have strong evidence for the functional relation between attention and the increase in contrast responses in the visual system. For simplicity, let us focus on the multiplicative mechanisms: In multiplicative gain, the response of the neuron is multiplied by a constant factor. For example, a neuron that responds to orientation will give a large response to its preferred orientation and a smaller response to other orienta-

tions to the extent that they are distant from the preferred orientation. (For example, a neuron that likes vertical lines will give a large response to vertical lines.) Since multiplying a larger number by a constant produces a larger effect, multiplicative gain is most effective for the preferred orientation. A second multiplicative response function is response gain in which the sensitivity of the neuron is multiplied by a constant factor. The effect is one of ratcheting up the response to stimuli of every orientation. The widely accepted normalization model of attention (Reynolds & Heeger 2009) explains the balance of these two mechanisms (and of additive gain) in terms of factors such as the relative size of the target and the attentional field. The attentional function of a given neuron can show more multiplicative gain or more response gain or more additive gain depending on these factors. Here is my point. We can answer the question of what the difference between these response functions is with respect to increasing apparent contrast. For example, multiplicative gain increases the apparent contrast more for the preferred orientation and response gain increases apparent contrast more for unpreferred orientations. What is the answer to the corresponding question for salience? Does multiplicative gain increase salience more for preferred or unpreferred orientations? Is it the same as for contrast? If so, then maybe “salience” is being used as a synonym for contrast. A different answer would be: multiplicative gain and response gain are equally mechanisms of salience. In this latter case it looks as if “salience” is just being used to mean attention. To repeat the general point: Those who advocate a “salience” explanation of the phenomena have to show that there is a property that is (1) perceptual, (2) not contrast and (3) acts in the ways indicated above.

Sometimes the issue is put in terms of “phenomenal salience” (Wu 2014). I think this way of talking just muddies the waters. Perceptual properties can operate in both conscious and unconscious perception. (At least: it would be an amazing discovery that there is a perceptual property that only appears at the conscious level.) Attention—at least exogenous attention—operates in unconscious perception in a sim-

ilar manner to conscious perception (Chica et al. 2011; Kentridge et al. 2008; Norman et al. 2013). Further, it has recently been discovered using optogenetic methods that top-down activation of visual area V1 is about the same in awake and anesthetized mice (Zhang et al. 2014). This top-down activation involved feedback from a brain area in the mouse that corresponds to a locus of voluntary attention in humans. If salience is a perceptual property, it should be operative in unconscious perception. So the salience issue is an issue about perception, not about just conscious perception.

The upshot is that it is not at all clear how a salience objection would work, so the burden is on those who advocate it to explain it. I raised the issue of whether we are aware of where we are attending in connection with whether we are aware of salience, so I now turn briefly to that question.

7 Are we aware of where we are and are not attending?

There are a number of ways of approaching this issue, none of them very satisfying. We are certainly aware of some aspects of voluntary attention—when we “pay attention” to one thing rather than another (“endogenous attention”). But much of attention is involuntary (“exogenous”). Any perceptibly sudden movement, appearance or disappearance or sound will be likely to attract exogenous attention. Subjects in perceptual experiments can try to ignore sudden movements and sounds but they attract exogenous attention nonetheless. Exogenous attention ramps up more quickly (120 ms vs 300 ms) and dies off more quickly. Eye movements can also be voluntary or involuntary. Awareness of where the eyes are pointing is a rough index of awareness of attention. There is some evidence that people are not very aware of the time and direction of their “saccades”, the quick ballistic eye movements that occur when we are visually exploring our environment. Heiner Deubel et al. showed that subjects seem to “have no explicit knowledge about their...eye position” and often don’t “notice the occurrence of even large saccadic eye movements” (1999, p. 68).

However, this is not conclusive evidence that they don't know where they are attending since they may confuse movement of attention with movements of the eyes. And the visual system could track attention even if subjects are not aware of where they are attending.

Perhaps more illumination can be achieved from work on the “landscape of attention” (Datta & DeYoe 2009). Brain imaging shows a complex rapidly shifting map of spatial attention in the visual system. Spatial attention can be “focused” at one location even though there is almost as much attention at a number of other locations and some attention throughout half the visual field. The attentional field often has a “Mexican hat” shape with amplification at the center surrounded by a ring of inhibition and then an increase outside that ring. Certainly no one is aware of all that dynamic detail though I have been unable to find any specific study addressing the issue. I think it is safe to say that in normal perception there is no phenomenology that specifies much of the detail of where one is and is not attending—nor how much one is attending. So any attempt to explain Carrasco's results that appeals to our awareness of where we are attending takes on the burden of showing that we do have sufficiently fine-grained awareness of where we are attending.

8 Veridicality and representationism

In Carrasco's experiments, an attended $.20^\circ$ gap is not discriminated from an “unattended” $.23^\circ$ gap. I think the best conclusion is that attention changes perceived size and contrast. (Recall that I am talking about spatial attention rather than attention to a property instance or an object.) Do the gaps just fail to look different or do they look the same?

In Carrasco's main paradigm, subjects are forced to choose which stimulus is bigger (or faster or higher in contrast). In the case of an attended $.20^\circ$ gap as compared with an “unattended” $.23^\circ$ gap, subjects are as likely to choose one option as the other. In this sense these options are not discriminable. However, I mentioned that when subjects are asked instead

whether the items are the same or different, the effect of attention is slightly smaller. And that may suggest that there is substantive daylight between not looking different and looking the same. (Of course this difference matters very much in some contexts, for example, as mentioned earlier, the context of the phenomenal Sorites issue; Morrison 2013.) As I mentioned earlier; Anton-Erxleben et al. and her colleagues argue persuasively that the smaller effect is due to the same/different paradigm being a less sensitive measure (2011). In what follows I will assume that the attended $.20^\circ$ gap looks the same in respect of size as the “unattended” $.23^\circ$ gap.

I put the “unattended” in quotes because I mean no commitment to the improbable claim that there is no attention on the $.23^\circ$ gap. There is no agreement on whether there can be conscious perception or even unconscious perception with zero spatial attention or whether zero spatial attention is even possible.¹² Indeterminacy in our concept of attention may even make this an unanswerable question. Still, I will adopt the abbreviatory convention of referring to stimuli that are not focally attended as “unattended”.

Since the apparent size of the gap differs depending on where one is attending, the question arises as to which of these various percepts of the gap gets its size right (or most nearly right) and which gets its size wrong (or most nearly wrong). Veridicality is a matter of getting things right and veridicality in perception is a matter of the world being as it appears to be. There would be no good reason to decide that the veridical percept of the gap is one in which one is attending to a spot one inch away from it; why pick one inch rather than one centimeter? (Recall that the attentional landscape of amplification and inhibition varies from place to place and from moment to moment.) The most obvious candidate for a non-arbitrary answer to the question is: the veridical percept of the gap (if there is any veridical percept) is the one in which one is attending to the gap itself.

¹² Spatial attention does not require feature-based attention or attention to an object. See Wayne Wu's book on some of these issues (2014).

I think of veridicality as all or none, but for the sake of accommodating different opinions I can countenance degrees of veridicality. One innocuous use of such a phrase is that if one represents a $.19^\circ$ gap as $.20^\circ$, the percept is more veridical than if one represents it as $.21^\circ$. Also we could say that other things equal, a percept that attributes a higher probability of being $.21^\circ$ to a $.21^\circ$ gap is more veridical.

But once it is stated that the most veridical percept of the gap is one in which one is attending to the gap, one wonders why one should believe this hypothesis rather than the *opposite* hypothesis that attention distorts by magnifying, illusorily, for the purpose of getting information and that the attended item is seen illusorily. Is the perception of the gap with less attention really illusory in the sense of a discrepancy between stimulus and perception?

In an article on Carrasco's discovery, [Stefan Treue \(2004, p. 436\)](#) says this:

In summary, this study provides convincing support for an attentional enhancement of stimulus appearance. It completes a triangle of converging evidence from electrophysiology, functional brain imaging and now psychophysical findings, which argues that attention not only enhances the processing of attended sensory information but manipulates its very appearance. ...attention turns out to be another tool at the visual system's disposal to provide an organism with an optimized representation of the sensory input that emphasizes relevant details, *even at the expense of a faithful representation of the sensory input.* (italics added)¹³

I quote Treue not because I agree with him but in order to get a statement of that view on the table. There is no sufficient reason to accept the view that an attended perception of a gap allows us to see it as it really is rather than the view that attention in perception is like a magnifying glass, distorting for informational pur-

poses at the cost of illusion. I can imagine considerations that might incline one towards adopting one or the other of these positions—that attention falsifies or that attention “veridicalizes”—but the adoption would be for purposes of one or another kind of utility, *not as a principled reason to think that the highest degree of veridicality is really to be found in that case.*

The challenge is to find a principled reason for regarding seeing a thing or place with a certain degree of attention to be more veridical than seeing it with a different degree of attention. Sufficiently decreasing attention to something can move the perception below the threshold of visibility. But not seeing something that is too small to see or to faint to see need not be a matter of illusion.

Chris Hill (in conversation) and [Sebastian Watzl \(forthcoming\)](#) have argued that there is an optimal level of attention and perception with all other values engender illusion. Watzl's version of this view appeals to the idea that the function of attention is to make perceptual representations usable—as opposed to the function of perception of veridically representing the world. These functions will conflict in normal circumstances. The optimal level of attention for fulfilling the function of perception—veridicality—will be achieved in an idealized scenario of no attention, or one of equal attention to everything. This is an interesting point of view, but is contradicted by the point made earlier that veridicality conditions require a history of veridical representation.

Epistemicists about vagueness think that there can be an unknowable fact of the matter as to a sharp border between bald and not bald, a number of hairs that a bald man can have even though adding a single hair will make the man not bald. But if there can be a fact about a border even though there could be no principled reason to regard any particular border as the real one, why can't there be a fact about what degree of attention engenders veridicality that no one could have a principled reason to accept? Epistemicists should not regard the cases as analogous since they think there is a principled reason to hold there is a fact about a border and a principled

¹³ Carrasco ([Carrasco et al. 2008, p. 1162](#)) has been interpreted as agreeing with Treue by [Stazicker \(2011a\)](#) and [Watzl \(forthcoming\)](#). Carrasco tells me she did not mean to endorse the Treue view.

explanation for our ignorance (Sorenson 2013).

It may be objected that there is good reason to accept Treue's point of view since after all, attention to the .20° gap makes it look, illusorily, to be the same size as the unattended .23° gap. But why not blame the illusion on the percept of the unattended gap rather than the attended gap? One can blame the mismatch, but that does not help in deciding whether attention to an individual item engenders veridicality or illusion. I think the issues are clearer when one avoids the comparative perception and just asks, say of the situation in Figure 5, whether perception of the gap can be veridical when it is cued and one is attending to it or when it is not cued and one is attending elsewhere. There is no adequate justification for one answer over the other. Some may wish to abandon the notion of veridicality as applied to perception but that would be to abandon the notion of representational content as applied to perception and so to abandon representationism. The representational content of a perception is—constitutively—the veridicality conditions. There is a strong a priori case for perceptual representation (Siegel 2010). And in any case the science of perception makes essential use of veridicality (Burge 2010).

In the discussion of the analogous issue with regard to inhomogeneities in the visual field, I noted that the sort of differences in perception caused by spatial inhomogeneities are paralleled by differences due to temporal inhomogeneities—that is variation from percept to percept due to random factors. Any two percepts of the same items at the same point in the visual field with the same degree of attention are likely to differ in apparent contrast (and other properties) due to these random factors. It is hard to see a rationale for treating spatial inhomogeneities differently from temporal inhomogeneities and it is hard to see a rationale for treating either of them differently from the inhomogeneities due to distribution of attention. Claiming that all engender illusion would make most perception illusory.

We are considering the question of whether the veridical percept of the gap is the

attended one or the unattended one. But is there a well formed question here? Is it endogenous attention that counts? Or exogenous attention? We are talking about spatial attention but what if feature-based or object based attention goes counter to spatial attention? That is, one can be attending to a place but also to a property that is instantiated in another place. And is it the absolute or relative value of spatial attention that matters? That is, is it some absolute attentional value or is it the most attended place that is seen veridically? Talking on a fake cell phone drains away spatial attention, causing the subjects to miss seeing objects in the centers of their visual fields (Scholl et al. 2003). (Scholl et al. used a fake cell phone to avoid the unnecessary source of variability of features of the responses from the other end of the line.) If it is absolute value that counts then when talking on a fake cell phone (and presumably a real one too), all vision would be illusory. That is a conclusion that we would have to have some very good reason to accept.¹⁴

One caution: I am speaking oversimply in a number of respects in asking whether attention engenders veridicality or illusion. I mentioned the issue of whether veridicality is graded. And there is an independent issue of relativity to what property one is talking about. In the experiment pictured in Figure 5,

¹⁴ It may be thought that the issue of which percept is veridical is avoided by forms of direct realism that hold that there are no perceptual illusions. For example, Bill Brewer holds that in the Müller-Lyer illusion (so called) in which lines of the same length look to be of different lengths, what one is seeing is a resemblance between the situation in front of one's eyes and what he calls a paradigm of different lengths. The idea is that that is what equal lines look like when surrounded by opposite-facing arrowheads. And the way equal lines look in that circumstance is like pairs of unequal lines one has seen. On this form of direct realism, the "illusion" to the extent that one can speak of such a thing is in the mistaken inference that the lines in front of one's eyes are of different lengths. They resemble pairs of lines of unequal lines but one should not conclude that they are unequal.

However, Brewer requires differentiating between cases in which one sees a property instantiated before one's eyes that is not a resemblance to something unseen and the cases in which one sees a resemblance. In effect, the cases in which one sees a resemblance to something unseen is a pseudo-illusion category that he has to recognize. So the question arises of whether this pseudo-illusion arises in the case of attention or in the case of the lack of it. That is, is one seeing a resemblance to a non-existent thing when one attends or when one does not attend? And this is an unanswerable question for the reasons explored in this section.

the attended percept is certainly more likely to be veridical in respect of which side of the square the gap is on. And in the experiment pictured in Figure 6, the comparative percept—that is, the percept of the comparative size between the right and the left is distorted by attention to one side and improved by attention to the fixation point. So veridicality is certainly affected by attention—though in different ways for different properties. The question I am asking about gap size is whether a single gap is perceived more—or on the contrary, less—veridically if it is attended. More generally, there are certain properties—I have mentioned size, contrast, color saturation and others—for which attention to an individual item changes appearance of that property. Which is more veridical, the pre-change or post-change appearance?

One might think that there is a simple way to get at the issue of whether attention magnifies, illusorily, for the purposes of getting information, or whether attention makes things look more as they really are. You could just ask people how contrasty a patch is or how big a gap is and then consider whether those answers correspond better to reality when perception is attentive or inattentive. But the human ability to make such absolute judgments for at least some relevant dimensions is remarkably poor, certainly orders of magnitude worse than our ability to discriminate stimuli (Chirimuuta & Tolhurst 2005a). In particular, the uncertainty of absolute identification (absolute in the sense of the ability to say what the contrast is in percentage terms) is far larger than the effects of attention. Even if there were some sort of statistical advantage or disadvantage to conditions of attention in estimating contrast or gap size one would have to ask whether the advantage could be ascribed to better perception or to better inference from a percept that did not differ in veridicality.

I will assume in what follows that attended and unattended perception can both be veridical. Considerations of the same sort mentioned here also apply to the veridicality of perception in both the upper and lower visual field.

9 Indeterminate contents and the phenomenal precision principle

As I mentioned, an attended $.20^\circ$ gap looks the same size as an unattended $.23^\circ$ gap. Of course the comparative percept—the gaps looking the same—is illusory. But what about the percepts of each gap, considered separately? Is the percept of the attended $.20^\circ$ gap illusory? Is the percept of the unattended $.23^\circ$ gap illusory? I argued that we would need a better reason than we have to suppose that one but not the other is illusory. And I claimed that we should not suppose that both are illusory. The option I have argued for is that both are (or rather can be in normal circumstances) veridical. As I mentioned, the simplest perceptual representations contain two elements, a singular element that represents an individual item and a perceptual “attributive” in Burge’s terminology that attributes a property to that individual item (2010). In the gap-size case, the perceptual attributive attributes sizes to gaps. A veridical percept attributes a size to a gap only if the gap has that size. In order for the attributed property to apply to both gaps, that property will have to be “intervalic”, i.e., a somewhat imprecise property—for example, the property of being within the range of $.20^\circ$ to $.23^\circ$ (inclusive of endpoints). Since both gaps are in that range, both percepts are veridical (in respect of gap size).

Perhaps a probabilistic treatment of these ranges of values is in order? But how can one justify one probability distribution rather than another without making assumptions about whether the attended gap is seen more veridically than the unattended gap? For example, to say that the unattended percept of the $.nn^\circ$ gap represents the gap as most likely to be $.nn^\circ$, whereas the attended percept represents the same gap as most likely to have some other value is to regard the unattended percept as more veridical than the attended percept. A probabilistic treatment would perhaps pass the sufficient reason test though if the same probability were attributed to both ends of the range.

It will be useful to move back to the example of contrast. The data portrayed in Figure

7 comes from the bottom right of Figure 9. Figure 9 contains four comparisons, each of which is keyed to one of the four little squares between the patches. If one fixates on one of the squares, the patch to the left of the square attended is the same in apparent contrast as the patch on the right unattended. The 22% patch can be unattended—in which case it has the same apparent contrast as the 16% patch when it is attended, or the 22% patch can be attended in which case it has the same apparent contrast as the 28% patch when it is unattended. So different veridical percepts of the 22% patch could represent it as the same as patches that are 6% more or 6% less in contrast.

Consider the contrast phenomenology of an attended percept of the 22% patch. That phenomenology is the same as the phenomenology of a 28% patch unattended. Assuming that there is not normally a phenomenology that specifies what one is and is not attending to, a matter discussed above in section 7—the phenomenology of a 22% patch attended does not carry the information of whether it is the phenomenology of a percept of a 22% patch or of a 28% patch. So in order for both percepts with that phenomenology to be veridical, the representational content would have to be at a minimum 22%-28% (inclusive of 22% and 28%).

However, there is a determinate difference in phenomenology between percepts of the 22% patch and the 28% patch when serially fixated and attended as you can verify by looking at Figure 9. (There are larger differences of this sort to be described later and as I mentioned in section 3, inhomogeneities in the visual field produce larger differences of this sort.) I believe that this determinate difference is appreciable if one moves one's attention while fixating the little square but the difference is even more obvious if one moves fixation as well as attention.

The 22% and 28% patches look determinately different if one is attending to and foveating (looking right at) each in turn. So if representationism is true, there can be veridical representational contents of 22%-28% only if the phenomenal precision of the percepts of the patches seen attended and foveated is narrower than the phenomenal precision of at least one of

the percepts seen in the periphery with only one attended. This is a version of what I called the phenomenal precision principle in section 2. If two things look the same (veridically) when seen in peripheral vision with at least one unattended, but the same two things look determinately different—also veridically—when seen foveally and attentively, then the phenomenal precision of the attended and foveal percepts must be narrower than at least one of the prior percepts. And we can guess that it is the unattended prior percept that has to be less precise.

Recall that perceptual representations that are imprecise in that they attribute ranges can still be fine-grained. Suppose for example that a percept attributes a broad range of sizes to a gap of $.10^{\circ}$ – $.50^{\circ}$. That is a different representational content from $.11^{\circ}$ – $.51^{\circ}$, and that is different from $.12^{\circ}$ – $.52^{\circ}$. So our ability to see small differences can be based on absolute representation even if perception is imprecise. But if the representational contents of the foveal percepts almost totally overlap, as with $.11^{\circ}$ – $.51^{\circ}$ $.12^{\circ}$ – $.52^{\circ}$, how could those representational contents ground the determinately different phenomenologies?

Consider an analog for inattentive peripheral perception of color in which there is a red patch on one side and a blue patch on the other and the subject fixates in the middle. Suppose—and as far as I know this is science fiction—that there is some distribution of attention such that the two patches seen briefly and inattentively in the periphery can look the same and look red-blue and have the representational content red-blue. I don't mean reddish blue. I mean indeterminate as between central red and central blue or in between. They could be red, they could be blue, or they could be in between. Since attentive foveated percepts of red and blue in normal conditions are determinately different from one another (and from other colors) in phenomenology, the representational contents of red and blue seen foveated, attentively (and leisurely), would have to be more precise than the supposed contents seen peripherally, inattentively (and briefly). Otherwise there would be increasing precision in phenomenology without increasing precision in representational

content and representationism cannot allow that.

In short, representationism requires that inattentive peripheral perception be less precise representationally than attentive and foveal perception.

Now here is the striking fact: there is evidence that peripheral inattentive perception of many properties is not less representationally precise than foveal attentive perception. This conclusion conflicts with the application of the phenomenal precision principle to the cases at hand. I have already discussed the peripheral vs foveal aspect of this point and I will go over some of the evidence for the attentional component in section 11 below.

I will explain the argument just sketched in more detail. But first I must discuss a piece of the puzzle, the notion of a just noticeable difference.

Figure 9: If one maintains fixation on one of the 4 little squares while varying attention to the patches on either side of the square, the patch to the left of the square seen with attention has the same appearance as the patch to the right without attention. I am grateful to Marisa Carrasco for this figure.

10 Just noticeable differences

A ubiquitous feature of perception is that perceptual discrimination is more fine-grained than perceptual identification. Even those with absolute pitch can identify perhaps 100 pitches (depending on exactly how absolute pitch is defined), but can discriminate many thousands of pitches from one another (Raffman 1995). Those who have absolute pitch are no better

than other musically literate people in pitch discrimination (Levitin 2005, 2008). Given the disparity between identification and discrimination one might wonder whether our ability to make fine grained perceptual discriminations misleads us as to the precision of our perceptual representations. It certainly seems to us that each of those thousands of pitches has a distinct phenomenology but maybe that judgment feeds more off of the phenomenology of discrimination of differences than off of the phenomenology of individual pitches.

I have argued that the phenomenology of perception does not allow for a large degree of imprecision.¹⁵ I appealed to the “just noticeable difference” of contrast of 2%. I said:

The representationist may retort that the point is not that the contents are fuzzy or represented indeterminately but that they are abstract relative to other contents, as determinables are to determinates, for example as red is to scarlet. But this line of thought runs into the following difficulty: the variation of 6% due to attention is way above the ‘just noticeable difference’ threshold, which for stimuli at these levels is approximately 2%. (Or so I am told. In any case, just looking at the stimuli in Figure 4 [Figure 9 here] shows that the difference is easily detectable. And you may recall that in the discussion of the tilt aftereffect, there was evidence that at higher levels of contrast, the increase due to attention was as much as 14%.) The point is that there is no single ‘look’ that something has if it is 22% plus or minus 6% in contrast. By analogy, consider the supposition that something looks as follows: rectangular or triangular or circular. That disjunctive predicate does not describe *one* way that something can look—at least not in normal perceptual circumstances (Block 2010, p. 52).

Jeremy Goodman (2013) has criticized my reasoning. He says:

¹⁵ In Block (2010). Actually, I spoke of “indeterminacy” and—mistakenly—of “vagueness” of perception.

Ned Block, when considering the hypothesis that perceptual appearances are ‘abstract relative to other contents, as determinables are to determinates, for example as red is to scarlet’, objects that ‘the variation of 6% due to attention is way above the “just noticeable difference” threshold, which for stimuli at these levels is approximately 2%’ (p. 35).

Goodman goes on to speak of “Block’s objection that our discrimination thresholds place an upper bound on the unspecificity of perceptual appearances...” (2013, p. 35). Although it may have sounded that way, I did not intend to claim that discrimination places an upper bound on either representational or phenomenal imprecision. But I think that a certain kind of discrimination is relevant to both imprecisions as I will explain.

An ability to discriminate between two observable magnitudes does not prove that one’s percepts of the magnitudes actually differ (in either representational content or phenomenology). One example that I have used to illustrate this point (Block 2007, p. 540) is the phenomenon of “beats” (alternating soft and loud sounds) caused by interference between guitar strings of very slightly different pitches even when the two pitches are phenomenally the same on their own. (The frequency of beats in response to two pure pitches is the difference in frequencies.) Another is the color border effects that allow one to see that two colors are different even when the colors themselves would not be distinguishable if separated slightly. Even for achromatic objects, slight differences are amplified by a well known border phenomenon that is responsible for the famous “Mach Bands” illusion. Goodman uses the example of two trees that look to have slightly different heights because of how far they stick up above the tree canopy. His point is that vision might represent overlapping but slightly different intervallic values, but one could also use the example to illustrate heights that don’t look at all different when seen separately while nonetheless allowing one to see a difference when seen next to one another.

It is intuitive to think that the way the visual system detects differences between one thing and another is by registering the properties of each thing separately and comparing those registrations. But this is not always the case: Differences are often detected via different processes than the processes that register the entities or properties that differ. Beats are produced by interference between two sound waves, allowing one to detect differences between sounds that would otherwise be inaudible.

As the examples just given illustrate, discrimination may be possible without any difference in the phenomenology of the individual percepts. Two pitches can be indiscriminable even if one knows they differ because of beats. However, there is no reason to think that specialized discrimination mechanisms are at work in the experiments described. Specialized discrimination mechanisms can be expected to depend on the specific features of the perceptual situations and so not robust to changes in the situation of the perception. For example, if you change your angle of view you might see the full vertical length of the trees but not their differential protrusion above the canopy. Border contrast effects are fragile—move the color samples just a bit apart and the effect vanishes. (This is nicely illustrated in the Wikipedia entry for “Mach Bands”.) However, the attentional effects I have been talking about apply to color, speed, size of a moving object, spatial frequency (stripe density), time of occurrence, flicker rate, motion coherence (the extent to which many moving items are going in the same direction), as well as to contrast and gap size. What is the chance that there is some specialized discrimination method at work for all these magnitudes? Most impressively, these effects can be exhibited in visual short term *memory*—that is, they don’t even require simultaneous perception. This was shown by Martin Rolfs & Marisa Carrasco using a different experimental paradigm than the ones so far discussed (2012; Rolfs et al. 2013). I won’t describe it except to say that the patches are compared in respect of contrast by comparing a patch seen earlier with a currently seen patch, and with similar results to those already described. As I mentioned in section 3,

a similar experiment shows that a perceived patch at one location in the visual field can be compared with a remembered patch at a different location with results that show the inhomogeneities in the visual field (Montaser-Kouhsari & Carrasco 2009). The likelihood that there is some method of comparison that does not depend on the individual percepts themselves but survives all these variations does seem slight.

So the kind of discrimination that is not based on specialized mechanisms of detecting differences independently of registering absolute value can be used to make a better case.

But even if we can make very fine grained discriminations and even if the percepts involved in the discriminations are distinct, it does not follow that the percepts are not highly imprecise—as mentioned earlier. Suppose for example, that perceptions of contrast are so imprecise as to cover nearly all the range of contrasts. Consider a representation of contrast of 4%-98%. Still, 4.1%-98.1% would be another equally imprecise content that is nonetheless distinct from the first one. And so more generally discriminability has little in the way of immediate consequences for imprecision.

The notion of a just noticeable difference is not very useful for my purposes. Discrimination can be finer than absolute registration as in the case of beats. And strong ability to discriminate is compatible with a high degree of imprecision. Further, the notion of a just noticeable difference combining as it does, perception with cognition, allows the possibility of a difference in conscious percepts that is not cognitively accessible.

11 Absolute representation

The phenomenal precision principle tells us that if the phenomenology of perception is grounded in its representational content, then peripheral unattended perception must be more imprecise than foveal attended perception. This result applies to contrast, size, spatial frequency and some other properties but not location. However, experimental results to be described in the next section suggest that contrast perception is as precise in foveal attended perception as in

peripheral unattended perception. But what this evidence does not tell us is how precise they both are, i.e., whether both are relatively precise or relatively imprecise.

I mentioned a study by Mazviita Chirimuuta & David Tolhurst (2005a) that is relevant to the issue of how precise absolute representations of contrast are in foveal attended perception. Chirimuuta and Tolhurst have a behavioral result that shows that performance in classifying contrasts falls off sharply after 4 contrasts. They have a neural model of contrast identification that suggests that the brain is capable of representing only 4-5 contrasts and that this limit is compatible with very fine-grained discriminations. Chirimuuta's view is that the response probabilities in the visual system for contrasts are very broad, with the tails of every distribution covering much of the span of possible contrasts. (That is, there is a non-zero probability across almost the whole range of contrasts.) Contrasts can only be identified when the response is near the peak of the probability distribution but two responses can be compared when responses are in the tails so long as the tails do not overlap much.

I'll start with the behavioral result. She presented subjects with a number of patches of up to 8 grades of contrast that were labeled "1" through "8" in each sequence of trials. Subjects looked at the contrasts and labels for as long as they liked and could have a refresher any time in the midst of the experiment if they liked. They had to hold the pairs of digits and contrasts in working memory and assign numbers to contrast stimuli. Then, patches were presented for half a second and subjects had to try to give the digit label. Performance was good up to 4 items and fell off drastically for larger sets.

Performance on 4 contrasts was near perfect. Then when new contrasts outside the original range were added, performance fell off, even for the original 4 contrasts. This is a pattern often seen in working memory experiments. For example, wild monkeys participated in an experiment in which an experimenter sets up two buckets and ostentatiously places, one at a time, a number of pieces of apple in each bucket. For example, there might be 4 in one

bucket and 3 in the other. The result is that for numbers of slices of 4 or less, monkeys reliably go to the bucket with more but with more than 4 items, performance falls off to chance (Barner et al. 2008; Hauser et al. 2000). Human infants show similar results with a limit closer to 3 (Feigenson et al. 2002).

The number 4 figures in working memory experiments in which subjects are asked to remember digits but are given another simultaneous distraction task to prevent overt strategies of “chunking” digits into units. Subjects can typically remember about 4 digits. In a completely different paradigm, George Sperling showed subjects a grid of letters briefly (1960). Subjects often said they could continue to see all or almost all the items faintly after the patch disappeared. (This kind of image has been called a visual “icon”.) When the grid had 3 rows of 4 items, and subjects were asked to recite as many letters as they could, they could name 3-4 letters. However Sperling gave subjects a cuing system: a high tone for the top row, a medium tone for the middle row and a low tone for the bottom row. When cued, subjects could report 3-4 from any given row.

In a different paradigm, honeybees were trained on a maze in which they had to choose to go either left or right at a T-junction to get a reward. At the entrance of the maze there were dots on each side and the bees had to choose the side with more dots to get the reward. The bees could learn to choose 4 rather than 3 but not 5 rather than 4 (Gross et al. 2009).

The working memory significance of roughly 4 items is so ubiquitous that it stimulated an article called “The magical number 4 in short-term memory: A reconsideration of mental storage capacity” (Cowan 2001). Up until 5-10 years ago, “slot” models of working memory were popular. I think it would now be agreed that roughly slot-like behavior emerges from an underlying working memory system in which there is a pool of resources that is distributed over items differently depending on number and complexity (Ma 2014). George Alvarez & Patrick Cavanagh (2004) suggested that there might be a limit of around 5 items of ideally simple structure but Alvarez’s recent work sug-

gests a more complex picture in which there are a variety of components of working memory that may independently fit a more slot-like or a more pool-like structure (Suchow et al. 2014). Slot-like working memory depends on simple stimuli that are hard to confuse with one another. Stimuli that have shown slot-like behavior include alphanumeric characters, horizontal/vertical rectangles and colors that differ substantially from one another. (I am indebted to conversations with Weiji Ma on this topic.)

So I would suggest that Chirimuuta’s behavioral result probably depends on the fact that subjects had to hold a number of pairs of digits and contrasts in mind in order to categorize the next contrast. (You could try it yourself for say 5 lengths.) They did well up to 4 such pairs and then performance declined radically. The article contains an anecdote that further supports this idea:

DJT [one of the subjects and experimenters] performed an experiment in which 4 contrasts of grating were chosen that were close together whilst still allowing near-perfect identification performance over 50 trials of each: 1, 8, 18 and 27 dB. [Note from NB: this is a different way of quantifying contrast than the percentages used here.] In the 50 trials of each contrast, 1 error of identification was made for each of the 8 and 18 dB gratings. Then, two more contrasts were added to the stimulus set at the lower end (40 and 50 dB); contrast 40 dB should have been easily discriminable from 27 dB. In fact, addition of contrasts 40 and 50 dB resulted in an increase in the errors of identification of the original set of four contrasts over 50 trials of each (8dB – 2 errors; 18dB – 9 errors; 27dB – 6 errors). (Chirimuuta & Tolhurst 2005a, p. 2965)

There are two notable aspects of this anecdote: first, performance over 50 trials of each of 4 contrasts were near perfect despite the fact that the gratings covered only part of the spectrum of contrasts. This suggests that the limit of 4 does not have to do with representations of con-

trast per se. The second aspect is that in this case as in so much of the work on working memory, adding more possibilities to a set of 4 decreases performance in the original set of 4. I conclude that the behavioral result probably has more to do with working memory than with any limit on perception.

Chirimuuta's second result, the one that motivates the idea that visual representations of contrast are so indeterminate that only 4-5 levels of identification are possible, is the modeling result based partly on data from monkey V1 neurons. (V1 is the first cortical area that processes vision, the lowest level of the visual system.) The striking fact about this result is that it does not concern working memory at all or indeed any kind of memory. It is only concerned with perceptual representation in V1. The model of V1 neurons comes from another paper that is concerned with the "dipper function", a notable curve shape in which one contrast stimulus is "masked"—diminished by the processing of another stimulus that follows right after it (Chirimuuta & Tolhurst 2005b). The model predicts that V1 can represent 4 contrasts perfectly with a sharp fall-off at 4, with a capacity to represent slightly more than 5 items.

However, the model based on V1 neurons gets some important facts wrong, for example it predicts poorer performance at high and low contrasts, whereas people actually do better at high and low contrasts. A version of the model with some postulated features that are not based on anything neural can get that right. However, this "curve fitting" approach deprives the model of the neurophysiological support that motivated the original model. Another problem with the model is that what is predicted is "mutual information" shared between contrast stimuli and V1 responses of 2.35 bits. Mutual information is a measure of shared information—in this case between stimuli and V1 neurons. A mutual information value of 2 bits would allow 2^2 (=4) contrast identifications; a mutual information value of 3 bits would allow 2^3 (=8) identifications. This shared information, as Chirimuuta notes (Chirimuuta & Tolhurst 2005a, p. 2968), is "essentially looking at per-

fect, 100% performance." For this reason, mutual information is not very useful as a psychophysical measure. And as Chirimuuta notes, its utility is limited for another reason: it is a compressive measure and so large increases in neural activity can be expected to make small differences in information. The issue of 100% performance is especially troublesome since in perceptual systems no performance can be perfect. In particular the convention for a "just noticeable difference" is distinguishability 75% of the time. So it is difficult to know how to compare the absolute identification level of 2.35 bits with a more visually sensible visual identification level.

Further, our experience seems to conflict with the idea that we have distinct visual representations of only 4-5 contrasts. A good reproduction of Figure 8 seems to reveal 6 phenomenologically different contrasts even though the figure covers only a third of the range of contrasts. And the Carrasco results apply to many different parameters, gap size, spatial frequency, etc. You might test it out if you happen to be near a brick wall. Look at the height of one brick, two bricks, three bricks and four bricks. If you are close enough so that those sizes look different from one another, ask yourself whether there are other sizes that look different from all four of those sizes. If Chirimuuta's result applies more widely, the answer is no. It has to be said though that that sense of distinctness could be due to discriminatory abilities.

Whatever the facts are about how precise foveal attentive perception is, the next section presents evidence that it is not more precise than inattentive peripheral perception.

12 Attention may not increase representational precision

I said that if 2 things look the same when seen in peripheral vision with at least one unattended, but the same two things look determinately different when seen foveally and attentively, then the phenomenal precision of the attended and foveal percepts must be greater than at least one of the prior percepts. (As I

mentioned, the assumption of veridicality is required to justify the imprecise representational contents of the peripheral percepts.)

It is common for philosophers to claim that attention increases “determinacy” of perception (Boone 2013; Nanay 2010; Stazicker 2011a, 2011b, 2013; but not Speaks 2010). The relevant kind of determinacy as I have been saying is precision. But it will be useful to distinguish precision from other forms of determinacy. Responses to attended stimuli are certainly less variable than responses to unattended stimuli. And attention increases acuity in the sense of spatial resolution, e.g., the ability to distinguish one dot from two dots. I will argue that spatial attention may not increase precision even if it reduces variability and acuity, and that further, in a rationally designed system spatial attention would not be expected to increase precision.

Figure 10: A textured figure used by Yeshurun & Carrasco (1998). Using stimuli like this one, stimuli were presented in which the square immediately to the right of the plus sign could appear at different eccentricities. When the resolution was low in peripheral areas, attention increased the subjects’ ability to detect the square. But when the resolution was high—nearer to the fixation point—attention *decreased* the subjects’ ability to detect the square because the increased resolution obscured the forest in favor of the trees.

Yeshurun & Carrasco (1998) showed that attention can increase resolution, making subjects (paradoxically) less likely to see the attended stimulus. For textured figures like the square to the right of the fixation plus sign in Figure 10, there is an optimal degree of resolution. If resolution is too high, the subjects miss the forest for the trees, failing to see the larger scale textured figures. Too low a resolution can cause subjects to miss the trees as well. Yeshurun and Carrasco presented textured figures at varying degrees of eccentricity. Since resolution is better for stimuli that are closer to the

fovea, this had the effect of presenting the figures at varying degrees of resolution. They also varied resolution by manipulating where subjects were attending, using cues of the sort described earlier. Putting together the contributions to resolution from eccentricity and attention, they were able to show that there were different optimal degrees of resolution for different figures.

One neural mechanism by which attention increases resolution is shrinking of the “receptive fields” of neurons in the visual system. Recall that a receptive field is the area of space that a neuron responds to. Resolution increases when neurons respond to smaller areas. Another mechanism is the shifting of receptive fields from adjacent areas that was mentioned earlier.

As I mentioned, the sensitivity of high “spatial frequency” channels increases—probably as a result of these mechanisms. Recall that spatial frequency in the case of a stripy stimulus like the “Gabor patches” used in many of the figures in this article (e.g., Figure 15) is a measure of how dense the stripes are. Boosting the sensitivity to high spatial frequencies makes resolution higher, thereby improving perception of textured figures when the resolution is too low and impairing perception when resolution is too high. The Yeshurun and Carrasco paper concerns exogenous attention. Later work (Barbot et al. 2012) shows that endogenous attention is more flexible, raising or lowering the sensitivities of high spatial frequency channels so as to improve perception.

I mention the increase in resolution and the sensitivity to high spatial frequencies in order to be sure that the reader is distinguishing these matters from an increase in precision.

Representational precision is a matter of how wide a range of values is allowed by the representational content, what values are compatible with the veridicality of the percept. (Phenomenal precision is a matter of “crispness” of the appearance.) One dot and two dots may look the same in peripheral vision even though we can clearly see the difference in foveal vision. That is a difference in acuity rather than a difference in precision. Increasing preci-

sion for representation is sharpening the representational content.

The relation between variability and precision is more complex. Imprecision is often cashed out in terms of reliable correlation between a representation and the world (Stazicker 2013). In that sense, since attention decreases variability it must increase precision. However, there are different sorts of noise. As we will see in the first experiment to be described below, attention may decrease noise across the whole spectrum without affecting what might be thought of as intrinsic variation in the signal and thus not increasing a kind of systematic precision. As I will explain, the experiment to be described helps us to precisify what precision comes to.

I will describe two experiments that will help to make the notion of precision more precise or at least concrete and will suggest that spatial attention does not narrow representational precision. Before I do that, let me say briefly why one should expect that spatial attention will not make the attended properties any more precise. Increasing precision normally involves suppression of responses outside the expected range. It would not make sense for a system to be designed to suppress some values without some indication of the irrelevancy of those values. Spatial attention tunes for spatial area, suppressing responses to other spatial areas (Montagna et al. 2009). So spatial attention can be expected to increase precision for spacial location but not for contrast, size, spatial frequency or speed.¹⁶ For feature-based attention, the opposite is true. If one is looking for the red thing, it makes sense to suppress sensitivity to other colors. Spatial attention should tune for space only and feature-based attention should tune for the property attended to.

The first experiment uses the “attentional blink”, a phenomenon in which there is a series of stimuli and two targets amid distractors. In part of the experiment, the targets were squares and the distractors circles. The general finding is that if the subject consciously sees the first

target square, and if the second target square is presented 200-400 ms after the first square, the subject will be much less likely to consciously see the second square. The mechanism has been shown to depend on the first target absorbing the subject’s attention so that there is insufficient attention to consciously see the second square. The second square is described as “blinked”, where the blinking deprives the square of attention. Asplund et al. (2014) used this technique with a paradigm in which the target squares were colored and in which subjects had to report the color of the second square by moving a mouse to click on a color wheel that had 180 colors on it. The idea is that the effect of attention on how intervalic the perceptual representation is could be assessed by examining the effect of the presence or absence of attention on the precision of subjects’ identifications of the color using the color wheel.

The experimental procedure is diagrammed in Figure 11. The subject saw a fixation point (lowest square on the left). Then there were 7-13 colored disks, then a target, T1, a square that was either black or white (RSVP = rapid serial visual presentation), then some number of colored disks, then another square, then 3 more disks. Then subjects reported the color of T2 using the color wheel. They got immediate feedback in how far off they were on identifying the color (in degrees on the color wheel) for 500 ms, then they indicated whether T1 was white or black. If the subject got T1 wrong, that trial’s report of T2 was disregarded. This design allowed for comparison of precision of reporting the color of T2 between trials in which attention was maximally reduced (T2 presented 2 items after T1, described as “lag 2”) with trials in which the lag was so long or so short that there was no attentional blink at all. The key result is that although the lag time was strongly correlated with the average correctness of the response (as always in the attentional blink), *the precision of the responses that were not random was not affected significantly*. The same experiment was done with faces using a slightly different form of the attentional blink. T1 was one of two faces that subjects had to recognize and the response wheel for T2 had a

¹⁶ This is oversimple since attention increases sensitivity to high spatial frequencies (Barbot et al. 2012).

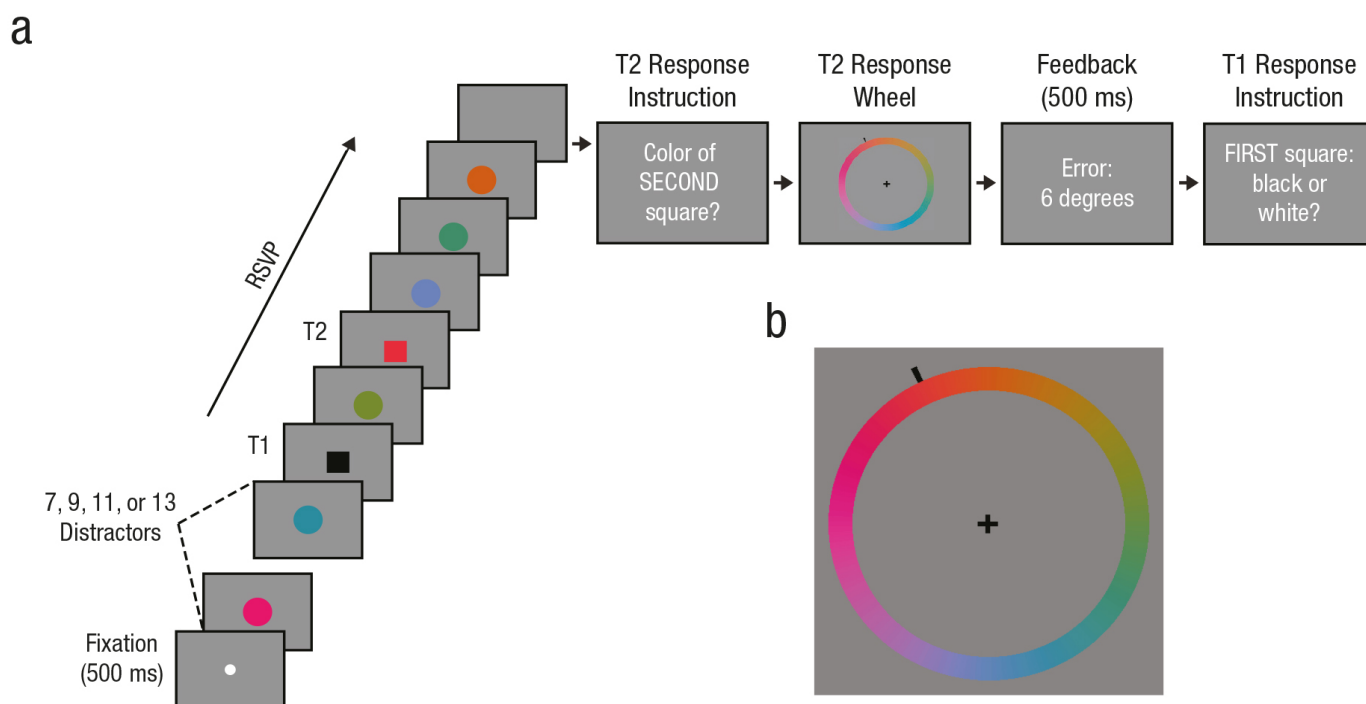

Figure 11: Procedure from [Asplund et al. \(2014\)](#). Understanding of this diagram is aided by color reproduction. Thanks to Chris Asplund for supplying this figure.

series of 150 face morphs based on 3 faces, with 49 intermediate faces interposed between them. The results were the same with faces as with colors. The key result for both studies is that the identification of T2 was either random (much more likely at the critical “lag 2” for an attentional blindness effect of 200-400 ms) or just as precise at lag 2 as at lag 8. Note that the experiment does not directly test the precision of any single percept. The assumption is that the precision of representation of a blinked color will be reflected in how tightly clustered the different responses are. [Asplund et al. \(2014\)](#) conclude (p. 6): “Across both stimulus classes (colors and faces) and experimental designs ..., we found that the reported precision of a target item is not affected in the AB [attentional blink], even though our paradigms had the sensitivity to detect such effects.”

But wait, you may ask: “Didn’t I say that attention decreases variability? And why is there supposed to be a difference between (the inverse of) variability and precision?” (Indeed, the inverse of “variance”, one measure of variability, is a common notion of precision.) The answer is that if you look at the raw data in

this experiment, the blinked color identifications are much more variable than the ones that are not blinked. However, the authors were able to show via modeling that the response distribution was a superimposition of two very different distributions. One distribution was uniform over the whole color wheel with no clustering around one color, whereas the second distribution was tightly clustered around the correct color, *just as tightly as when the color stimulus was not blinked*. They reasoned that the first (random) distribution represented cases in which the subject simply did not see the stimulus. However, when the subject did see the stimulus, the precision of the response was just as if it had not been blinked. (They considered and rejected a “variable precision” model that predicted the data less well; [van den Berg et al. 2012](#)). So overall variability of response is not a good guide to the precision of the representation. And this shows an important flaw in crude correlational approaches to precision. The precision of a perceptual representation should not be taken to be a matter of how well perceptual representation correlates with stimuli since what is really

Figure 12: This is a modified form of a figure from [Asplund et al. \(2014\)](#). The figure compares response errors for lag 2—the value with the maximum effect of the attentional blink with lag 8—the value with the minimum attentional blink. What the figure shows is that the precision of the responses in which the subject actually saw the stimulus was the same. And the figure shows an increase in random responses for the blinked stimulus. Thanks to Chris Asplund for supplying the figure which has been modified here.

relevant is the cases in which the subject actually sees the stimulus.

This point is illustrated in Figure 12 in which the response error profile for lag 2 in which the attentional blink is most powerful is compared with the response error profile for lag 8 in which the attentional blink is least powerful. The widths of the distributions are the same. What differs is the number of random responses as indicated by the higher “tails” of the distributions.

Note the difference between precision and veridicality in this experiment. Precision is a matter of how tightly the responses cluster and veridicality is a matter of whether the responses cluster around the value of the item that was seen regardless of how tightly they cluster. If the color seen was focal red, responses could

pick out focal green in a very precise manner, but be non-veridical nonetheless. Conversely, the average of the responses might be the color seen (focal red) and thus the responses are on the average veridical even though the intervalic content is very wide.

An objector might say that the cases in which the blinked stimulus is reported in a non-random manner might be cases in which it was not in fact deprived of attention by the first percept. Imaging studies of the attentional blink do suggest a general deprivation of attention of the blinked stimulus ([Sergent et al. 2005](#)) but I don’t know of one that looks specifically at this issue. There are always potential confounds and the general remedy is to approach the same issue in more than one way. In the case of this result, the same con-

clusion has been reached by approaches that do not share vulnerabilities.

Another approach recorded from single neurons in a monkey visual area (V4) that is known to be sensitive to shape and form (David et al. 2008). Orientation tuning was not narrowed by spatial attention, but it was narrowed by attention to a specific orientation—feature-based attention. A recent review (Ling et al. 2014) summarizes this approach as follows:

Although initial physiological reports suggested that directing spatial attention to an item sharpens the band-width of orientation-selective cells in macaque visual area V4..., this was later shown not to necessarily be the case. Follow-up studies using a more sensitive measure for tuning band-width found no effect of spatial attention on the width of the orientation tuning function... Rather, these studies instead only found changes in the responsivity and baseline firing rate of neurons coding for the spatially attended location. Thus, the neurophysiological evidence appears to indicate that spatially attending to a location leaves a neuron's feature tuning unaffected.

A psychophysical study came to the same conclusion, that spatial attention boosts activation but not precision.

Ling et al. (2009) contrasted spatial and feature-based attention. The stimuli were random-dot cinematograms in which dots move in one direction or another for short distances. In the low noise condition shown on the left side of Figure 13, the dots show a high degree of coherence in that most of them move in the same direction. As noise increases, motion coherence decreases. Subjects had to make a series of judgments of the orientation of overall motion of these cinematograms. In the spatial attention version, they could be cued as to the place the stimulus would appear. In the feature-based attention version, they were cued to one of four directions of motion and had to report the observed motion as a clockwise or counterclockwise deviation from the cued motion. Ling et al.

were especially interested in comparing two different models for how attention boosts performance in detecting the direction of motion, using stimuli that could move in different directions. See Figure 14.

Figure 13: Random-dot cinematograms in which dots exhibit local motion. In the low noise condition, most of the dots are moving in the same direction. As noise increases, the spread of directions increases and motion coherence decreases. From an experiment comparing spatial attention with feature-based attention. With permission of *Vision Research*.

According to the gain model of (a), the response to the stimulus is increased as if the volume—i.e., the signal strength—were simply turned up equally for all movement-direction detectors. (Orientations of motion are indicated by arrows along the x-axis. The signal strength was turned up in the sense that the signal strength prior to attention is multiplied by a constant factor. For the values that are already high—i.e., at the peak—the multiplying a large value by a constant factor has a bigger effect than at the tails of the distribution where multiplying the constant factor times a zero yields zero.) According to the sharpening model of (b), the effect of attention is not to turn up the response but rather to suppress the irrelevant noise in the stimulus, narrowing the intervalic range of the response profile. These two models make different predictions for “threshold vs. noise” curves pictured in the bottom of Figure 14. The gain model predicts an increase in discriminability only when the external noise is low compared with internal noise. When external noise is low, there is a benefit to turning up the volume—even though the volume in-

creases both signal and external noise—since the effect of turning up the volume is to “swamp” the internal noise. (Internal noise is a blanket term for variation in the visual system, whatever makes visual responses vary even when the external signal remains the same.) As external signal and noise dominates the percept, internal noise decreases in importance. This kind of gain has a similar effect as decreasing the internal noise. If internal noise were zero, there would be no benefit at all in raising the volume on both the signal and the noise. The benefit of raising the volume however dwindles away as external noise increases since the increase in volume increases the effects of external noise too. This is indicated by the lowered threshold on the bottom left of (a) where the advantage in lowering the threshold decreases as external noise rises.

A different picture emerges from the model of the bottom right (b) where the benefit of tuning is greatest when external noise is greatest. (Note that if there is no external noise, tuning is of no benefit.) Thus the benefit should increase as noise increases as pictured in the bottom right (b). These models were tested by a procedure somewhat like that in Figure 5, except using voluntary attention. A line indicated where the subjects were supposed to attend and then a tone indicated that the stimulus was about to appear. Subjects could be cued to one of 4 locations where their task was to report the direction of motion of a stimulus. Sometimes there was a tone but no cue. The result was unequivocal: a pattern like that of the bottom left of Figure 14, indicating an effect of gain but no tuning. “The data showed that spatial attention yielded benefits strictly with low external noise, and no benefits with high external noise” (Ling et al. 2009, p. 1201). They also used the same setup with feature-based attention in which the subjects were cued with an indicator of what the direction of the stimulus would be. In this version, there was both tuning and gain, showing a hybrid of the patterns of a and b in Figure 14.

Again, spatial attention does not appear to narrow representational precision, contrary to the representationist position. This is graphic-

ally shown in the tuning model of Figure 14: suppression of values outside the selected value directly reduces precision. This is what does not happen with spatial attention.

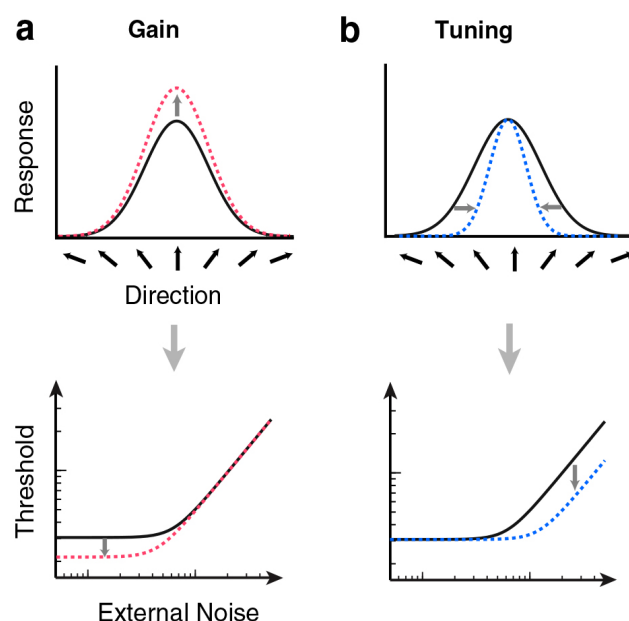

Figure 14: Two models of how attention boosts performance. According to the gain model indicated in the top left (a), the boost derives from increasing the firing of all directional feature detectors. The arrows along the x-axis indicate receptors for motion in different directions. The dotted lines represent the change due to attention (as compared with the solid lines). The tuning model at the top right (b) says performance is boosted by sharpening the response, decreasing the range of the intervalic content, as indicated by the narrowed shape of the dotted line. See the text for an explanation of the bottom diagrams. From Ling et al. (2009). With permission of *Vision Research*.

But why does this result concern representational precision rather than phenomenal precision? I considered an analog of this question concerning peripheral vision in section 2. There I noted that the anatomical asymmetries that are the probable basis of the inhomogeneities discussed are bound to affect unconscious perception in the same way as conscious perception. And a similar point applies here. The narrowing of receptive fields that is the main underlying mechanism of the attentional effects concerns perception *simpliciter* rather than conscious perception *per se*. As I mentioned earlier, spatial attention operates in unconscious per-

ception in a similar manner to conscious perception (Chica et al. 2011; Kentridge et al. 2008; Norman et al. 2013).

The dimensions used in both of the experiments described are “metathetic” as opposed to “prothetic” (Stevens & Galanter 1957). Prothetic dimensions have a zero point and intrinsic directionality, whereas metathetic dimensions have neither (Fuller & Carrasco 2006). Color saturation is prothetic because there is a zero point—achromaticity—and colors are more or less saturated. Hues are metathetic. At least for primary hues such as red and green, neither has more of any hue. Carrasco’s work shows that the attentional effects involved in increasing size, speed, flicker rate and the like work for prothetic dimensions like color saturation but not metathetic dimensions like hue (Fuller & Carrasco 2006). And that fact leads to the question of whether the conclusion that attention does not change precision depends on the magnitude tested being metathetic.

The studies on prothetic dimensions are not as easy to interpret as the ones I just described. One reason is that for metathetic dimensions, the psychological meaning of a difference is roughly the same throughout the dimension. A 90° shift in direction has roughly the same significance independently of the starting direction. But for prothetic magnitudes that is dramatically not so. A one inch change in a length of .01 inch has a different psychological significance than a one inch change in a length of one mile. Baldassi & Verghese (2005) give some evidence that spatial attention does not change the intervalic range of detection of contrast—a metathetic magnitude—though feature-based attention does narrow intervalic range.

The review I mentioned (Ling et al. 2014) surveys many different studies on this issue, concluding (references removed):

By and large, studies using psychophysical techniques to assess selectivity have converged on results that square quite nicely with the neurophysiological results...: feature-based attention to an item selectively changes psychophysical tuning curves..., while directing spatial attention to that

item leaves behavioral feature tuning untouched...

I mentioned that increasing precision normally involves suppression of responses outside the expected range. There is no reason for spatial attention to increase the precision of anything else other than spatial area. In particular, why would spatial attention suppress some directions of motion and not others? However if attention is directed towards motion in a certain direction (feature based attention) then increasing precision does make sense. The point applies equally to prothetic as to metathetic dimensions. Why should spatial attention tune for some values but not others of contrast or gap size given that tuning involves suppression of some range of contrasts or gap sizes. So there is good reason to expect these results to apply to prothetic dimensions.

Let me return to the issue of peripheral perception as compared with foveal perception. I mentioned the experiment that shows that discrimination of contrast in the periphery is as good as in the fovea. But there is an additional fact about peripheral vision, a phenomenon of “crowding” in which things lose the quality of “form...without losing crispness...” (Lettvin 1976). We can ignore crowding for the purposes discussed here so long as we confine ourselves to perception of what the visual system treats as single objects. For more on this, see Block (2012, 2013).

To conclude, there is evidence that attended and foveal perception can be greater in phenomenological precision without being greater in representational precision, contrary to representationism. In direct realist terms, there is evidence that attended and foveal perception can be greater in phenomenological precision without involving awareness of more precise environmental properties.

13 Abstraction and indeterminacy

The purpose of this section is to argue that the 6% difference between the attended 22% and unattended 28% patches underestimates the effect of attention. The reader who is will-

ing to take that on faith can skip to the conclusion.

I argued that since the attended 22% and unattended 28% patches look the same when seen in peripheral vision but look determinately different from one another when seen foveally and attentively, we can conclude that the precision of the phenomenal and therefore representational content of the attended foveal percepts must be greater than that of the prior percepts—if representationism is true and all the mentioned percepts are veridical. The reader may not be convinced however that the 22% and 28% patches do look determinately different when seen foveally and attentively. Perhaps the sense that they look different is a matter of an ability to discriminate rather than an appreciation of appearances that are determinately different.

The Carrasco lab experiments reported so far use stimuli that are 4° from the fixation point. But you might have noticed that when you fixated the bottom left square in Figure 9, you could also see the 28% patch to the far right. And some of the Carrasco lab's experiments have been done with 9° angle of separation.

If one combines the two different angles of separation as in Figure 15 an attended 16% patch looks the same in contrast as an unattended 28% patch, a larger difference than mentioned earlier for this absolute level of contrast. (The differences produced by attention increase with absolute level.) Of course the logic of the case is the same as before. I introduce it because I think it is easier to be sure that the patches in Figure 15 look determinately different when foveated and attended.

Of course there is a difference between the relations between the perceiver and the two patches—in the different angles of separation from the fixation point. Does that ruin the case for my purposes? Note that there was a difference in the relations between the perceiver and the two patches in the experiments of Figure 6 and Figure 7, namely one was on the left of fixation and the other was on the right. Why would there be a difference in relevance between left/right and number of degrees of peripherality?

Recall that imprecise contents were introduced in the first place via the following reasoning. An attended 22% patch looks the same as an unattended 28% patch. But both percepts with that same contrast phenomenology are veridical. In order for percepts with that phenomenology of contrast to be grounded in the representation of contrast, the imprecision of the representational content has to be at a minimum 22%-28% (inclusive of 22% and 28%). Suppose the representationist had said “No no, those phenomenologies are different since one is leftish and one is rightish so there can be no legitimate demand for a representational content in virtue of which they have the same phenomenology. That argument would look silly and be silly because we have an appreciation of how contrast looks independently of which side it is on. We can easily abstract the percept of contrast from a total percept of contrast on the left or contrast on the right. The sense of ‘abstract’ here is a question of appreciation of the phenomenology of contrast independently of perceived location: I speak of abstraction because location is abstracted away from.”

I suggest that the same reasoning applies to Figure 15 even though the difference in peripherality is causally implicated in producing the apparent contrast. The point is that we have an appreciation of that contrasty look independently of degree of peripherality and can appreciate that the two patches look the same in contrast when I am attending to the one on the left. The point is that a 16% patch can look the same in contrast as a 28% patch with the right distribution of attention and we need a representational account of what it is in virtue of which these apparent contrasts are the same. And with respect to that issue there is nothing illicit about comparing 4° with 9°.

The issue of abstraction I just mentioned comes up often in discussions of problem cases for representationism. Consider the phenomenal difference in seeing the round rim of a drinking glass and feeling it with one's hand. Both are percepts of one property, circularity, but the phenomenology is different. How can representationists cope with this case? Michael Tye (1995, p. 157; 2000, p. 93-95) has noted

Figure 15: If you fixate at the “+” sign and attend to the left patch, it should look approximately equal in contrast to the right patch. My thanks to Jared Abrams for help in constructing this figure.

that the “total” percepts involve representation of different properties. These “collateral” properties might be shininess for the visual percept of the circularity and temperature for the tactile experience. The difference between the percepts can be blamed on the perceptions of these different properties. That is, what we are visually representing is circularity-&-shininess and what one is tactually representing is circularity-&-coldness. Can one abstract the visual impression of circularity from the total visual percept? Can one abstract the tactile impression of circularity from the total tactile percept? Tye says he cannot make sense of such abstraction. However, our ability to abstract shape from location on the right vs the left suggests the Principle of *Spatial* Abstraction: perceptual placing of a feature at a location can be abstracted from the perception of the location. I have a visual appreciation of the color of an object even as it moves, changing location. To the extent that this principle is accepted it licenses the use of Figure 15 in the

premise that the contrast percepts are determinately different.

14 Conclusion

I can now summarize the overall argument. First, the short version. The 22% patch and the 28% patch look different when foveated and attended one after the other. However, fixating in between them and attending to the 22% patch, they look the same. How can this be explained representationally without supposing that the precision of attentive foveal vision is narrower than that of inattentive peripheral vision? As before, this is a burden of proof argument that does not explicitly utilize the idea of phenomenal precision.

And as before, here is the long version:

1. The attended 22% patch and the unattended 28% patch, being the same in contrast-phenomenology are the same in contrast-representational contents.

2. Both are veridical.
3. The contrast attributed by vision to the two patches has a minimum span of 22%-28%.
4. Attended and foveal percepts of 22% and 28% (seen sequentially) are determinately different in phenomenology.
5. Phenomenal precision principle: the phenomenal precision of the percepts of the patches seen attended and foveally is narrower than the phenomenal precision of at least one of the percepts seen in the periphery with only one attended. And it is plausible to suppose it is the unattended percept that has the wider precision.
6. So the phenomenal precision of the attended foveal percepts must be narrower than at least one of the peripheral percepts (probably the unattended one).
7. Representationism requires that a difference in phenomenal precision be grounded in a commensurate difference in representational precision.
8. So representationism requires that the precision of the foveal attended percepts be narrower than at least one of peripheral percepts. We have already seen that peripherality *per se* probably does not decrease precision so if precision is decreased, it probably is due to withdrawal of attention. But empirical results suggest that withdrawal of attention does not decrease precision.
9. Conclusion: there is some reason to think that the phenomenology of perception is not grounded in its representational content.

Thus, for the perception of some properties, we have reason to believe that the representational content of perception neither grounds nor is grounded by the phenomenology of perception.

I argued that an attended .20° gap looks the same in respect of size as an unattended .23° gap. The comparative percept—the gaps looking the same—is illusory. But what about the percepts of each gap, considered separately? I argued that we would need a good reason to suppose that one but not the other is illusory and that the view that that both are illusory would undermine the notion of representational content altogether. I said that both are (or

rather can be in normal circumstances) veridical. A similar point applies to the version of the experiments involving contrast in which an attended 22% patch looks the same in contrast as an unattended 28% patch. If the two patches look the same and if looking the same is a matter of sameness in representational content, and if the percepts are veridical, the size properties the patches are represented as having must be intervallic. And the interval—an index of precision—must be wide enough to encompass both patches. So the representational content has to have a precision range of 6%. And further considerations I mentioned suggest a range of 12%. The phenomenal precision principle says if percepts of 22% and 28% are phenomenally the same with one unattended in peripheral vision but determinately different when attended and foveal, then the attended and foveal percepts must have a narrower phenomenal precision than at least one of the peripheral percepts. The 22% and 28% patches do look determinately different if foveated and attended. So the attended and foveal percepts must have a narrower phenomenal precision than one of the peripheral percepts. The only way that this can happen on the representationist point of view is if one of the peripheral representational content is less precise than the foveal attended content. But experimental results that I cited suggest that may not be true. It may not be true of foveal vs peripheral vision independently of attention, and it may not be true for attention independently of foveal vs peripheral perception.

In the section on inhomogeneities of the visual field, I mentioned a route to the same conclusion based on introspection. And I will update that point to include attention. The more introspective route is this: it is natural to feel that the phenomenology of seeing the contrast between the lines and spaces on a piece of lined paper attentively and foveally differs in precision from seeing the same lines inattentively and peripherally. The foveal attentive percept seems more “crisp” than the inattentive peripheral percept. As we have seen, location is indeed represented more precisely but the same is not true for other properties such as hue or

contrast. If this intuitive judgment is correct, there is introspective evidence for a discrepancy between the precision of phenomenology and the precision of representational content.

As I mentioned at the outset, the phenomenal precision principle needs more clarification and justification. It depends on notions of overlapping and of determinately different phenomenologies that are not as clear as one would like. My rationale is that if any advance in understanding of the phenomenology of perception is possible, it will have to start with underdeveloped ideas. I believe that there is enough in these ideas to give some credence to the conclusion. A second issue is whether the percepts that I say are determinately different in phenomenology really are.

The reader will have noticed that for the experimental results I have discussed it can often be difficult to figure out what aspects of the results concerned visual phenomenology and what aspects concern visual representation. As I mentioned earlier we have a real science of perception but very little science of the phenomenology of perception. If we are ever to turn what we know about perception into a scientific approach to the phenomenology of perception, we have no alternative but to start with some vague intuitive notions and proceed from there.

Although there are some loose ends, I think I have said enough to suggest a disconnect between the representational content of perception and what it is like to perceive.

I am grateful to Worth Boone, Tyler Burge, Marisa Carrasco, Jeremy Goodman, Eric Mandelbaum, John Morrison, Susanna Siegel, James Stazicker, Thomas Metzinger, Jennifer Windt and two anonymous reviewers for the Open MIND Project for comments on an earlier draft. And I am especially grateful to Jeremy Goodman and James Stazicker for discussion of these topics.

Glossary

Acuity	Also known as spatial resolution-- is the ability to resolve elements of stimuli. Common measures in the case of vision are the extent to which the subject can distinguish one dot from two dots, detect a gap between two figures, determine whether a rotating figure is rotating clockwise rather than counter-clockwise, ascertain whether two line segments are co-linear, distinguish a dotted from a solid line or detect which side of a Landolt Square a gap is on.
Attention	William James (1890, p. 404) famously said attention “...is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others.” Except for the exclusion of unconscious attention, most scientists would accept something like that characterization today. Spatial attention is attention directed to portion of environmental space and is distinct from attention to a thing or a property.
Content	See representational content.
Contrast	Contrast in an environmental layout is often defined as the average difference in luminance between light and dark areas. (Luminance is the amount of light reflected.) More specifically, it is the luminance difference between the lightest and darkest areas divided by the sum of those luminances. There are alternative ways of defining the notion but the differences won’t matter here.
Determinately different	For items to look determinately different in contrast, their contrast phenomenologies cannot be almost completely overlapping. I noted that this notion makes sense from a representationist perspective. I said that if one patch is represented as 10%-30% in contrast and another patch as 10.5%-30.5% the representationist would need a good reason to deny that the phenomenologies almost completely overlap. Given that representationism is committed to phenomenal precision and phenomenal overlap, it is legitimate to assume them in an argument against representationism.
Diaphanousness	G. E. Moore (1903) famously said “... the moment we try to fix our attention upon consciousness and to see what, distinctly, it is, it seems to vanish: it seems as if we had before us a mere emptiness. When we try to introspect the sensation of blue, all we can see is the blue; the other element is as if it were diaphanous ...”
Direct realism	The view that the phenomenal character of perceptual experience is grounded in direct awareness of objects and properties in the world.
Endogenous attention	Endogenous attention is voluntary—what people often mean by “paying attention”.
Exogenous attention	Exogenous spatial attention is attention that is attracted, automatically by a highly visible change. It is sometimes referred to as “transient” attention, whereas endogenous spatial attention is “sustained”. Exogenous spatial attention peaks by 120 ms after the cue, whereas endogenous spatial attention requires at least 300 ms to peak and has no known upper temporal limit.
Fixation	To fixate a thing or area of space is to point your eyes at it.
Fovea	The fovea is the high density center of the retina. Foveal vision is the only vision that can be 20/20. If you hold your hand at arm’s length, your foveal perception encompasses about double the width of your thumb.

Gabor patches	The fuzzy (actually sinusoidal) grids in Figure 1 and other figures.
Grounding	phenomenology is grounded in representational content just in case it is in virtue of the representational content of an experience that it has the phenomenology it has.
Identity formulation of representationism	What it is for an experience to have a certain phenomenal character is for it to have a certain representational content.
Landolt Square	See Figure 2.
Phenomenal precision principle	(one form) If two things look the same in peripheral vision but determinately different in foveal vision, then the phenomenal precision of foveal vision is narrower than that of peripheral vision.
Phenomenal precision	As with everything phenomenal, nothing like a definition is possible. The best you can do is use words to point to a phenomenon that the reader has to experience from the first person point of view. The experience of a color as red is less precise than the experience of a color as crimson. According to representationism, phenomenal precision is just the phenomenology of the precision of representational content. We experience a percept with representational content of 10%-20% as having more precision than we experience a percept with representational content 10%-30%. For a direct realist, phenomenal precision is just the precision of the properties we are directly aware of. We can be directly aware of properties with different precisions, for example, crimson, or alternatively red. Similarly we can be directly aware of a 10%-20% contrast property and also a 10%-30% contrast property and the difference constitutes a phenomenal precision difference.
Prothetic vs metathetic	Prothetic dimensions have a zero point and intrinsic directionality, whereas metathetic dimensions have neither.
Receptive field	In vision, the receptive field of a neuron is the area of space that a neuron responds to. In tactile perception the receptive field of a neuron is often gauged physiologically—the field of sensory receptors that feed to that neuron.
Representational content	Condition of veridicality. A simple percept consists of a representation of an environmental property and a singular element that picks out an individual item (Burge 2010). The representational content is satisfied when the referent of the singular element has the property represented by the property-representation.
Representational Precision	The precision of a representation is a matter of the intervalic range. For example, the precision of a representation of contrast of 10%-20% is narrower than a representation of 10%-30%. Precision in the sense used here is not a matter of indeterminacy of interval borders.
Spatial frequency	A measure of how closely spaced light and dark areas are. One could think of it with regard to the Gabor patches as a matter of stripe density.
Supervenience formulation of representationism	If phenomenology supervenes on representational content, there can be no difference in the phenomenology of perception without a difference in its representational content.
Veridicality	The veridicality of the most basic percept representations is a matter of the item referred to by the singular element having the property represented by the property representation.

Phenomenal Precision and Some Possible Pitfalls

A Commentary on Ned Block

Sascha Benjamin Fink

Ground Representationism is the position that for each phenomenal feature there is a representational feature that accounts for it. Against this thesis, Ned Block has provided an intricate argument that rests on the notion of “phenomenal precision”: the phenomenal precision of a percept may change at a different rate from its representational counterpart. If so, there is then no representational feature that accounts for a specific change of this phenomenal feature. Therefore, Ground Representationism cannot be generally true.

Although the notion of phenomenal precision is intuitive, it is admittedly in need of clarification. Here I reconstruct Block’s argument by suggesting a way of estimating phenomenal precision that is based on the assumption that parts of perceptual wholes can share phenomenal features independently of their place in the whole. Understood like this, the overall argument shows what it is supposed to show.

A more thorough look at the notion of phenomenal precision suggests tension with Block’s other work: in order to be non-trivial, we have to accept that some of our phenomenality is not concrete, but only generic. Such “solely generic phenomenology”, however, is a position mainly held by opponents to Block’s *Access- vs. Phenomenal Consciousness*-distinction. Interpreting phenomenal imprecision as constituted by introspective imprecision does not suffice as a way out. It seems that phenomenal precision is either trivial, self-contradictory, or incompatible with Block’s position elsewhere. So some additional elucidation on this crucial notion is needed.

1 Introduction: Running representationism into the ground

Imagine yourself in an elevator. You press the button for the upmost floor when, all of a sudden, you smell something nauseating: a foul metallic odor permeates your nostrils and raises disgust until all your attention is focused (unfortunately) on this olfactory catastrophe. *How* it smells is not the question. The odor has a very determinate character—and it is funky! But *what* is it that you smell, what is this sensation *about*? Maybe you left a cheese sandwich

in your pocket and forgot about it? Maybe some wiring went faulty? Or the breaks? Maybe your colleague cut one out? Even though you don’t know *what* it is you are experiencing—what your experience is about, its content, or *representational* aspect—, you do know *how it is like* to smell this stench—you know its appearance, its character, its configurational¹ or

¹ For the distinction between representational and configurational aspects see Wollheim (1987). Nanay (2005) used these termini vis-à-vis

phenomenal aspects. What is the relation between content and character in such percepts?

Representationists give the following answer to this question: all phenomenal features of an experience (its appearance or character) are dependent on its representational features (its content): *how* you experience is determined by *what* you experience. Ned Block (forthcoming 2015)² has provided a useful way of taxonomizing Representationists further: Identity-Representationism (IR) is the claim that the character of an experience is nothing but its content. However, content here cannot be more basic than character, because identity is symmetrical. Character then determines content just as content determines character, because both are just one and the same. Also, if we want to *explain* or *reduce* character to content, then IR is not the way to go, because reduction—unlike identity—is *asymmetric*, and so is explanation.³

That an experience's content is more basic and determines its character (but not *vice versa*) can be captured in two ways: Supervenience-Representationism (SR) is the claim that every change in phenomenal character necessitates a change in the content of the experience, but not vice versa. But SR leaves open *which* change in content determines a specific change in character. In Ground-Representationism (GR), however, not any change will do: the change in character must have a change in content that *accounts* for the change in character.

Say you experience a change in the size of a gap, e.g. it grows larger. If that experience's character merely *supervenes* on its content, then the appearance of a growing gap does not necessitate that your experience is *about* a growing gap—*something* has to change in content, but it doesn't need to be this specific change. This appearance may be brought about by a change from being about a gap of size *x* to a smaller gap of size *y*, or about the gap changing color,

or about your toe starting to twitch while you look at the gap—any change might do without violating the letter of SR. However, if an experience's character is *grounded* in its content, then the change in content must account for the appearance. It seems that only being about a growing gap truly accounts for the appearance of a growing gap. If we want to be Representationists, GR seems like our best option: it allows us to (i) differentiate content from character, (ii) see content as more basic than character, (iii) capture that phenomenal character is dependent on content, but not *vice versa*, and (iv) make content accountable for character.

However, character is *not* grounded in content, Block argues:⁴ GR is false. This assessment is motivated by empirical considerations. There are many gems in Block's article, but I will focus mainly on the crown jewel, which is the argument based on "phenomenal precision". It is subtle and intricate, so my first step is to reconstruct it (with a bit of elaboration) in section 3. In section 4, I point to a few oddities and tensions I see with Block's other work. I do not see these tensions as offering a decisive blow to his argument, but as a plea for an elaboration on how Block thinks about phenomenal precision. (My main argument meanders through the main text. I keep it concise, but some points deserve some technical elaboration—thus the abundance of footnotes. They may be treated like beetroot on a buffet, i.e. skipped with clean conscience.)

2 "Phenomenal precision"

The notion of *phenomenal precision* plays an important role in Block's argument. He (this collection, p. 45 & 47) admits that it is a notion in need of clarification—but one where a lack of definition ought not give us headaches, since many concepts pertaining to phenomenality lack definability.⁵

aesthetic pictorial experiences. We may apply this distinction to experiences more generally.

² See also the article in this collection.

³ At least, most often explanations are seen as asymmetric. For example, Schindler (2013) has remarked that the mechanistic explanations à la Craver (2007) violate asymmetry, which he sees as a shortcoming of Craver's account.

⁴ This is not his first argument against Representationism (see e.g., Block 1996), but I will focus mainly on his *The Puzzle of Perceptual Precision* in this collection.

⁵ This has become somewhat like a signature move for Block. Consider e.g.: "You ask: What is it that philosophers have called qualitative states? I answer, only half in jest: As Louis Armstrong said when asked what jazz is, 'If you got to ask, you aint

We can think of precision as connected to bandwidth. What does that mean? Some variations in the external world do not factor into how the world feels to us. For example, one cannot differentiate a grating of 20% contrast from one of 20.2%, or a pain caused by heat of 480 millicalories per second per square centimeter from one caused by 640 mc/sec/cm² (Hardy et al. 1940; Hardy et al. 1952). However, there is a point where the variance in the stimulus becomes just noticeable, e.g., a pain of 660 mc/sec/cm² does feel different from one at 480. This can be measured behaviorally, namely if a subject is able to distinguish one item of type A from another of type B above chance based on the relevant feature (e.g., if 75% of all presented items are distinguished correctly). So all the variance that I cannot distinguish perceptually between two just noticeable differences (JNDs) is covered by percepts with the same phenomenal character. That is, if I have a percept *a*, different states of affairs may have caused *a*—and the phenomenal character of the percept does not convey its real cause. So percepts ought to count as a bit imprecise. The more cases are covered by a percept, the less precise: a visual-contrast-percept that can be caused by $20 \pm 1\%$ contrast is more precise than one that can be caused by $20 \pm 3\%$.

never gonna get to know.” (Block 1991, p. 217)

Or: “I cannot define [phenomenal consciousness] in any remotely noncircular way. I don’t consider this an embarrassment. The history of reductive definitions in philosophy should lead one not to expect a reductive definition of anything. The best one can do for [phenomenal consciousness] is in some respects worse than for many other concepts, though, because really all one can do is point to the phenomenon (cf. Goldman 1993a). Nonetheless, it is important to point properly.” (Block 1997, p. 230)

He continues by stating that synonyms and examples are the best way of conveying what is meant by “phenomenal consciousness”. I do not think that this is unreasonable, but instead intellectually honest. Chalmers (2011, p. 545) may have provided a good explanation of why it is so hard to provide a real definition for “phenomenality”: It might be a bedrock concept, which cannot be decomposed into more basic concepts, because it is itself most basic—it captures the fundamental distinction between reality and its appearance to us:

“[...] a dispute is bedrock relative to an expression: so the dispute over ‘Mice are conscious’ might be bedrock with respect to ‘conscious’ but not with respect to ‘mice’. A substantive dispute is bedrock relative to an expression *E* when no underlying dispute can be found by applying the method of elimination to *E* [i.e., replacing *E* in disputes by another expression where people agree on the meaning]: roughly, when there is no underlying dispute that does not involve *E* or cognates.”

If an expression is bedrock, then it cannot be elucidated by conceptual analysis—and there cannot be any non-stipulative real definition.

Percepts have representational and phenomenal aspects—content and character. Precision certainly makes sense when it comes to content, because “[t]he representational content of a perception is—constitutively—the veridicality conditions”, Block writes (this collection, p. 27).⁶ So we can look at the range of cases in the world that make a percept veridical, and thereby determine its degree of representational precision based on the range of cases that may have caused it in that obtaining condition. If, for example, a Gabor patch with 22% contrast looks just like one with a 28% contrast, then the representational content of this percept has a degree of precision of at least 6%, because all cases between 22% and 28% are covered by the same phenomenal appearance. Otherwise, these two Gabors would not look the same.

Representational precision makes sense—but how about *phenomenal* precision? Intuitively, phenomenal precision sounds good: things may appear *red* or *crimson*, and because all things crimson are a subset of all things red, the bandwidth of both ways of seeing-as differs—and therefore they ought to count as differently precise.

But if we can diagnose differences in the degree of phenomenal precision, we need a way of estimating its degree. How would we do this? GR provides an easy answer: phenomenal precision is grounded in representational precision, so we can use the same methods by which we estimate representational precision to estimate phenomenal precision. But in an argument where GR is under scrutiny, one cannot presume this without begging the question. So we must look for another way of estimating phenomenal precision.

For this purpose, Block suggests the Phenomenal Precision Principle (PPP), which we may reconstruct as: If the percept of item i_1 and the percept of item i_2 are phenomenally indistinguishable with respect to some feature *F* under condition *A*, but phenomenally determinately different vis-à-vis *F* under condition *B*, then the experience in *A* is less precise than in *B*.

⁶ This is in the spirit of Burge (2010, pp. 55–60), whom Block cites in this context.

Figure 1: If one fixates on one of the black dots but actively attends to the lower-contrast patch to the left, the two patches to the right and left of the dot will appear alike. If one gazes freely or attends to the right, the difference in contrast is obvious or even more pronounced. Taken from Carrasco et al. (2004, p. 310).

So if I cannot differentiate two stimuli by their contrast in condition *A*, but can differentiate the two by contrast in condition *B*, then my experience in *A* is less precise than in *B*. Why? Because if I can tell the two items apart phenomenally, then I can distinguish cases, and therefore the bandwidth of that experience is narrower.

Block uses differences in phenomenal precision prominently in an argument against GR: he believes that in some cases, phenomenal precision (*p*-precision) and representational precision (*r*-precision) can fall apart. If GR were true, such that representational features must account for phenomenal ones, then this cannot be the case. But this is exactly what happens, according to Block: “there is evidence that attended and foveal perception can be greater in [phenomenal precision] without involving awareness of more precise environmental properties” (this collection, p. 41). Then, GR is false.

3 Block’s precision argument

What evidence speaks for Block’s thesis that “attended and foveal perception can be greater in [phenomenal precision] without involving awareness of more precise environmental properties” (this collection, p. 41)? (For those who have read the original article and have a firm grasp of the argument based on precision, this part may be skipped for the discussion in section 4.)

3.1 The stimulus and the conditions of viewing

Consider the stimuli in figure 1 taken from Carrasco et al. (2004, p. 310), and mentioned by Block twice (figure 7 and 9 in his article). It shows three Gabor patches of 16%, 22%, and 28% contrast—call these stimuli g_{16} , g_{22} , and g_{28} respectively. If we look directly (i.e., foveate) *at* and *attend to* each of these stimuli, the percepts they cause are decidedly different to each other. Call this condition “SFAG” for *stimuli foveated, attention on gabors*. However, if we fixate on the black spot between the patches (such that the patches are more in the periphery of our visual field) but *attend* to the one with lower contrast (i.e., to the left of where we fixate), then the percepts they cause appear indistinguishable from one another. Call this condition “SPAL” for *stimuli peripheral, attention on lower contrast*. This comparative indistinguishability does not arise if we attend to the higher contrast patch or to the spot in the middle. Call these conditions “SPA H ” for *stimuli peripheral, attention to higher contrast* and “SPA F ” for *stimuli peripheral, attention to fixation spot*, respectively.⁷

⁷ See also table 1. We may also introduce the following formalism: $Ch(x)$ stands for the character of a percept of x (the external stimulus); $Ch(x\&y)$ stands for the character of perceiving stimuli x and y together, i.e., a mereological fusion of simultaneously occurring characters at a moment in time t . The comparative character is then:

Table 1: The character in each condition of viewing/attending to the stimulus of 22% and 28% in figure 1. (See also footnote 7.)

Abbreviation	Condition	Character
SFAS	Stimulus foveated, attention on stimulus	distinguishable
SPAS	Stimulus peripheral, attention on fixation spot	distinguishable
SPAH	Stimulus peripheral, attention on higher contrast	distinguishable
SPAL	Stimulus peripheral, attention on lower contrast	indistinguishable

3.2 The evidence for attention influencing appearance

It seems that attention alters appearance. Our main evidence is introspective: we can reliably produce such changes in appearance from SPAH to SPAF to SPAL by shifting attention. This works even if we know of the effect.

To an external observer, there is evidence available from naïve subjects: If these subjects have to name the orientation of the patch with the higher contrast (\swarrow vs. \searrow), they choose at chance level in SPAL *even if there is a contrast difference of 6%*.⁸ (The shift in attention was

SFAG: $Ch(g_{22}) \neq Ch(g_{28})$

SPAF: $Ch(g_{22} \& g_{28}) \approx (Ch(g_{22}) \neq Ch(g_{28}))$

SPAH: $Ch(g_{22} \& g_{28}) \approx (Ch(g_{22}) \neq Ch(g_{28}))$

SPAL: $Ch(g_{22} \& g_{28}) \approx (Ch(g_{22}) = Ch(g_{28}))$

Note that just because phenomenal parts share identical phenomenal character, these parts themselves need not be identical: they may occur at different moments in time, be part of different phenomenal wholes, or be arranged in a different manner; if any of these extrinsic properties were among the identity conditions of phenomenal parts, then $a \neq b$; however, the character of some a may still be identical to the character of b .

If phenomenally-unified percepts are mereologically organized, as suggested by Bayne (2010), as well as Wiese & Metzinger (2012), then: if a percept at $t1$ has $Ch(x \& y)^{t1} = (Ch(x)^{t1} \neq Ch(y)^{t1})$ and a percept at $t2$ has $Ch(x \& y)^{t2} = (Ch(x)^{t2} = Ch(y)^{t2})$, then $Ch(x)^{t1} \neq Ch(x)^{t2}$ or $Ch(y)^{t1} \neq Ch(y)^{t2}$. This is the case in the experiment by Carrasco et al. (2004, p. 310); so under these presumptions, the appearances of parts of the overall percept must change between the conditions, because the character of the whole changes.

⁸ That is, the point of subjective equality (PSE) differs between the conditions. PSEs are determined by that configuration where a forced choice between stimuli is chancy. Carrasco et al. (see 2004, p. 311, figure 5a) kept a g_{22} fixed (standard) and varied the other patch (test). So one condition (cue to test) covered what I call here SPAH and SPAL, as in some cases, the test patch had a lower, in some a higher contrast than the standard g_{22} . (This is merely a difference in presentation, which does not influence the overall argument. Their presentation simply provides a continuous psychometric

exogenously triggered by a visual cue 27ms prior to stimulus onset.) Because subjects have to decide which grating *looks* higher in contrast, and pick the lower or the higher contrast patch at random, it is reasonable to assume that the two look the same: they have identical character in SPAL. Thus, attention affects appearance.

3.3 The contents and degree of r -precision in different conditions

So the character of comparative percepts (the character of experiencing two patches together) differs between these conditions, even if the stimuli and the way we fixate remain the same. But what about the respective *contents*?

In SFAG, we can clearly tell the patches apart. If percepts are constitutively veridical (because otherwise they are not percepts, but illusions or hallucinations), then the content of a percept is determined by the actual world. Thus, the content of each percept of a patch is (approximately) its actual contrast.⁹

In SPAF, the patches look different. However, as our ability to tell contrasts apart is a bit lower in the periphery, the contrast-JND is a bit higher—say, 3%.¹⁰ So the content of the comparative percept is one where the content of each percept is less precise, but still discernible from another: its actual contrast within the range of a peripheral contrast-JND.

In SPAH, the comparative contrast between the patches is more pronounced. We cannot explain this if the content in SPAH is the same as in

curve.) If the fixation spot was cued, the PSE reflects reality: a g_{22} looks most like g_{22} ; if the standard (g_{22}) was cued, the test patch had to have a higher contrast to look similar: a g_{28} looked most like a g_{22} ; if the test patch was cued, the uncued patch had to have a lower contrast to look most similar to the test: a g_{16} looked most like a g_{22} .

⁹ The actual content is a bit more imprecise, i.e., within the range of 1 foveal contrast-JND, which is roughly 1%. Block suggests 2% overall. In personal communication, Frank Jäkel estimated that (under ideal experimental conditions with optimal stimuli) the contrast-JND could be a log-unit lower than that: 1% provides a good ballpark estimate for many conditions. He based this estimation on his own work done for the study published in Jäkel & Wichmann (2006). See also Carney et al. (2000), Pelli & Bex (2013), and the *locus classicus*: Fechner (1860, pp. 150ff.).

¹⁰ See Banks et al. (1991, p. 1779). Although they do not specifically mention JNDs, they do provide data about contrast sensitivity in different degrees of peripheral eccentricity, which suggests some increase: “[T]he ideal [contrast sensitivity functions] do not exhibit the large contrast sensitivity losses that one observes in humans with increasing eccentricity.”

SPAF. Somehow, the contents ought to differ more than in SPAF. One way to do this is to see one as more r -precise than the other. Then it is easier to tell the two apart, because there is no content-overlap. Another way would be to assume that one becomes less r -precise. Then it is easier to tell them apart because the respective minima and maxima are further apart.¹¹

Table 2: The content and its degree of precision in each condition of viewing/attending to the stimulus of 22% and 28% in figure 1. (See also footnote 12.)

Condition	Content + Bandwidth estimation
SFAS	% of actual contrast ± 1 foveal JND _{attended} ($\sim 1\%$);
SPAS	% of actual contrast ± 1 peripheral JND _{unattended} ($\sim 3\%$);
SPAH	% of actual contrast ± 1 peripheral JND _{attended} / ± 1 peripheral JND _{unattended} ; (my estimation: $\sim 2\% / \sim 3\%$; see also footnote 11)
SPAL	at least the open interval between actual contrasts, here $\geq 6\%$;

In SPAL, the comparative percept (g_{22} & g_{28} together) is such that the two patches are indistinguishable. So our percept is strictly speaking non-veridical. In order to make it veridical, one has to assign a quite imprecise content: it must at least cover both actual contrasts—i.e., be greater or equal to the interval that includes the actual contrasts as endpoints: $[22\%, 28\%]$.¹²

¹¹ Block might argue that we lack a principled reason to choose one over the other as being more or less imprecise. The argument mirrors the one he gives concerning veridicality (see Block this collection, pp. 26ff.). As veridicality determines the contents of percepts, one can easily adapt it: intuitively, one might think that the patch one attends to is more veridical; but attention changes appearance, so the unattended one might be more veridical; but as one mostly acts on what one attends to, it would be advantageous if what one acts on was most veridical. So we are stuck in a rut. The comparative percept in SPAL is illusory, but *as a percept*, it must be (partially) veridical. Block's suggestion is (or ought to be) that we should assume that each is veridical, but less r -precise. I'd agree. But I think we can do more: when we focus on the higher contrast Gabor, this increases the distance in r -precision between the compared percepts, and thereby ought to render them more discernible. If so, then this might apply to SPAL as well, such that the one we attend to is more precise. I pick up on this in footnote 12.

¹² See table 2. More formally, let $Co(x)$ stand for the content of our percept of x , and $Co(x \& y)$ for the content of the comparative percept of x and y together. Given the external content-determination of percepts and our understanding of JNDs, we can be a bit more precise about how imprecise content is in the different conditions.

SFAG: $Co(g_{22}) = 22 \pm \sim 1\%$; $Co(g_{28}) = 28 \pm \sim 1\%$

SPAF: $Co(g_{22} \& g_{28}) \approx (Co(g_{22}) \geq 22 \pm \sim 3\%, Co(g_{28}) \geq 28 \pm \sim 3\%)$

SPAH: $Co(g_{22} \& g_{28}) \approx (Co(g_{22}) \geq 22 \pm \sim 3\%, Co(g_{28}) \geq 28 \pm \sim 2\%)$

SPAL: $Co(g_{22} \& g_{28}) \approx (Co(g_{22}) \geq [22\%, 28\%], Co(g_{28}) \gg [22\%, 28\%])$

3.4 Estimating the degree of p -precision in the different conditions

So we know the percepts' contents and r -precision in the different conditions—but how about their p -precision? Block agrees that this is hard to estimate correctly. But the PPP gives us a rough guide: if the percept of item i_1 and the percept of item i_2 are phenomenally indistinguishable with respect to some feature F under condition A , but phenomenally determinately different vis-à-vis F under condition B , then the experience in A is less precise than in B vis-à-vis F . However, the case becomes more complicated, because we also have to think of the p -precision of *comparative percepts* (experiences as a whole) in addition to the *percepts compared* (the parts of whole experiences), akin to what we did in the case of r -precision.

3.4.1 Perceptual wholes and perceptual parts

At each moment, you have a broad range of different sensations; but all of these together are parts of one massive phenomenal *me-here-now-with-this-and-that-whole*: at a bar, you smell the mixture of spilt beer and sweat, taste the medicinal-peaty taste of your Lagavulin, while you ogle a lovely co-member of your species—who makes you feel your heart pumping in your chest. But you don't feel all these separately; they are fused into one fleeting holistic experience.

If phenomenal wholes are not character-identical, there must be a difference in their parts; but some distinguishable phenomenal wholes may still share parts with identical phenomenal character: the feel of your beating heart while ogling may be phenomenally identical to the feeling of your beating heart after escaping the oglee's significant other.

3.4.2 Unattended parts can share character with attended parts

Just as temperature can alter the taste of sugar to caramel without being sugar or caramel, attention can affect phenomenal character without itself having a phenomenal character: attention *alters* the appearance of x , but there seems to be no additional phenomenal character

as of *attending to x*. If so, then the phenomenal character of a perceptual part itself does not determine whether this part is attended to or not.¹³ So a percept that is now in the attentional limelight may share its character with a counterpart in the attentional shadow: If I attend to a leaf in a tree, the leaf I focus on may look just as green as a leaf in my visual periphery that I experience but don't care about. This is one interpretation of SPAL: the percept of the attended peripheral g_{22} shares its character with the percept of the unattended peripheral g_{28} -patch.¹⁴

3.4.3 An estimation of p -precision in the different conditions

Now, we may consider what the p -precision is in our cases. In SFAG, over the range of 1 foveal contrast-JND, all percepts look the same. This is the most p -precise that the character of a percept can be. The p -precision range is then roughly centered around some value $n \pm x\%$, where x is approximately 1 foveally attended contrast-JND.¹⁵

In SPAF, the patches look determinately different; and in SPAH, they look even more dif-

ferent. It is in the spirit of PPP (see p. 3) that the comparative percept in SPAH is more p -precise than the comparative percept in SPAF.

But because the character of a percept is independent of whether one attends to or foveates on it, each compared percept (the parts of which the comparative percept is composed) ought to be similarly p -precise as in SFAG: if parts inside and outside the focus of attention can share phenomenal character, and if this holds for all characters, then the same range of characters can appear anywhere in our visual experience. So we ought to expect the same range of PPP-cases in the periphery as in the fovea. Then, the character ought to count as similarly p -precise.

3.5 The argument

If I am correct so far, we can state the following: (P1) If the character of an attended and an unattended percept can be identical (section 3.4.2), then perceptual parts are overall more p -precise than r -precise, because the range of p -precision-values of compared percepts is stable in all conditions (table 3), but the range of r -precision must vary in order to account for the veridicality of percepts (table 2). (P2) If the character of an attended and an unattended percept can be identical, then our compared percepts (the parts of the comparative percept) are more p -precise than r -precise in SPAL.¹⁶ But if GR were true, then there must be a representational feature that accounts for each phenomenal feature. This applies to precision as well, because—according to Block— p -precision is a phenomenal feature of one's perception. So if GR were true, representational precision must account for phenomenal precision. But (P1) and (P2) stand in direct opposition to this. So, by *modus tollens*, GR ought to be considered false.

4 On the notion of “phenomenal precision”

Any argument against Representationism has an initial appeal to me. Ned Block's is at the cutting edge of empirical research and subtle in its argu-

¹³ One reviewer doubted whether this holds generally. It might be that a weaker version is easier to defend: an appearance does not *necessarily* specify whether it is attended to or not. I suspect that Block tends towards a stronger reading, as it seems to be in line with the dissociation between phenomenal consciousness and access. My reconstruction hinges on the strong version. For otherwise, the stability of p -precision I suggest in section 3.4.3 does not arise. So if there are good reasons to doubt the strong version, there are good reasons to doubt my reconstruction ↓ and also Block's argument itself, I believe. Here, I simply admit this weakness, but cannot follow up on this criticism due to lack of space. However, I see no good reason for assuming that attention has a unique and distinguishable perceptual character. (It might even be contentious whether it has a cognitive, active, or any phenomenal character at all, but I will not get into this here.)

¹⁴ It is unclear whether the identity in character must be part of the experience for Block's argument. It seems that he thinks this way. But consider Williamson (1990, p. 60; my emphasis), who writes that the “discriminability of a pair of characters as presented by a pair of experiences depends on *non-qualitative* relations between the experiences — relations not fixed by the way in which the experiences present their characters — which facilitate or hinder discrimination [...]” He envisions *where* the compared characters are placed in time and the visual field, but one might also consider, as I do in section 4.3, that our ability or inability to tell characters apart is a dependent on our cognitive abilities.

¹⁵ We cannot give the exact value of n , because the character of a percept is independent of whether one attends to it or foveates on it; and in SPAL, percepts of different actual contrast can share the same character. So we cannot associate the p -precision value with any value pertaining to a stimulus. Still, we may assume that it has a value. So I use some mock-value n .

¹⁶ Block's main argument rests on (P2)↓ but I hope that (P1) is in his spirit.

mentation. But I suspect that its crown jewel, “phenomenal precision”, has a few shady facets.

“Phenomenal precision”, Block admits, is in need of clarification. The guiding example for Block ([this collection](#)) is where “[t]he experience of a color as red is less phenomenologically [sic] precise than the experience of a color as crimson”. Here I want to focus a bit more on how we may understand p -precision, what it might and what it ought not to mean in the context of Block’s work.

Table 3: The approximated phenomenal precision in each condition of viewing/attending. How p -precise the comparative percepts ($g_{22}\&g_{28}$ *perceived together*) are can be ordered from lowest to highest: SPAH>SPAF>SPAL. (See also footnotes 7 and 12.)

Condition	Approximated Phenomenal Bandwidth
SFAG	$n_i \pm x\%$ of contrast, where x is roughly 1 foveal JND; $\text{Ch}(g_{22\%}) = n_1 \pm x\%$; $\text{Ch}(g_{28\%}) = n_2 \pm x\%$
SPAF	$\text{Ch}(g_{22\%}\&g_{28\%}) =$ $((\text{Ch}(g_{22\%}) = n_3 \pm x\%) < (\text{Ch}(g_{28\%}) = n_4 \pm x\%))$
SPAH	$\text{Ch}(g_{22\%}\&g_{28\%}) =$ $((\text{Ch}(g_{22\%}) = n_5 \pm x\%) \ll (\text{Ch}(g_{28\%}) = n_6 \pm x\%))$
SPAL	$\text{Ch}(g_{22\%}\&g_{28\%}) =$ $((\text{Ch}(g_{22\%}) = n_7 \pm x\%) = (\text{Ch}(g_{28\%}) = n_4 \pm x\%))$

4.1 Lower bounds of p -precision

The way I estimated phenomenal precision in my reconstruction was as follows: consider, first, how a controlled stimulus appears under ideal conditions (e.g., rested, attending, etc.) as some phenomenal feature. For example, how *blue*₃₄ in a standardized patch looks *as blue*, how an olfactory sample (e.g., a *CAS 93686-30-7, Ext. Sup. I, 1000ppm*) smells *as Ylang-Ylang*, how 480 mc/sec/cm² feels *as pain*, and so on. Then, see how much variance in the stimulus is *not* mirrored in the appearance as F : for example, the pain caused by 480 mc/sec/cm² is not reliably discernible from one caused by 640 mc/sec/cm²; instead both feel *as pain near maximal intensity*. Because I cannot differentiate between 480 mc/sec/cm² and 640 mc/sec/cm² by the feeling they cause, my pain feeling’s p -precision must at least cover these values. This provides us with a lower bound

for that specific feeling of pain. More broadly, for any phenomenal character—i.e., experiencing something as F (e.g., a color as red, a tone as $C\sharp$, a patch as having 28% contrast)—, the lower bound of its p -precision is that range of cases one cannot distinguish by experiencing as F under ideal conditions. That’s what the PPP suggests (see p. 3).

This allows us to make sense of the *red vs. crimson* example: *crimson* is a very specific phenomenal feel, which allows for very little variation while remaining crimson. *Red*, on the other hand, allows variation along the whole spectrum, from coral and vermillion, via crimson and oxblood, to maroon. So any experience of a color as *crimson* is also likely to be¹⁷ an experience of a color as *red*—but so is an experience of a color as *vermillion*. And the range of cases that may cause an experience of red compared to those that may cause an experience of crimson under ideal condition is larger. So experiencing as crimson is more p -precise than experiencing as red.

4.2 A need for solely generic phenomenology?

I think that triviality or contradiction looms if we do not add another constraint to be satisfied: In order for p -precision to be non-trivial, there must be the possibility of experiencing a color as red, but *not* as crimson₄₂, vermillion₁₁, coral₁₉, oxblood₈₁, etc. That is, there must be a way of experiencing something as a higher-order property \mathfrak{F} , *without* experiencing it as any first-order property F_1, F_2, \dots subsumable under \mathfrak{F} . Rick Grush (2007) has called this *Generic Phenomenology*—but I am speaking more specifically of *solely generic phenomenology* (SGP), i.e., generic phenomenology without an accompanying and subsumable concretum.¹⁸

Why ought we commit ourselves to SGP? Because otherwise the p -precision of an experience

¹⁷ Likely but not necessarily, because *experiencing as crimson* is not necessarily related to *experiencing as red*. Conceptual or nomological relations do not necessarily transfer to the realm of experiences. Imagine seeing an animal *as a mouse*. One does not thereby see it *as an owner of a heart*, or *as a member of the phylum chordata* even though all mice belong to each category necessarily.

¹⁸ See also the discussion and specifically Block’s response R2 on Block (2007) for more on generic phenomenology.

is either contradictory, generally minimal, or generally maximal, which trivializes the notion. Why?

Look at the color in figure 2. What is the p -precision of this color impression?

Figure 2: A stimulus of color 660000 or 16-86-94-42 CMYK.

You probably experience this color as red, but also as having a specific shade of red—for which you might lack a name, but let us baptize it *cayenne*₆₆. It is natural to assume that this holds for all color impressions, e.g., that whenever you experience a color as red, you also experience it as a most specific shade. In this case, there is no SGP—just a generic phenomenology accompanied by concrete and “subsumable” phenomenology. What might be the p -precision of your color impression in this scenario?

You might think that this color experience has two p -precision values:¹⁹ The first value is for being experienced as red, and the second for being experienced as *cayenne*₆₆. But this seems contradictory: why should one and the same experience of a color have two p -precision values, but only one for r -precision? And for that matter, why not three values for p -precision? You likely experience the color not only as *cayenne*₆₆ and as red, but also *as a color*? Why not four, then, if you experience it *as a visual experience*? Or five, if you experience it *as something*? Or even six, if you experience it *as phenomenal*? The more options we consider, the less sense it makes to speak of *the* p -precision of a percept at all. But this is needed for Block’s argument, where changes in p -precision are lower than the respective changes in r -precision. This hardly works if we allow multiple values. So we should assign experiences only one p -precision value.

If we have to assign this color experience only *one* p -precision value, we could either choose

the lowest or the highest feature. Either option looks arbitrary, which is already bad. But it gets worse if we reject SGP: If we chose the lowest feature (*cayenne*₆₆) and if there must always be a lowest feature, then all experiences of a type have the same level of p -precision *and* this value must be stable. If we chose the higher feature (red), then there is no reason to stop there: we certainly experience the color as a color, as a visual impression, or as *something*. But the character of *being something* applies to (almost) every experience. So all experiences would again be equally and fixedly p -precise. Both cases seem to trivialize the notion of p -precision, because it always stays the same. So p -precision seems either contradictory or static and trivial without SGP.

We ought to accept SGP in order to allow for variance in p -precision: we can experience some color as red, but *not* as e.g., *cayenne*₆₆ and so on. More generally, we can experience something *only* as a higher-order property \mathfrak{F} *without* experiencing it as any lower order property F_1, F_2, \dots subsumable under \mathfrak{F} . Then, different experiences allow for different degrees of indeterminacy and therefore different degrees of p -precision.

However, SGP has been introduced to argue *against* Block: According to Grush (2007), if we accept the possibility of generic phenomenology, then we could see something as *some* letter without seeing it as *a specific* letter (A, B, ...). This affects one’s interpretation of the Sperling experiment: Sperling (1960) showed participants a grid of letters, which they identified *as letters* from the short impression they got. Yet they could not identify and recount all of them. But when they were cued to repeat a specific line by a tone *after* the stimulus disappeared, they were able to recount the letters in that line without fault. Block (2007) has used this and other experiments to argue that phenomenality goes beyond what we can cognitively access: people have a full phenomenal impression, but cannot access all the information available in their experience. Their experience is concrete, but their introspective access is shaky. SGP proponents counter that one can have generic experiences while all the underlying concrete information is subconscious. So before the cue, subjects experience concretely according to Block, but generically according to

¹⁹ I speak as if we could know the determinate value of p -precision given as a real number here. But this is not required: There could be a determinate value without us being able to know it.

proponents of SGP. Allowing SGP thus blocks Block.

Additionally, generic phenomenology seems to be closely associated with *symbolic* or *rule-based*²⁰ representation. *Imagistic* representation, on the other hand, does not allow for such indeterminacy, because images exploit the isomorphisms between concreta. I can write “The cat is on the mat” without saying anything about whether the cat is a Siamese or a Maine Coon, or whether the mat is filled with feathers or made of bamboo, or whether the cat reclines, sits, or scratches on the mat. The sentence can represent the fact without resembling a cat or a mat at all. However, if I want to represent the fact that *the cat is on the mat* in an image, I have to depict something concrete: a specific cat at some position on a mat doing something. The common understanding of images is that they are concrete and as such determined in all their lowest-order properties. Analogue representations more generally exploit concreteness in order to represent by isomorphism.²¹

Introspectively, our phenomenal experiences resemble images. If phenomenal experience represents imagistically, then there cannot be SGP—and p -precision seems dangerously close to being trivial; if phenomenal experience is non-imagistic, then we can allow for SGP and render p -precision non-trivial—but this is in tension with some of Block’s other work and our introspective evidence.

Maybe a fixed p -precision value need not be bad for Block’s argument: if the p -precision of percepts is fixed, but r -precision varies, then there is a phenomenal feature that is not grounded in a representational feature. Thus, GR is false. However, Representationist have an easy reply: GR does not claim that all changes in representational features must be mirrored in phenomenal features; representational features only need to account for phenomenal features. If p -precision is fixed, then it might be grounded in

there being r -precision *at all*. For Block, accepting SGP might be a good option here—but not elsewhere.

4.3 Introspective imprecision?

There might be a way to reject SGP, but still account for our belief that we can experience a color as red without experiencing it as crimson. Maybe *experiencing as \mathfrak{F} without experiencing as any subsumable F* does not apply to phenomenal experiences, but to our *access* to them. That is, maybe there is *introspective* rather than phenomenal precision.²² This might go along the lines of Block’s interpretation of the Sperling experiment: we experience very specific shapes, but introspectively, we are only able to label them as *letters*, not as *A*, *B*, etc. So maybe the phenomenal aspects of our experience have fixed precision because it is never solely generic; but our introspective judgements are not fixed in precision because we can introspect some experience solely generically. That is, we may *judge* an experience of cayenne₆₆ to be red although we actually experience it as cayenne₆₆. If perception can be more or less imprecise, why can’t “internal perception”?²³

The notion of introspective imprecision, however, is not easily applied to the example of the patches in Carrasco et al. (2004): if we introspect on their appearance, then we judge them not as imprecise, but as of precisely the same contrast.

But maybe the imprecision of introspective access is not itself introspectively available: Our introspective access might be limited, such that all we can tell is that the patch

²² A reviewer noted that the limits of our vocabulary and our verbalization skills more generally might account for the lack of discrimination skills just as well as introspective imprecision. Even though this is a valuable point, I do not develop it here. First because I want to stick as close to the occurrent percepts as possible, not to our cognitive grasp of such percepts; second because introspective access precedes verbalization of the introspected; and third because failures of verbalization do not account for “introspective data”. Block is unapologetic about taking introspection seriously; a supportive critic should take it seriously as well.

²³ Many philosophers liken introspection to a form of perception, e.g., Locke (2008, II.xxvii.§9 & II.i.§4), Kant (2008, AA,III, tr.Äst.,§2), Brentano (1874), James (1890), Boring (1953, p. 170), Armstrong (1980, p. 61), Lycan (1996, p. 334), and to some degree Goldman (2006, pp. 242ff.) as well as Churchland (1985, 2005).

²⁰ The rule might be cultural, as with language, but also natural, as with causes: that the word “red” means the color ■ is based on a cultural rule; that *smoke* means *fire* is based on a natural rule.

²¹ This case has been made by Kosslyn (1980, p. 31) as well as Gombrich (2002). But see also Haugeland (1981), Lewis (1971), and Jackson (1960).

Figure 3: A 24-bit picture compared to a 6-bit picture. Shifting attention between the two while focusing on the + ought to provide some experience of indistinguishable character if experience in the periphery is more coarse grained.

we attend to is like the patch we don't attend to *in some respect*. However, our general introspective bias—that we think ourselves as authoritative about our own minds leads us to overrate what introspection offers: what we introspect as being more or less alike is judged as being strictly alike. This bias towards seeing ourselves as introspectively authoritative independent of whether we introspected successfully or not might lead to a wide variety of false beliefs about phenomenality.

The upshot would be that introspective imprecision is compatible with Block's distinction between access- and phenomenal consciousness. But introspective imprecision leaves it open whether SGP holds or not. It seems that we cannot decide based on introspection whether the character of our percepts or our introspective access to them is imprecise. We would need some other access to our phenomenality in order to settle the issue; but at this moment in time, nothing comes to mind that offers decisive evidence.²⁴

²⁴ This differs from the argument Block discusses: the attentional effect could be perceptual and conscious, but it is not really accessible what or how much actually changes in these circumstances due to introspective imprecision.

Block's writing suggests that he rejects introspective imprecision in this article (although he ought to accept it when defending the distinction between access- and phenomenal consciousness). If we reject it with him, how can we save the idea of percepts being more or less *p*-precise?

4.4 Limitation on characters?

The idea that parts of perceptual wholes can be more or less imprecise seems to stand in tension with the idea that all appearance-features can turn up anywhere in the phenomenal field: any appearance of contrast may appear in the fovea or periphery or where I attend or don't attend, etc. This had the odd consequence in my reconstruction that all phenomenal parts have the same degree of *p*-precision. How might we avoid this?

We could assume that the range of characters in the focus of attention and in the fovea is most fine-grained. Imagine being able to experience 100 shades of crimson in the attended fovea, but only 20 shades of crimson in the unattended periphery. This is reasonable for

contrasts as our sensitivity to it declines with eccentricity (Banks et al. 1991).

But this suggests that our experience is less continuous in the periphery. Instead, it is stepwise. This fits to the idea of precision having to do with bandwidths: in the attended fovea, we experience with a higher bit-rate than in the unattended periphery. It is like seeing a picture in 24- instead of 6-bit color depth (see figure 3).²⁵

But the coarse-grained character of experience outside of attention is not introspectable: if a light slowly changes color in our periphery, it does not look like it is doing so stepwise. It looks smooth and continuous. So somehow this idea only makes sense if we add the idea of introspective imprecision—and thereby inherit its problems.

So it is open how we should marry the idea of variances in phenomenal precision of a specific character with Block's overall view of conscious experience. Some more elucidation would be highly appreciated.

5 Conclusion

Ned Block has provided a beautiful argument against Ground Representationism—the position that for each phenomenal feature there is a representational feature that accounts for it. At its core is the notion of “phenomenal precision”: if we accept it, it seems that the degree of phenomenal precision of a percept changes differently to its degree of representational precision. Thus, there is no representational feature that accounts for this change in phenomenality—and Ground Representationism is false.

I have suggested a way of estimating phenomenal precision based on the assumption that parts of perceptual wholes can share characters independently of where they occur in the perceptual whole, and on the notion of a just noticeable difference as a lower bound of p -precision, which is inspired by Block's Phenomenal Precision Principle. Understood in this way, the argument shows what it is supposed to show: Ground Representationism is false.

But a deeper look at the notion of phenomenal precision suggests some tension with

Block's other work or with introspective evidence, which Block takes seriously. In order to allow for variation in the degree of precision, we have to accept that some of our experiences are not concrete, but solely generic. Such “solely generic phenomenology”, however, is a position mainly held by opponents to Block's *Access- vs. Phenomenal Consciousness-distinction*. Without accepting solely generic phenomenology, however, phenomenal precision seems either trivial (there is no variation) or contradictory (a percept can simultaneously have various degrees of p -precision). So the argument against Ground Representationism either hinges on a trivial or self-contradictory notion, *or* it is incompatible with Block's positions elsewhere. Patching this problem by allowing a limited range of characters outside our attention is again at odds with Block's other writing and with introspective evidence.

What is needed is a better understanding of phenomenal precision. What is it? How can we estimate it? I have suggested some possible ways to answer these questions, but all that I could come up with seems at odds with what Block has in mind. This certainly does not mean that there cannot be a suitable version of phenomenal precision that avoids these pitfalls—I am just unable to find it, and all that I can construct somehow goes against Block. I hope that Block has some ace up his sleeve, because the notion of phenomenal precision appears too fruitful to be abandoned too hastily.

Solely Generic Phenomenology

A Reply to Sascha Benjamin Fink

Ned Block

If representationism is true, phenomenal precision is given by representational precision. But what if representationism is false as I claim? Can we make sense of phenomenal precision? Fink argues that there is a danger of trivialization of phenomenal precision and that the one way out may be incompatible with my view that consciousness overflows cognition. I try to say more about how to clarify phenomenal precision and its relation to my views on overflow.

1 Introduction

I am grateful to Sascha Benjamin Fink for a thoughtful and insightful critique ([Fink 2015](#)) of my article ([Block 2015](#)). Fink's critique is full of novel and interesting ideas, formulations and proposals but is far too rich for me to respond to everything. I will focus on Fink's arguments to the effect that the concept of phenomenal precision is defective because there will be no unique precision to a phenomenal experience, specifically that phenomenal precision is either contradictory or trivialized by a "minimal" or "maximal" interpretation. I think Fink is right to focus on the concept of phenomenal precision since as he says

it is the aspect of my paper that most needs clarification. I argue that the key to solving the problem that Fink raises is to ask what the representationist should say about it. I then argue that the anti-representationist can make a similar move. In the last section I consider some variants of Fink's proposal for how to clarify phenomenal precision.

2 The thesis of solely generic phenomenology

I will start with the SGP thesis in Fink's terminology—the thesis that there can be "solely

generic phenomenology”. An example would be the experience of something as red without an experience as of any specific shade of red. Fink says I am forced to accept solely generic phenomenology but that it “has been introduced to argue *against* Block” (p. 10).

Fink is talking about my “overflow” arguments. These arguments are based partly on an experiment by George Sperling (Sperling 1960) that is covered in all respectable introductory psychology courses and on experiments from Victor Lamme’s lab in Amsterdam that combine Sperling with “change blindness” (Lamme 2003). The upshot of these lines of research is that there is more “capacity” in phenomenology than in cognition—or so I have argued. In the Sperling experiment, subjects are presented briefly with an array of letters, for example, 3 rows of 4 letters. Subjects say they see all or almost all of the letters but when asked to name the letters they saw after the stimulus has disappeared they can name only 3 or 4. Sperling’s innovation was to “cue” subjects to report one specific row after the offset of the stimulus, using a tone to indicate the row. The finding is that subjects can report 3 or 4 items from any given row, supporting the idea that their phenomenal “iconic” representation really did include information about the specific shapes of all or almost all the letters in the array.

In Lamme’s experiments the subject is briefly shown an array of, for example, 8 oriented rectangles. After the array is turned off, the screen goes dark for up to 4 seconds, then there is a second array of 8 rectangles in which one of the rectangles may have a different orientation (e.g., vertical rather than horizontal). A cue—a line pointing to the location of one of the rectangles—can occur when the screen is dark or, alternatively, when the second array appears. The subject’s task is to say whether the rectangle in the cued location has changed orientation. If there is no cue or if the cue comes after the new array has overwritten the iconic representation of the first array, subjects have a capacity of about 4 items. But subjects say they have a kind of image of the array in the dark period after the stimulus has gone off. When the cue is presented in the dark period

(up to 4 seconds later in some versions) after the stimulus has gone off they have a capacity of up to 7 of 8 items. I have argued that this pattern of results indicates that subjects have a persisting conscious mental iconic or imagistic representation of 7 of the 8 rectangles of sufficient specificity to compare orientations of the initial rectangles with the final display of rectangles even though they can “cognize” only about 4 of them—in the sense of storing them briefly in “working memory”. The upshot according to me is that there is more capacity in the phenomenal iconic representation than in cognition and thus that phenomenology “overflows” cognition.¹

The subjects report seeing all or almost all of the items and the cuing experiments—showing as they do “partial report superiority”—appear to back up what the subjects say. However, as Fink notes, my opponents² criticize my appeal to what the subjects say about their experience (Byrne et al. 2007). What is in the subjects’ consciousness might be just a generic representation—e.g., indicating that there is a circle of rectangles or array of letters without indicating the specific orientations of the rectangles or specific shapes of the letters. After all, we can’t expect naïve subjects to have a grip on the distinction between generic and specific phenomenology. Subjects say they have an image of all or almost all the items because they have a solely generic representation i.e., a representation that specifies the location of the items and their abstract category (letters, rectangles) but without the specific details (letter identity, orientation).

How do my opponents explain the fact that the subjects can get 7 of 8 rectangles right and 3 to 4 letters from any cued row if their phenomenal icons do not contain the specific information needed to do these tasks? According

¹ For experiments from the Lamme lab, see (Sligte et al. 2008, 2010, 2011; Vandenbroucke et al. 2011). This result has been replicated by other labs. See for example, (Freeman & Pelli 2007). My discussions of these experiments appear in (Block 2007a, 2007b, 2008). See also (Jacobson 2014) for a discussion of a different relationship between the dissociation between access and phenomenal consciousness and the dissociation between phenomenal character and representational content.

² He references (Grush 2007) but the point is also made in other critiques (Kouider et al. 2007; Papineau 2007; Van Gulick 2007)

to these opponents, the specific details of the shapes are registered unconsciously. And when subjects think they are reading details off of an already present conscious image, what they are really doing is making unconscious details conscious (Phillips 2011). Fink concludes that “Allowing SGP thus blocks Block.” (p. 10)

My response to Fink consists of three points: (1) my argument for “overflow” does not require any blanket rejection of solely generic phenomenology. (2) I have not issued any such blanket rejection and I have given qualified endorsement of some kinds of solely generic phenomenology. (3) I think there are some crucial cases—notably some spatial geometry cases in which there is reason to doubt solely generic phenomenology. I will explain these points.³

Why does Fink suppose I cannot accept generic without specific phenomenology? Part of his argument is that for an imagistic representation there cannot be generic without specific phenomenology because images are “concrete”. He says

Imagistic representation... does not allow for such indeterminacy, because images exploit the isomorphisms between concreta....Introspectively, our phenomenal experiences resemble images. If phenomenal experience represents image-like, then there cannot be SGP—and p-precision seems dangerously close to being trivial; if phenomenal experience is non-imagistic,

³ For the record, I used the generic/specific distinction in earlier papers (though not using that terminology including the one that these critics were replying to. For example, in discussing the Lamme experiment in the BBS paper to which all of these opponents were replying (Block 2007a), I said:

This supports what the subjects say, and what William James said, about the phenomenology involved in this kind of case. What is both phenomenal and accessible is that there is a circle of rectangles. What is phenomenal but in a sense not accessible, is all the specific shapes of the rectangles. (p. 488)

The phenomenology as of a circle of rectangles is generic phenomenology; the phenomenology as of the specific shapes is specific phenomenology. Further, in an earlier version of the argument based on the Sperling experiment in 1995 I also appealed to a version of the generic/specific distinction, although somewhat less explicitly (Block 1995, p. 244)

Here is the description I *think* is right and that I need for my case: I am P- conscious of all (or almost all - I will omit this qualification) the letters at once, that is, jointly, and *not just as blurry or vague letters*, but as specific letters (or at least specific shapes), but I don't have access to all of them jointly, all at once. [italics added]

then we can allow for SGP and render p-precision non-trivial—but this is in tension with some of Block's other work and our introspective evidence. (p. 10)

A similar argument to his was made by Robert Van Gulick (2007) and in a different form by Rick Grush. Van Gulick says

If one holds a “movie screen of the mind” model of phenomenal consciousness, it may seem impossible that there could be letters that are phenomenally present as letters without being present as specific letter shapes. But such a model is at best problematic, and if one rejects it, then there seems no reason why the characters of which the subjects are aware could not be indeterminate in ways that exactly match their limited cognitive access to those features. (p. 529)

In my 2007 reply to Van Gulick I rejected this argument and—contrary to what Fink says about my argument—I endorsed a version of the SGP. I said

Van Gulick notes that the “movie screen of the mind” view would say that you cannot have generic phenomenology without specific phenomenology, implicitly suggesting that I am relying on the “movie screen of the mind” view, and on the fact of generic phenomenology, to argue for specific phenomenology...I reject the principle – applied by ... Van Gulick – that pictorial representation has to specify the relevant details. I call this principle the “photographic fallacy” (Block 1983). More specifically, the photographic fallacy supposes that pictorial representations have to represent details of anything in view in the manner of a prototypical photograph. To see the fallacy, note that an impressionist painter might represent a hand in broad brush strokes that do not explicitly represent the number of fingers or whether one of them has a ring. (Block 2007b, p. 533)

It may be said that endorsing generic without specific phenomenology on my part is just incoherent since it undermines my own position. Recall that the reason Fink says I cannot endorse generic without specific phenomenology is that my opponents use it to argue that what is in consciousness in the Sperling and Lamme experiments is solely generic, the specific details being perceived unconsciously. My approach has not been to issue a blanket denial of the possibility of solely generic phenomenology but rather to argue against the claim that the highly specific representations in these experiments are unconscious (Block 2007a, 2011, 2014b).⁴

Is solely generic phenomenology possible? There certainly are some intuitively plausible (though not compelling) cases. For example, if one sees a red thing in the distance one may perhaps see it as red without seeing it as having any specific shade of red. (See Stazicker 2011, forthcoming for defenses of solely generic phenomenology.) However, even if there is generic phenomenology, I think it is doubtful in some cases, notably certain spatial cases. In particular, I doubt that there can be generic phenomenology of an oriented rectangle that does not specify the rough orientation of the rectangle.⁵

My rationale for this view is partly introspective and partly a result of informal reports of imagery experiments from Stephen Kosslyn. I have discussed doing experiments on this issue with Kosslyn and Dan Reisberg.

Imagine that you are in a house, going down the stairs and out the front door. In front of you is a picket fence with a gate. You go out through the gate and walk to the corner where you mail a letter.

⁴ If you want to get a brief taste of the kind of argument I have in mind, look at one of: (Block 2014a, 2014b). In one of the articles cited (Bronfman et al. 2014), evidence is provided of specific information about uncued rows in a Sperling-like experiment. What I especially like about this experiment is that the authors provide 3 different tests of the claim that the specific information in the uncued rows is conscious.

⁵ In (Block 2011), I said “...generic conscious representations of non-square rectangles that do not specify between horizontal and vertical orientations is difficult to accept.” Note that this is not a blanket denial of the possibility of solely generic phenomenology but rather a denial of one specific kind of solely generic phenomenology. Hilla Jacobson and Hilary Putnam relate this kind of point about imagery to a principle of “cohesiveness” of the various aspects of an image (Jacobson & Putnam forthcoming).

Stop now and answer the question: which way did you turn when you went out through the gate? Kosslyn reports in conversation that when he gives such spatial vignettes to subjects they do not report that there was no particular direction. The experimental challenge is to design an experiment that distinguishes between an answer made up on the fly and an answer based on what was “already there” in the image.

To summarize so far: Fink says “Allowing SGP thus blocks Block.” I reply that my argument for “overflow” does not require any blanket rejection of solely generic phenomenology; that I have not issued any such blanket rejection; that I have endorsed the possibility of solely generic phenomenology; and that I think there are some specific cases in which solely generic phenomenology is not very plausible.

3 Is the concept of phenomenal precision incoherent?

According to Fink, if there is no solely generic phenomenology (i.e., generic without specific phenomenology) then the concept of phenomenal precision is threatened by incoherence. What is Fink’s argument for this conclusion? Suppose there is no solely generic phenomenology. Then, according to Fink, “...the p -precision of an experience is either contradictory, generally minimal, or generally maximal, which trivializes the notion.” (p. 9) And why is that? Because, according to Fink, if you experience the color of his Figure 2 as cayenne₆₆, then if you also experience it as red, then there will be no unique precision to the experience. For red has a much wider precision range (i.e., lower precision) than cayenne₆₆. His solution is to allow for experiencing it as red without experiencing it as any specific shade: generic without specific phenomenology.⁶

Let us approach this issue by asking what *the representationist should say by way of response to Fink’s concern that there will be no unique visual precision*. Then we can ask whether some version of that response is available to me.

⁶ Of course uniqueness does not require solely generic or solely specific phenomenology. Any sole level will do.

Recall that representationists must acknowledge phenomenal precision (assuming they acknowledge representational precision) since on their view, if the representational precision of one conscious perceptual representation is greater than the representational precision of another conscious perceptual representation, then the phenomenal precisions must follow suit. Phenomenal precision—on their view—is just the shadow of representational precision. But when we see a cayenne₆₆ object as cayenne₆₆, do we thereby also see it as red? It is often supposed that this is some sort of necessity (Confession: I once thought that). To his credit, Fink points out that this is false. He says (footnote 17):

Conceptual or nomological relations do not necessarily transfer to the realm of experiences. Imagine seeing an animal as a mouse. One does not thereby see it as an owner of a heart, or as a member of the phylum chordata even though all mice belong to each category necessarily.⁷

Certainly Fink is right that seeing something as a mouse does not require seeing it as a chordate. However, he thinks any experience of cayenne₆₆ is “likely” to be an experience of red. He doesn’t say how he knows this.

Here is a tempting but wrong view that I believe may stand behind what Fink says (and is also exemplified I believe in Begby 2011 and in a more complex form in Siegel 2010). Look at the cayenne₆₆ patch in Fink’s Figure 2. I know what a red thing looks like and I can tell from looking that it is red because...well...it looks red. So I visually represent it as red. Similarly, it looks colored. And a baseball bat looks like a baseball bat, so I visually represent it as a baseball bat.

However, I also know what a 1969 Chevrolet Camaro looks like, as well as what a 1961 Jaguar E-type looks like. Do I thereby visually represent the property of being a 1969 Camaro or a 1961 E-type? I know what my wife looks

like. Do I thereby have a singular visual representation that represents her? Perhaps what I am really visually representing in each of these cases is just constellations of low level properties that are recognitionally equivalent to the property of being a 1961 Jaguar E-type or to the singular property of being my wife.

I have argued that the extent of seeing-as in the sense of visual representation is not a matter for the armchair (Block 2014c). From the armchair one does not know whether something’s looking like a 1961 Jaguar E-type is a matter of representation of constellations of colors, shapes, textures, illumination, motion and other low level properties as opposed to an actual representation of the property of being a 1961 Jaguar E-type.

For example, I give evidence that we can visually represent facial expressions (high level property) and in addition constellations of colors, shapes, textures, etc. (low-level properties). The evidence is that there are distinct “adaptation” effects for both the low and high-level properties. (Adaptation is the neural “fatigue” effect underlying afterimages.) For example, if you vary the low level properties but keep the face identity (or expression or just faceness) constant, you get smaller adaptation effects, showing an extent of low level perception. And the fact that there is a residual face adaptation effect is one of many items of evidence favoring face-specific perception.

You can experience such an adaptation effect for yourself. Stare at the picture on the right for 1 minute, covering the two pictures on the left with something. Then very briefly look at the center picture asking yourself whether it looks more fearful or more angry. Now cover the two pictures on the right and stare at the picture on the left for one minute. Now look at the center picture very briefly again. It will appear to have a different expression. The center picture is a morph of a fearful face and an angry face. When you adapt to the fearful expression you are more likely to see the morph as angry-looking and conversely for adapting to the angry expression. This doesn’t prove that there is an adaptation effect for facial expression over and above adaptation effects for constellations

⁷ By “owner of a heart” he must mean some sort of biological classification (on a par with chordate) since obviously any individual mouse could lose its heart (even briefly staying alive) and still be a mouse.

of low level properties. The best one can do is form hypotheses about what those low level properties might be and vary those properties keeping expressions constant.

In addition, one can look for other signs of visual representation of faces or facial expressions. For example, faces show “visual popout”. Since typically “conjunctive” properties do not show visual popout, that fact suggests that visual representations of faces are not “conjunctive” properties and hence not conjunctions of low level features. The upshot of this and other work I cannot describe here (Block 2014c) is that it is very likely that there are representations of face-attributes such as facial expressions in addition to representations of low level properties.⁸

Figure 1: From Butler et al. (2008) with permission of Elsevier

The upshot of all this is that a single visual experience can represent both low level properties and high level properties. So: there can be distinct precisions for the different representations. For example, the precision of the experiential representation of fearfulness could be ascertained by investigating how much variation in the percentage of fearfulness in a morph like the middle one in the figure above is compatible with exactly the same visual representation of fearfulness. And similar methods could be used to ascertain precisions for the low level properties that are represented. There is no reason to expect these precisions to be the same.

An experience that represents cayenne₆₆ could also represent red and there could be dis-

tinct precisions for each of these representations. And what goes for representational precision also works for phenomenal precision. If more than one property is genuinely present in phenomenology then there can be distinct precisions for the distinct properties. So the solution for the representationist works even if representationism is false.

So why is there supposed to be a problem concerning unique precisions? Fink argues as follows

You might think that this color experience has two p-precision values: The first value is for being experienced as red, and the second for being experienced as cayenne₆₆. But this seems contradictory: why should one and the same experience of a color have two p-precision values, but only one for r-precision? And for that matter, why not three values for p-precision? You likely experience the color not only as cayenne₆₆ and as red, but also *as a color*? Why not four, then, if you experience it *as a visual experience*? Or five, if you experience it *as phenomenal*? [NB: p-precision is phenomenal precision; r-precision is representational precision]

The argument is not spelled out but one can guess that it depends on the idea that there is incoherence because there is no end to the number of properties that are present in experience. (Fink seems to suppose that there are not multiple representational precisions but does not say why.) We don’t need to see exactly what the argument is supposed to be to see that this premise is wrong. There is absolutely no evidence that experiences of colors present (or represent) colors as colors or as something or as phenomenal. These presentations and representations cannot be simply postulated. The reason that I went through the example of fearfulness was to give the reader a sense of how much work has to be done to show representation of a high level property. The problem in Fink’s argument is the assumption that you “likely” experience his Figure 2 not only as cayenne₆₆ but as a

⁸ In his reply to me (2014), Burge is more skeptical than I am about the power of appeals to adaptation, arguing that adaptation needs to be combined with other methods.

color and the insinuation—not explicitly stated—that you experience it as something and as phenomenal. There is simply no reason to believe this.

On my view, color experience—like all perceptual experience—is non-conceptual. But the point is even stronger if color experience is conceptual since then the concept of color and the concept of something would be required to see the cayenne₆₆ patch as colored and as something. Ask yourself whether an animal that can visually represent the color patch in Figure 2 as cayenne₆₆ must also represent it as red or as colored. Must the animal be able to attend to or notice the redness or the coloredness as well as the specific shade? Or consider 4 month old human babies whose color perception is known to be good but who do not appear to notice colors to the extent of being able to use color information to judge whether there is one or two items. Even two year old children are so bad at conceptualizing color that a term was coined in the early 20th Century, “*farbendummeit*” (color stupidity), to describe their cluelessness. Darwin thought his own children were color-blind because they were so poor at learning color names (Bornstein 1985; Campbell 2014).

To conclude this section: uniqueness of precision is not required for coherence. The representationist can reasonably hold that to the extent that there is more than one representational content, there is more than one precision: precision of representation depends on what representation is in question. And the same can be said of what properties are *presented* in perception as opposed to represented in perception, even if as I argue, representationism is false.

4 How not to clarify phenomenal precision

Here is a tempting idea about representational precision. Representational precision is just a matter of how much the stimulus can change without changing the representational content of the subsequent perception. And the same idea extends to phenomenal precision: phenomenal precision is a matter of how much the stimulus can change without changing the phenom-

enal character of the perceptual state. Of course these ideas would not be useful if one included stimulus changes that don’t make a difference when the subjects’ eyes are closed or in the dark or in a dust storm. So the proposal does not get even to first base without specifying that the circumstances of perception must be ideal.

Here is an example: Suppose one is looking at an oriented line. If a change of up to but not beyond plus or minus 1 degree makes no difference in the percept of the orientation in ideal conditions, then the representational precision is plus or minus 1 degree. And the same thought also covers phenomenal precision. If a change of up to but not beyond plus or minus 1 degree makes no difference in the phenomenology of the percept of the orientation in ideal conditions, then the phenomenal precision is plus or minus 1 degree. One advantage of this conception of precision is that representational and phenomenal precisions will be comparable. And representationist ideas can be tested. If phenomenal precisions are smaller, i.e., more precise than representational precisions, then representationism is definitely over.

I like this idea of precision for cases in which it is fairly clear what ideal conditions would consist in. But if one is concerned that phenomenal precision is not a coherent notion, this suggestion will not be of much help. The problem with this suggestion is that the notion of ideal conditions will inevitably smuggle in the ideas that are supposedly being explained. In the case of representational content, the problem has often been called the “problem of error” (Fodor 1987): representational states correlate best—not with their truth conditions—but with conditions that include systematic error. A notion of ideal conditions that avoided this consequence would itself have to distinguish between veridical and falsidical representations (see Adams & Aizawa 2010).

Fink’s proposal about phenomenal precision sometimes sounds like the correlational idea just mentioned—that phenomenal precision is a matter of how much the stimulus can change without changing the phenomenal character of the subsequent perception in ideal cir-

cumstances. However, Fink goes on to explicate the notion of *change in the phenomenology of the percept* in terms of discernability: “for example, the pain caused by 480mc/sec/cm² is not reliably discernible from one caused by 640 mc/sec/cm².” And he goes on to spell this out in terms of the lower bound on p-precision being the range of cases “one cannot distinguish by experiencing as *F* under ideal conditions.” (p. 8). In the conclusion of the paper, Fink describes his proposal in terms of the notion of a “just noticeable difference [JND] as a lower bound of p-precision.” (p. 12)

However, what one can distinguish from what is a matter not just of phenomenology but of an interaction between phenomenology and cognition. As I noted (Block 2015, sections 6 & 10), discriminability is neither necessary nor sufficient for phenomenal difference. It is not sufficient because there are sometimes ways of discriminating between percepts that do not depend on a phenomenological difference, such as beats on vibrating strings. And it is not necessary because not all phenomenological differences need be accessible to the cognitive apparatus of the subject. I mentioned phenomenal Sorites cases (Morrison 2015) in connection with this point. As has often been noted, colors A and B may be indistinguishable because the difference between color A and color B is below the JND. And B may be indistinguishable from C for the same reason even though A is distinguishable from C. One way of thinking about this is that A and B may actually look different—i.e., produce percepts with different phenomenologies, but the difference in phenomenologies may be cognitively inaccessible. If so, noticeable differences will not track phenomenal differences.⁹

In short: phenomenal precision can be explicated in terms of the extent to which the stimulus can change in ideal conditions without changing the phenomenology of the resulting percept; but explaining changes in the phenomenology of the percept in terms of noticing or in terms of discrimination brings in an interaction with cognition that ruins the explication.

I welcome Fink’s suggestions about how to explicate phenomenal precision so long as the notions of discrimination and noticing are stripped from the explication and it is acknowledged that we have no reductive account of ideal conditions. And I acknowledge the possibility of solely generic phenomenology but I don’t think it creates the problem Fink mentions for my overflow arguments.

⁹ Fink seems to acknowledge such points in footnotes 14 and 22 but somehow ignores them in explicating phenomenal precision.

Rules: The Basis of Morality... ?

Paul M. Churchland

Most theories of moral knowledge, throughout history, have focused on behavior-guiding *rules*. Those theories attempt to identify which rules are the morally *valid* ones, and to identify the *source or ground* of that privileged set. The variations on this theme are many and familiar. But there is a problem here. In fact, there are several. First, many of the higher animals display a complex social order, one crucial to their biological success, and the members of such species typically display a sophisticated knowledge of what is and what is not acceptable social behavior—but those creatures have no *language* at all. They are unable even to *express* a single rule, let alone evaluate it for moral validity. Second, when we examine most other kinds of behavioral skills—playing basketball, playing the piano, playing chess—we discover that it is surpassingly *difficult* to articulate a set of discursive rules, which, if followed, would produce a skilled athlete, pianist, or chess master. And third, it would be physically impossible for a biological creature to identify *which* of its myriad rule are relevant to a given situation, and then apply them, in real time, in any case. All told, we would seem to need a new account of how our moral knowledge is stored, accessed, and applied. The present paper explores the potential, in these three regards, of recent alternative models from the computational neurosciences. The possibilities, it emerges, are considerable.

1 Introduction

An old college teacher of mine once remarked to me that “[a] philosopher’s fundamental mistakes often appear on the very first page of his major treatise”. A possible instance of this eyebrow-raising historical insight is the opening page of the long section on moral philosophy found in the prominent undergraduate philosophy textbook entitled *Introducing Philosophy*—from *Oxford University Press*, no less—skillfully edited by Robert C. Solomon (2001). Solomon there begins his broad survey of this profound and important topic with the following explanatory definition:

The core of ethics is morality. Morality is a set of fundamental rules that guide our actions.

You may well wonder how there could be anything controversial about this lucid statement, for it does indeed capture the focus of at least ninety percent of the moral philosophers’ writing in the Western traditions of religious and academic philosophy. It also captures the focus of most contemporary moral discussions, even in the marketplace and at the dinner table. We are all familiar with, and frequently argue about, presumptive “moral rules,” both major and minor. We are all familiar with the competing rationales often offered in explanation of the presumed authority of such rules—that they come from God, or that they are part of the social contract, or that (when followed) they serve to maximize collective welfare, and so forth. How *else* should we focus and pursue our con-

cern with moral reality? How else might one even *begin* to address the topic?

Hereby hangs a tale. For there are indeed other ways of approaching the topic, both as engaged citizens and as theorizing philosophers. A monomaniacal fixation on *rules* and on the source of their *authority* may reflect a fundamental misconception of what is actually going on inside successful moral agents when they engage in typical moral cognition. It may misrepresent the underlying nature of anyone's precious moral virtue. It may misrepresent the learning process by which the moral virtues are acquired. And it may misrepresent the ways in which those virtues are actually exercised in our day-to-day moral reasoning.

Before citing historical/moral authorities in hopes of winning some credence for this admittedly audacious suggestion, let us survey some of the many *non-moral*, *empirical*, or *factual* reasons for entertaining an approach to understanding morality that is not focused on rules. Such extra-moral reasons are not hard to find.

First, and perhaps foremost, rules in the literal sense require a language in which they can be expressed (and taught, and imposed, and discussed, and modified). But none of the many social creatures on this planet—excepting only humans—possess any language at all, and certainly none equal to the task of expressing even the simplest of social rules. Chimpanzees, wolves, baboons, and lions, for example, are quite innocent of language, and yet their collective behavior displays a complex social order that the adult animals must respect—on pain of punishment or retribution from their peers—and which the juveniles must learn to recognize, understand, and eventually protect with their own watchful behavior. They, too, live within a more-or-less stable moral order that serves many if not most of the same functions served by our own moral order. An adult chimp will chide, sometimes severely, a juvenile chimp that steals food from the hands of an infant chimp, and will even return the stolen food to the aggrieved victim. Wolves, and even domestic dogs, will offer comfort and solace to a wounded com-patriot and will spring to defend it against fu-

ture threats. The trust, social foresight, and mutual dependence displayed by a pack of lions organizing and executing a hunt to bring down a gazelle is a marvelous example of collective purposeful activity. And the subsequent sharing of the spoils among all who participated in the hunt is a striking example of distributive justice, even if momentary squabbles occasionally break out over access to the choicest bits of the kill. (Nobody is morally perfect, especially a tired and hungry lion.)

In sum, moral perception, moral reasoning, moral activity, moral norms, moral defense, and moral retribution all exist elsewhere in the animal kingdom (presumably for many of the same reasons that they exist in us), but in none of those other cases do language or discursive rules play any role at all in the moral phenomena at issue. The whole thing happens—most of it, anyway—but without language.

So what is going on? What is it that regulates or steers their behavior, if not rules? Before canvassing possible answers to this question, let us ponder some additional data, this time concerning humans. Adult humans occasionally fall victim to something called *global aphasia*, a stroke-induced brain malady in which the cortical areas responsible for the manipulation, production, and comprehension of *language*—in any form: spoken, written, or printed—are totally destroyed. The loss of this critically important neuronal machinery (roughly, Broca's area and Wernicke's area, typically on the left side of the brain) leaves the victim without any capacity to formulate, process, or comprehend any linguistic structures whatsoever. That dimension of cognitive representation is now completely out of business. There is nothing wrong with the victim's sensory inputs or motor outputs; these peripheral systems remain entirely functional. The cognitive deficit lies deeper. The capacity for even *forming* linguistically structured thoughts has disappeared entirely. The victim cannot formulate or comprehend any declarative sentence, nor any interrogative sentence, nor any imperative sentence, nor any rule. These elements, so familiar to the rest of us, no longer play any role in their cognitive lives.

And yet their cognitive lives in other respects remain surprisingly unaffected, despite this disaster where specifically *linguistic* structures are concerned. Some three decades ago, we had such a left-brain stroke victim in our own extended family. Aunt Betty, as she was fondly called, could still drive a car around town, shop for the groceries, cook a dinner, and watch a football game on TV with understanding and enjoyment. More to the point, her basic trust in other humans, and her own basic trustworthiness, were quite intact. During visits, her comprehension of the moral flux around her, especially where the adventures and interactions of our youngish children were concerned, seemed quite undiminished, as were her skills in providing comfort for the teary-eyed and fairness in the distribution of small pastries at lunch. Her moral cognition was up and running smoothly, evidently, much as before—but without the benefit of any rules to tell her what to do. She could no longer comprehend or even contemplate them, and yet somehow, she didn't need them.

Another illustration of the superfluity of rules to moral character emerged, without warning and to much amusement, in an interview of a moderately charming Georgia Congressman on the TV comedy show *The Colbert Report*. The topic of their extended discussion was a recent higher-court ban on the public display of the Judeo-Christian Ten Commandments in the foyer of a Louisiana courthouse, and the justice/injustice of their subsequent court-ordered removal from that public venue. The congressman, a Mr. Lynn Westmoreland, was defending their public, cast-bronze-on-granite display on a variety of grounds, but most trenchantly on the grounds that, collectively, those ten rules constitute the very foundation of our morality, insofar as we have any morality. Their public display, therefore, could only serve to enhance the level of individual morality.

Sensing an opportunity, Steven Colbert nodded his presumptive assent to this claim, and asked his guest, “Could you please cite them for us, congressman?” Westmoreland, plainly taken aback by the request, gamely began, “Don't lie, . . . don't steal, . . . don't kill,

. . .” as Colbert, with his eyebrows raised in expectation, held up first one finger in response, then two, then three. After an awkward pause at that point, the congressman, who had plainly drawn a blank beyond those three, bravely and with evident honesty said, “No, I'm sorry. I can't name them all”. My immediate reaction (oh, alright, my second) was sympathy for the congressman, because I don't think I could have named them all, either. At which point Colbert ostentatiously thanked his guest for his wisdom and brought the interview, before a large audience, to an uproariously received and laughter-filled conclusion.

The comedic point was plain enough and doesn't need any further elaboration from me. But there is a deeper lesson to be drawn from this exchange. The fact is, the congressman is probably as good an example of worthy moral character as one is likely to encounter at one's local post office or grocery store. After all, he inspired sufficient public trust to get himself elected, and he thinks morality important enough to defend it, with some passion and resourcefulness, on television. He is a presumptive example of a conscientious man with a morally worthy character. But if he is, these welcome virtues are clearly *not* owed to his carrying around, in memory, a specific list of discursive rules, rules at his immediate command, rules that he literally consults in order to guide his ongoing social behavior. He could remember only three of the ten “commandments” at issue, and, if you check the bible, he didn't get two of those three quite right in any case. If we are looking (and we *are*) for an explanation of the actual ground or source of people's moral behavior, the proposal that we are all following a specific and finite set of discursive *rules* in order to produce that behavior is starting to look strained and threadbare, to put it mildly.

Before addressing an alternative explanation, let us note one further domain of empirical evidence, relevant to our issue concerning the role of rules. Moral expertise is among the most precious of our human virtues, but it is not the only one. There are many other domains of expertise. Consider the consummate skills displayed by a concert pianist, or an all-star bas-

ketball player, or a grandmaster chess champion. In these cases, too, the specific expertise at issue is acquired only slowly, with much practice sustained over a period of years. And here also, the expertise displayed far exceeds what might possibly be captured in a set of discursive rules consciously followed, on a second-by-second basis, by the skilled individuals at issue. Such skills are deeply inarticulate in the straightforward sense that the expert who possesses them is unable to simply *tell* an aspiring novice *what to do* so as to be an expert pianist, an effective point guard, or a skilled chess player. The knowledge necessary clearly cannot be conveyed in that fashion. The skills cited are all cases of knowing *how* rather than cases of knowing *that*. Acquiring them takes a lot of time and a lot of practice.

To be sure, the point-guard can instruct the novice, “When you get possession of the ball at your end, dribble it down the floor toward the opposition’s basket, and when the defense starts to resist, pass the ball to whichever of your teammates has the best chance of sinking a shot.” But this rule, even if it is tattooed on the novice’s forearm, will hardly make him an effective player. It doesn’t tell him how to *dribble* effectively, nor could any other list of rules. It doesn’t tell him how to *recognize* a teammate’s fleeting opportunity to take a high-percentage shot, or perhaps set one up for yet a third player. It doesn’t tell him how to *pass* the ball so as to avoid interception, or how to *deceive* the defense with various kinds of fakes and feints. It doesn’t even address the issue of how to execute any one of the dozen or so different kinds of shots he himself might have to take, or when to take them. It doesn’t tell him .01 percent of what he needs to know to be a skilled player. And even if he did somehow memorize 10,000 rules on all of these diverse topics, he couldn’t possibly recall, from that vast store, exactly the rule relevant at any instant and then apply it swiftly enough to steer his ongoing play. The game unfolds much too quickly for that plodding strategy to be effective. Something else is going on inside the basketball player’s head. Something else entirely.

The game of chess is much slower, of course, and simpler too. But the same lesson emerges here as well, although from an unexpected direction. Unlike the basketball case, and because of the discreteness and comparative simplicity of chess, computer programmers have indeed written computer programs—that is, large sets of literal rules for the computer to consult and follow—that will enable a computer to play a creditable game of competitive chess. These programs were common by the early 1980s, and they were competent enough to defeat non-expert human chess players (such as me) quite regularly.

The computer-guiding rules were written so as to address any arbitrary configuration of chess pieces on the board, as might emerge in the course of a game, and to evaluate, in sequence, the cost or benefit of each of the perhaps thirty legal moves (or something in that neighborhood—it will vary) then available to the computer. To be at all effective, this strategy requires that the computer also considers the potential cost/benefit (to the computer) of its opponent’s possible *responses* to each of those contemplated moves. Each such response would of course present the computer with a new set of possible moves of its own, each requiring evaluation, and so on, for another cycle of possible moves-and-responses. If the computer is to look ahead in this fashion for only two cycles of play, it will already be evaluating something like $(30 \times 30) \times (30 \times 30) = 810,000$ or almost a million possible move-sequences! And if it presumes to look forward, in this brute-force evaluative fashion, a mere *four* cycles of play, its task explodes to examining the cost/benefit ratio for almost a *trillion* possible move-sequences.

Now you and I could never hope to execute a game-strategy of this kind, but a computer can, although just barely. Let us assume that the computer’s central processing unit (CPU) has a clock-frequency of, say, 100 Megahertz (= 100 million elementary computations per second), a fairly modest machine, these days. Such a computer will take only $(1 \text{ trillion moves to be evaluated}) / (100 \text{ million evals/sec}) = 10,000 \text{ seconds}$, or about three hours to com-

plete its evaluation of four cycles of play, assuming that the cost/benefit estimate for each move-sequence (a comparatively simple matter) can be calculated in a single elementary computation.

“But this is still ridiculous,” you might say. “Three *hours* of mulling per turn!? That’s not even legal. And looking ahead only four move-cycles? *That’s* not going to defeat a really good human chess player.” And you would be right. But in fact, some artful pruning of the decision-tree constructed by the computer’s program (e.g., through ignoring some possible moves, on both sides, that are likely to be irrelevant) will substantially reduce the combinatorial explosion in the number of moves that need to be evaluated. This can reduce the time of evaluation from three hours to perhaps three minutes, though at some cost to security. A somewhat faster CPU might further reduce it to less than three seconds. And the occasional deployment of a slightly more penetrating five or six-cycle lookahead evaluation for the occasional moves of potentially great value, positive or negative, can add some deeper, if localized, insight without adding too much in the way of a computational burden. In these ways the programmed computer can be brought into the range of real-time chess competence, even excellence.

Still, it is worth remarking that it took over three decades of program and computer development before a chess-playing computer was finally able to defeat a world-champion human chess master. The Russian master Gary Kasparov (poor devil) finally went down to an IBM monster computer named “Deep Blue” in 1997, to the celebration of nerds and technophiles everywhere (Campbell et al. 2002). That is, the gross strategy of applying discursive rules, again and again at blistering speeds, finally paid off. But it did so only because the computer CPU’s clock-speed was roughly a million times faster than any cyclic process in a human brain (which maxes out at a mere one hundred cycles per second) and only because the conduction velocity of the electrical signals inside the computer (almost the speed of light) was roughly a million times faster than the conduction velo-

city in a human nerve fiber (about the speed of a fast bicycle rider). These make the computer about (a million times a million =) a *trillion* times faster than we are. Without these singular and *superhuman* physical advantages, the computer and its list of rules—its program—would be dead in the water. And so would we humans, if the rule-based strategy were how human chess-playing competence is grounded. But plainly it is not. It couldn’t possibly be. Something else is going on inside the human chess-master’s head. Something else entirely.

2 An alternative account of moral skill

We have only recently begun to understand what that “something else” is. It has to do with the peculiar way the brain is wired up at the level of its many billions of neurons. It also has to do with the very different style of representation and computation that this peculiar pattern of connectivity makes possible. The basics are quite easily grasped, so without further ado, let us place them before you.

The first difference between a conventional digital computer and a biological brain is the way in which the brain *represents* the fleeting states of the world around it. The retinal surface at the back of your eye, for example, represents the scene currently before you with a pattern of simultaneous (repeat: simultaneous) activation or excitation levels across the entire population of rod- and cone-cells spread across that light-sensitive surface. Notice that this style of representation is entirely familiar to you. You confront an example of it every time you watch television. Your TV screen represents your nightly news anchor’s face, for example, by a specific pattern of brightness levels (“activation” levels) across the entire population of tiny pixels that make up the screen. Those pixels are always there. (Tiptoe up to the screen and take a closer look.) What changes from image to image is the *pattern* of brightness levels that those unmoving pixels collectively assume. Change the pattern and you change the image.

It is the same story with any specialized population of neurons, such as the retina in the eye, the visual cortex at the back of the brain,

the cochlea of the inner ear, the auditory cortex, the olfactory cortex, the somatosensory cortex, and so on and so on. All of these neuronal areas, and many others, are specialized for the representation of some aspect or other of the reality around us: sights, sounds, odors, tactile and motor events, even features of social reality, such as facial expressions. These neuronal activation-patterns need not be literal *pictures* of reality, as they happen to be in the special case of the eye's retinal neurons. But they are *representations* of the fine-grained structure of some aspect of reality even so, for each activation-pattern contains an enormous amount of *information* about the external feature of reality that, via the senses and internal brain pathways, ultimately produced it.

Just *how much* information is worth noting. The retina contains roughly 100 million light-sensitive rods and cones. (In modern electronic camera-speak, it has a rating of one hundred megapixels. In other words, your humble retina still has *ten times* the resolution of the best available commercial cameras.) Compare this to the paltry representational power of a typical computer's CPU: it might represent at most a mere 8 bits at a time, if it is an old model, but more likely 16 bits or 32 bits for a current machine, or perhaps 64 or 128 bits for a really high-end machine. Pitiful! Even an old-fashioned TV screen simultaneously activates about 200,000 pixels, and an HDTV will have over two-thirds of a million ($1,080 \times 640 = 691,200$ pixels). Much better. But the retina, and any other specialized population of neurons tucked away somewhere in the brain, will have roughly 100 million simultaneously activated pixels. Downright excellent. Moreover, these pixels—the individual neurons themselves—are not limited to being either on or off (i.e., to displaying a one or a zero), as with the elements in a computer's CPU. Biological pixels can display a smooth variety of different excitation levels between the extremes of 0 percent and 100 percent activation. This smooth variation (as opposed to the discrete on/off coding of a computer's bit-register) increases the information-carrying capacity of the overall population dramatically. In all, the representational technique

deployed in biological brains—called *population coding* because it uses the entire population of neurons simultaneously—is an extraordinarily effective technique.

The brain's *computational* technique, which dovetails sweetly with its representational style, is even more impressive. (As with any computer, a computational operation in the brain consists in its *transforming* some input representation into some output representation.) Recall that any given representation within the brain typically involves many millions of elements. This poses a *prima facie* problem, namely, how to deal, swiftly, with so many elements. Fortunately, what the brain *cannot* spread out over *time*—as we noted above, it is far too slow to use that strategy—it spreads out over *space*. It performs its distinct elementary computations, many trillions of them, each one at a distinct micro-place in the brain, but all of them at the *same time*. Let us explain with a picture so you can see the point at a glance.

At the bottom of figure 1 is a cartoon population of many neurons—retinal neurons, let us suppose. As you can see, they are currently representing a human face, evidently a happy one. But if the rest of the brain is to *recognize* the specific emotional state implicit in that sensory image, it must *process* the information therein contained so as to activate a specific pattern within the secondary patch of neurons just above it. That second population, let us further suppose, has the proprietary job of representing any one of a range of possible *emotions*, such as happiness, sadness, anger, fear, boredom, and so forth. The system achieves this aim by sending the entire retinal activation-pattern upward via a large number of signal-carrying axonal fibers, each one of which branches at its upper end to make fully eighty *synaptic connections* with the neurons at this second layer. (Only some of these axonal fibers are here displayed, so as to avoid an impenetrable clutter in the diagram. But every retinal neuron sends an axon upward.)

When the original retinal activation-pattern reaches the second layer of emotion-coding neurons, you can see that it is forced to go through the intervening filter of (4,096 axons \times

80 end-branches each = 327,680) almost a third of a million synapses, *all at the same time*. Each synaptic connection magnifies, or muffles, its own tiny part of the incoming retinal pattern, so as collectively to stimulate a *new* activation-pattern across the second layer of neurons. That new pattern is a representation of a specific emotion, in this case, happiness. The third and final layer of this neural network has the job of discriminating these new 80-element patterns, one from another, so as to activate a single cell that codes specifically for the emotion still opaquely represented at the second population. That is achieved by tuning a further population of synaptic connections from every cell in the middle layer to each of the five cells in the final layer. In all, what was only *implicit* in the original retinal activation-pattern (mostly in the mouth and eyebrows) is now represented *explicitly* in the top-most activation-pattern across the five cells there located.

Figure 1

This trick is swiftly turned by the special configuration of the various *strengths* of each of the intervening synaptic connections. Some of them are very large and have a major impact in exciting the upper-level neuron to which it is attached, even for a fairly weak signal arriving from its retinal cell. Other connections are quite small and have very little excitatory impact on the receiving cell, even if the arriving retinal

signal is fairly strong. Collectively, those 327,680 synaptic connections have been carefully adjusted or tuned, by prior *learning*, to be maximally and selectively sensitive to just those aspects of any face image that convey information about the five emotions mentioned earlier, and to be “blind” to anything else. The complex “pattern transformation” they effect plainly loses an awful lot of information contained in the original (retinal) representation. Indeed, it loses most of it. But it does succeed in making explicit the specifically emotional information that this little three-layer “neural network” was designed to detect.

This style of computation is called Parallel Distributed Processing (PDP), and it is your brain’s principal mode of doing business on any topic. Even in this cartoon example, you can see some of the dramatic advantages it has over the “serial” processing used in a digital computer. A typical 8-bit CPU has a population of only eight representational cells at work at any given instant, compared to fully 4,096 just for the sensory layer of our little cartoon neural network. The CPU performs only eight elementary transformations at a time, as opposed to 327,680 for the neural network, one for each of its 327,680 synaptic connections. When we consider the human brain as a whole instead of the tiny cartoon network above, we are looking at a system that contains roughly a thousand distinct neuronal populations of the same size as the human retina, all of them interconnected in the same fashion as in the cartoon. This gives us (1,000 specialized populations × 100 million neurons per population =) a total of 100 *billion* neurons in the brain as a whole. As well, the total number of synaptic *connections* there reaches more than 100 *trillion*, each one of which can perform its proprietary magnification or minification of its arriving axonal message at the very same time as every other. Accordingly, the brain doesn’t have to do these elementary computations in laborious temporal sequence in the fashion of a digital computer. As we saw, a PDP network is capable of pulling out subtle and sophisticated information from a gigantic sensory representation *all in one fell swoop*. That is the take-home lesson of our cartoon net-

work. The digital/serial CPU is doomed to be a comparative dunce in that regard, however artificial may be the *rules* that make up its computer program. They simply take too long to apply.

Enough of the numbers. What wants remembering in what follows is the holistic character of the brain's representational and computational activities, a high-volume character that allows the brain to make penetrating interpretations of highly complex sensory situations in the twinkling of an eye. You are of course intimately familiar with this style of cognition: you use it all the time. Every time you recognize frustration in someone's face, evasion in someone's voice, hostility in someone's gesture, sympathy in someone's expression, or uncertainty in someone's reply, a larger version of the neuronal mechanism in figure 1 has made that subtle information almost instantly available to you.

Now, however, you know *how*: massively parallel processing in a massively parallel neural network. Or, to put it more cautiously, almost three decades of exploring the computational properties of artificial neural networks, and almost three decades of experimenting on the activities of biological neural networks have left us with the hypothesis on display above as the best hypothesis currently available for how the brain both represents and processes information about the world. No doubt, the special network processor inside you, the one that is responsible for filtering out specifically emotional information, has more than the mere two layers depicted in our cartoon. In fact, anatomical data suggests that your version of that network has the retinal information climb through four or five distinct neuronal layers before reaching the relevant layer(s), deep in the brain, that explicitly registers the emotional information at issue. The original retinal information will thus have to go through four or five distinct layers of synaptic filters/transformers before the emotional information is successfully isolated and identified. But that still gives us the capacity for recognizing emotions in less than a few tenths of a second. (The several neuronal layers involved are only ten milliseconds apart.) On matters like this, we are *fast*, at least when our myriad synaptic connections have been appropriately tuned up.

The PDP hypothesis also gives us the best available account of how that synaptic tuning takes place, that is, of how the brain *learns*. Specifically, the size or "weight" of the brain's many transforming synapses *changes* over time in response to the external patterns that it repeatedly encounters in experience. The overall configuration of those synaptic connections and their adjustable weights is gradually shaped by the recurring themes, properties, structures, behaviors, dilemmas, and rewards that the world throws at them. The resulting configuration of synaptic weights is thus made selectively sensitive to—one might indeed say *tuned* to—the important features of the typical environment in which the creature lives. In our case, that environment includes other people, and the pre-existing structure of mutual interaction and social commerce—the *moral order*—in which they live. Learning the general structure of that pre-existing social space, learning to recognize the current position of oneself and others within it, and learning to navigate that abstract space without personal or social disasters are among the most important things a normal human will ever learn.

It takes time, of course. An infant, before his first birthday, can distinguish between sadness and happiness, but little else. A grade-school child can pick up on most of the more subtle emotional flavors listed three paragraphs ago, though probably only in the behavior of young children like themselves. But a normal adult can detect all of those flavors, and more, quickly and reliably, as displayed by almost any person she may encounter. (Only psychopaths defeat us, and that's because they have deviant or truncated emotional profiles.)

Withal, learning to read emotions is only a part of the perceptual and interpretational skills that normal humans acquire. People also learn to pick up on people's background *desires* and their current practical purposes. We learn to divine people's background *beliefs* and the current palette of factual information that is (or isn't) available to them. We learn to recognize who is bright and who is dull, who is kind and who is mean, and who has real social skills and who is a fumbling jerk. Finally, we learn to *do* things. We learn how to win the trust of others, and how to

maintain it through thick and thin. We learn how to engage in cooperative endeavors and to do what others rightfully expect of us. We learn to see social trouble coming and to head it off artfully. And we learn to apologize for and to recover from our own inevitable social mistakes.

These skills of moral cognitive *output* (i.e., our moral behavior) are embodied in the same sorts of many-layered neural networks that sustain moral cognitive *input* (i.e., our moral perception). The diverse cognitive interpretations produced by our capacity for moral perceptions are swiftly and smoothly transformed—again by a sequence of well-trained synaptic filters/transformers—into patterns of excitation across our *motor* neurons (which project to and activate the body's muscles) and thereby into overt social behaviors, behaviors that are appropriate in light of the moral interpretations that produced them. Or at least, they will be appropriate if our moral education has been effective.

This weave of perceptual, cognitive, and executive skills is all rooted in, and managed by, the intricately tuned synaptic connections that intervene between hundreds of distinct neuronal populations, each of which has the job of representing some proprietary aspect of human psychological and social reality. That precious and hard-won configuration of synaptic weights literally constitutes the social and moral *wisdom* that one has managed to acquire. It embodies the unique profile of one's moral *character*: it dictates how we see the social world around us, and it dictates our every move within it. It is not an exaggeration to say that it dictates who we are. If our character needs changing or correcting, it is our myriad synapses that need to be reconfigured, at least in minor and perhaps in major ways. In all of these matters, then, don't think *rules*. Think information-transforming *configurations of synaptic weights*, for it is they that are doing the real work.

3 Reconceiving moral competence in non-classical terms

What *is* that “real work”? If the neural networks that make up our brains are not in the business of applying rules, vast libraries-full of

them, just what business *are* they engaged in? How should we think of what they are doing, if not as administering rules? What is the positive alternative to this traditional construal, expressed in non-technical language?

What those networks are doing is (trying to) interpret any *new* experience or situation as being an instance of some prior category that the brain already understands. They are trying to assimilate each new social/moral situation to an already grasped prototype situation, a template or prototype that has been incrementally created by the brain's prior experience with its surrounding social/moral reality. They are trying to grasp each of the endless novelties that they encounter as being just a modified case of some kind-of-thing that they have already encountered many times, and with which they have already become familiar. They are trying to interpret the fleeting here-and-now (which is always specific) in terms of their comparatively enduring background concepts (which are always general). They are trying to identify which of their various categories, categories that past experience has constructed for them, is the one into which their current experience fits most closely and most accurately. In sum, they are trying to apply their acquired conceptual and practical wisdom to their current situation.

Why should they, or rather, you, be trying to do that? For the very good reason that your acquired concepts or prototypes are precisely what contains your accumulated information about the world, information beyond what your current and highly specific experience happens to make evident. Those abstract prototypes contain presumptive information about the wide range of *features* that any instance of an applied concept can typically be expected to display, about the wide range of *relations* it will typically bear to other things, about the ways in which it will typically unfold or *behave* over time, and about the ways in which it can typically be *controlled* or *steered*. That is the point, after all, of having a conceptual framework in the first place. It embodies your accumulated understanding of the world's enduring background structure, your grasp of the unchanging background framework within which the ephemer-

eral and the changeable are always constrained to unfold.

Consider, for an example of moral perception in particular, the arrival of lunchtime in a typical elementary-school classroom. Every student retrieves a paper-bag lunch from the cloak-room and settles down to consume its contents. You are one of those students and, while eating, you perceive Johnny surreptitiously attempt to remove a banana from the lunch-bag next to Michael. On the face of it, you are witnessing a case of theft. And that interpretation implies many things: that the banana belongs to Michael, that Michael will be seriously aggrieved when he discovers Johnny's affront, that Johnny has inadequate self-control, that a noisy conflict will ensue if events are left to themselves, and so on and so on. This situation, as described, warrants some immediate intervention.

Most obviously, you might just openly berate Johnny in front of the other students. Or, more boldly, you might seize the banana from Johnny and quietly return it to Michael. Or you might call the teacher and rat Johnny out. These hardly exhaust your possible responses, but they are all typical sorts of responses to a typical sort of problem, and which response you choose will depend on contextual factors such as how big and mean Johnny is, how susceptible he is to collective disapproval, and how reliable the teacher is at dispensing justice. Perhaps the first path is the best response, with the second and third left as backups if the first path fails to return the situation to a just equilibrium.

And so that is what you do: berate him on the spot. All within a second of witnessing the presumed theft. Because your eight-year-old brain is already keenly tuned to that sort of possibility and to thousands of other social possibilities as well. Given your well-trained neural networks, it takes only the external perceptual situation itself to provoke the interpretation of theft. And it takes only that conceptual interpretation itself, in the context of one's ever-present character and background information, to activate your overt social response.

Your interpretation, of course, might be incorrect. Perhaps Johnny was just trying to retrieve his own banana, earlier stolen by the avari-

cious Michael. Perhaps your openly berating *Johnny* was inappropriate, since everyone in the class except you witnessed Michael's earlier theft but was too frightened of Michael to do anything about it. If so, Johnny has now been victimized twice over, once by Michael and once by you.

To be sure, there are many other convoluted possibilities, in addition to or beyond this one. But they are increasingly unlikely, compared to your first take on the situation. This is why your brain fell so swiftly and easily into that straightforward interpretation: *theft* is the simplest, most obvious, most probable explanation of what you have actually seen, and that's why it's the explanation that the brain tries first. Furthermore, once that explanatory assumption is in place, an immediate attempt at restitution is the most natural expression of your antecedent character and your acquired social skills.

What is impressive here is not just the swiftness with which your cognitive resources get tapped. It is the enormous *range* of alternative possibilities to which your brain is/was no less prepared to respond, and with equal swiftness, insight, and know-how. If, instead of a banana theft, you had witnessed Mary accidentally press her hand against the point of a newly sharpened pencil, your recognition of her pain and your comforting response would have been just as quick. If you saw the class's pet rabbit escape from its (poorly locked) cage, you would know to retrieve it and return it to its proper home. If you had turned to see a small fire blazing in the classroom's bookcase-corner library, with Johnny (him again!) slipping a plastic lighter into his pocket, you would grasp the significance of the event instantly and let out a loud warning to everyone in the room. If (here we deliberately choose something unlikely) Superman, with cape swirling, then bursts through the open classroom window and asks, "Which way did the fire-bug go?!", you would know to point to Johnny's fleeing backside as he hightails it out the classroom door. If . . . if . . . if . . . for a thousand thousand "ifs" and more, even your eight-year-old self would be competent to recognize the situation and to respond to it swiftly and appropriately.

This extraordinary breadth of capacity is a consequence, in part, of the *combinatorics* of

the already large number of neurons the brain uses to represent any sort of social situation. It is the same trick, once again, used by your television screen, in order to display an almost endless variety of possible pictures, despite a (large but) finite set of pixels with which to portray them. The retina of the eye uses the same trick, recall, but boasts many more “pixels” than a TV screen. Your perceptual capacities, accordingly, far exceed the modest range of that familiar technology.

Of course, simply representing something at the perceptual level does not mean that you *understand* it, and that is strictly what concerns us here. To understand a perceptual input is, as we saw above, to assimilate it to one of the brain’s learned *prototype* situations, to one of the standard, recurring, well-patterned kind of circumstances that one’s past experience has impressed upon your memory and your habits of behavior. That memory and those habits, you will recall, are a matter of the acquired configuration of the brain’s synaptic connections and their synaptic strengths or “weights.” For it is those collective synaptic “filters” or “transformers”—the ones that intervene between each of the brain’s many reality-portraying neuron populations—that steer the initial perceptual representations into the higher-level prototype patterns that fit those percepts most closely.

Look again at the toy network of figure 1 and note that its 327,680 synaptic connections were there adequate to steer a wide variety of possible input face images into one or other of exactly five emotional prototypes. If we suppose that this ratio (i.e., 327,680 synapses for every five categorial prototypes) is roughly typical, then a brain like yours, with 100 *trillion* synaptic connections, should be able to learn, and to deploy immediately (when appropriate), something in the neighborhood of $(5 / 327,680) \times 100 \text{ trillion} = 1.5 \text{ billion}$ distinct categorial prototypes! Now, presumably we don’t have quite *that* many distinct categories awaiting activation. That number is best viewed as a theoretical upper limit on what we might achieve. But in light of how our cognitive systems evidently do their jobs, it is small wonder that even your grade-school self is hair-trigger ready for

such an astonishing range of situations, social and otherwise—and ready, note well, with an astonishing range of understanding and relevant skills.

4 Moral conflict and moral reasoning

Alas, our cognitive systems don’t always work perfectly. Sometimes we misinterpret what we are seeing and hearing. That is, sometimes we assimilate the case at hand to a category or prototype of which it is not an instance, to which it positively does not belong. When that happens, you become the victim of the entire family of expected features, relations, developmental profile, and presumptively appropriate behavioral responses that automatically come with that prototype, but that fail to accurately characterize or suit the case at hand. Some dimensions of the activated prototype may fit (that’s why you deployed it in the first place), but others do not, as you slowly come to appreciate. As the case before you unfolds, and perhaps as you learn more about its initial stages, your prototype-driven expectations are violated and your cognitive dissonance grows. You have somehow failed to understand the situation correctly.

At some point, the accumulated new input or evidence may be sufficient to kick your brain’s activational activity *out* of the prototype-category that initially captured it and *into* a different and more appropriate prototype, one whose overall profile finally does fit the case at hand. At that point you may have the familiar “click” experience, where the problematic case suddenly re-presents itself in a new and coherent light, and you think to yourself, “Oh my god, I misunderstood what was happening.” You may then struggle to repair the social/moral damage that your automatic but ultimately inapt behavior may have produced.

This happens to all of us, and quite often. It reflects the fact that our moral cognition is not infallible. Happily, such mistakes can be corrected, and regularly they are, sometimes by oneself and sometimes with the help of others. Unhappily, sometimes they are not corrected. We are all familiar with people who have too

quickly taken a superficial interpretation of some social/moral issue and then stubbornly refuse to respond to, or even to see, its failures to capture adequately the social/moral complexities that the issue presents.

When this happens, we have a typical case of moral conflict. If the issue is pressing, we may begin a round of moral reasoning and moral argument with the person or persons who take the competing interpretation of the issue, and who propose a problematic response or policy in light of it. Such arguments, it must be admitted, often begin with both sides citing some favored “moral” or other, a rule that supposedly compels us to take their response to the situation or to embrace their policy recommendation. But this rarely settles the conflict, since the real disagreement is usually about how we should *interpret* the situation in the first place.

Classic examples are right in front of us. The public debate over abortion involves a presumptive conflict between the rule “Any innocent human person has the moral right to continue living” and the rule “Any woman has the moral right to control her own internal reproductive activities.” But the debates typically focus on how these rules should be *interpreted*, what *qualifications*, if any, should limit their application, and which of these conflicting rules carries the greater *authority*. Ultimately, as both sides of the debate usually *agree*, the issue boils down to whether or not the fertilized egg and/or the early fetus that develops therefrom really is, or should be counted as, a *human person* in the first place. The right-to-life folks say “yes.” The defenders of choice say “no.”

Our point in rehearsing this issue is that, even in the case of this most celebrated of moral conflicts, the primary issue, once again, is not really about rules. It is about how we should interpret or categorize, rationally and accurately, the early fetus. One side will argue, “It’s just a clutch of unfolding stem cells, without a brain or nervous system, without any character or personal identity, without any will or consciousness, without any of the dimensions of genuine personhood. It is no more a person than a recently-planted acorn is already an oak tree.” The other side will argue, “Personhood begins

at conception, at fertilization. That is when God places a human soul into the now-developing egg. Accordingly, that is when the right to life begins, a right not to be subsequently denied. (And by the way, acorns don’t have immaterial souls.)”

The first side will respond, “We don’t accept your utterly unverified theory of immaterial souls implanted by a divine being at conception, and we resist your attempt to thus impose your arbitrary and fantastical religious beliefs on the rest of us. (And by the way, modern science implies that humans don’t have immaterial souls either.)” To which the second side will counter, “Your position acknowledges *no* clear or well-defined point at which the developing fetus begins to acquire rights. If it is acceptable to terminate the life of the developing fetus, why isn’t it acceptable to terminate the life of a developing *newborn baby*? That would plainly be over the top, but the case of a fetus is different in no fundamental respect.”

And so it goes. Each side of the debate typically attempts to get the other side to see the problematic case “in a different light,” to interpret it as relevantly similar to a distinct but salient prototype whose moral status is not under dispute, to assimilate it to a category that is factually more adequate to the problematic case at hand. Thus the category “mindless clutch of cells” vies with the category “innocent and defenseless person” for our cognitive apprehension of the conceptus and early fetus. Arguments here are not conducted by repeatedly citing moral rules and deducing consequences therefrom. They are conducted by repeated attempts to highlight diverse factual similarities, and dissimilarities, between each of the contesting moral prototypes, on the one hand, and the conceptus/early fetus on the other.

I deploy this example of a moral disagreement and its typical discussion not to try to settle the issue in favor of either side here, but to illustrate the forms that moral disagreements and moral arguments typically display. It is, most assuredly, *not* the aim of this naturalistic and brain-focused essay to try to deduce any substantive moral rules from our growing understanding of how the brain conducts its moral

cognition. Brains arrive at their moral wisdom by a long process of learning, often painful learning, whether in the lifetime of an individual or in the centuries-long development of a society, and there is no substitute for this learning process. It is rather like the development of *scientific* wisdom, if I may draw an optimistic analogy. At present, we are also learning how human brains engage in scientific cognition, but that does not obviate the need for our scientific communities to continue to generate theories and test them against our unfolding experience. Knowing *how* the brain works so as to generate and constantly improve our scientific understanding will not obviate the need to *keep it* working toward that worthy end, though it may help us to improve our pursuit thereof. Similarly, knowing *how* the brain works to generate and constantly improve our *moral understanding* will not obviate the need to *keep it* working toward that worthy end, though it may help us to improve our pursuit thereof. I will close on this hopeful note.

Applied Metascience of Neuroethics

A Commentary on Paul M. Churchland

Hannes Boelsen

This commentary is the first case study in the applied metascience of neuroethics, that is, the application of a metascientific approach to neuroethical research. I apply a bottom-up approach to neuroethics to Churchland's publication. The bottom-up approach to neuroethics is a quantitative approach (based on scientometric methods) that, among other things, allows us to outline the field from 1995 until 2012 through the development of fifteen subject categories or topic prototypes. Each subject category or topic prototype is defined by up to thirty-one keywords that appear frequently in the abstracts and titles of the publications in the Mainz neuroethics bibliography. The connection strength between two subject categories or topic prototypes depends upon the number of shared publications, that is, the number of publications that can be assimilated to both subject categories or topic prototypes. Accordingly, a keyword-based search of the abstract and title of any publication in neuroethics allows us to assimilate it to (at least) one subject category or topic prototype and, thereby, localize it within neuroethics and reveal its degrees of relevance to neuroethical research, as measured by the connection strengths between the subject categories or topic prototypes. A case study on Churchland's publication led to the following results: the publication is localized in the subject category or topic prototype *Moral Theory*, has high degrees of relevance to research that can be assimilated to the subject categories or topic prototypes *Neuroimaging*, *Philosophy of Mind and Consciousness*, and *Economic and Social Neuroscience*, and has low degrees of relevance to research that can be assimilated to the subject categories or topic prototypes *Addiction*, *Brain Death and Severe Disorders of Consciousness*, *Brain Stimulation*, *Enhancement*, *Legal Studies*, *(Medical) Research and Medicine*, *Molecular Neurobiology and Genetics*, *Neuroscience and Society*, *Neurosurgery*, *Psychiatric and Neurodegenerative Diseases and Disorders*, and *Psychopharmacology*. Such results can be fed back into neuroethical research, which, in turn, can optimize neuroethics itself and, hence, improve our pursuit of moral understanding. The take-home messages are as follows: potential follow-up studies on Churchland's publication should consider my case study results and analysis and, furthermore, future neuroethical research should be more careful to take applied metascience of neuroethics into account. This can be done at different stages of research. If this general idea is on the right track, then applied metascience of neuroethics is complementary to (and perhaps even extends) Churchland's argument, only on a different level.

1 Introduction

In *Rules: The basis of morality...?*, Churchland points at several problems for classical rule-based accounts of moral knowledge that attempt to identify morally valid behavior-guid-

ing rules and the sources of their authority. Those problems (all based on the fundamental assumption that rules in the literal sense require a language) show that we need a non-

classical non-rule-based account of moral knowledge. Hence, the author proposes an alternative account from computational neuroscience based on “the best hypothesis currently available for how the brain both represents and processes information about the world [...] [and] of how the brain learns” (Churchland this collection, p. 8; emphasis omitted): parallel distributed processing (PDP). In PDP, a neural network embodies a conceptual framework that contains knowledge about the world, that is, a configuration of attractor regions, a family of prototype representations, or, rather, a hierarchy of categories (Churchland 2012, p. 33): against this background, moral knowledge is a configuration of synaptic weights in a neural network. Subsequently, this insight is used to reconceive moral competence, moral conflict, and moral reasoning. Moral competence is the personal level competence to apply sub-personal level knowledge to a moral situation by assimilating it to a prior learned category or prototype. A moral conflict, however, is (at least partly) the consequence of a moral situation that has been assimilated to a category or prototype of which it is not an instance. In short, the fallibility of moral cognition leads to competing interpretations of a moral situation and thereby to a disagreement with others. Accordingly, moral reasoning is (at least mostly) not about rules and the sources of their authority but about adequate assimilation of a moral situation to a category or prototype in the first place. Finally, the author concludes: “[k]nowing how the brain works to generate and constantly improve our moral understanding will not obviate the need to keep it working toward that worthy end, though it may help us to improve our pursuit thereof” (Churchland this collection, p. 13; emphasis omitted).

Churchland’s publication has my full support. I agree with what he says, as I do with his general approach. What follows is a complementary (and perhaps even extending) attempt to improve our pursuit of moral understanding, only on a different level: applied metascience of neuroethics (NE), that is, the application of a

metascientific approach to neuroethical research.¹

In this commentary, I apply the (as-yet unpublished) bottom-up approach to NE² offered by Hildt et al. (forthcoming)³ to Churchland’s publication. Thereby, I attempt to achieve my epistemic goal, which is both to localize the publication within NE and reveal its degrees of relevance⁴ to neuroethical research; as well as my argumentative goal, which is to demonstrate that applied metascience of NE can optimize NE itself and, hence, improve our pursuit of moral understanding.

In the following, I introduce NE and present three typical examples of (disadvantageous) contemporary top-down approaches to NE. I then introduce a bottom-up approach to NE. Following this, I apply the bottom-up approach to NE to Churchland’s publication and present my case study results. After this, I analyze my case study results. Finally, I conclude with some suggestions for future research.

2 Top-down approaches to neuroethics

NE, as a combination of applied ethics⁵ and neurophilosophy⁶ (Hildt 2012, p. 11), is an interdisciplinary field at the intersection of neuroscience, medicine, and philosophy that deals with philosophical, ethical, anthropological, and socio-cultural issues related to neuroscience (Metzinger 2012, p. 36). In 2002, this versatile field emerged in the wake of several US-American conferences that were products of the *Zeitgeist*, that is, the Decade of the Brain from 1990 to 1999 (Hildt

1 In general, applied metascience is not limited to NE, but can be performed with any kind of scientific discipline.

2 A bottom-up approach to NE is data-driven, whereas a top-down approach to NE is definition-seeking.

3 I would like to thank my colleagues in the Mainz Research Group on Neuroethics/Neurophilosophy for providing me the opportunity to use the bottom-up approach to NE for the purpose of this commentary.

4 The degrees of relevance of publications to neuroethical research, as measured by the connection strengths between the subject categories or topic prototypes, indicate the probabilities that publications will prove fruitful for neuroethical research.

5 NE is neither another branch of applied ethics (Levy 2011, p. 3) nor reducible to medicine ethics, bioethics, or a subfield thereof. Nevertheless, there is much overlap (Hildt 2012, pp. 11–12) between these fields.

6 Neurophilosophy is a naturalistic and reductive approach towards a unified theory of the mind-brain that requires detailed knowledge about neuroscience (Walter 2013, p. 133).

2012, p. 9). In particular, it is common to identify the dawn of NE with a conference that was held in San Francisco on May 13th and 14th, 2002: *Neuroethics: Mapping the Field* (Marcus 2002). Before this, “most people saw no need for any such field” (Levy 2007, p. 1), but the aforementioned issues came to be perceived as far more important at this time. Nevertheless, we should ask: what exactly is NE? Alongside the first approximation given above, I present three typical examples of contemporary top-down approaches to NE (which I don’t claim to be exhaustive).

From a knowledge-driven perspective (Racine 2008, p. 33), Roskies divides NE into two divisions: the ethics of neuroscience and the neuroscience of ethics. According to Levy, the former “seeks to develop an ethical framework for regulating the conduct of neuroscientific enquiry and the application of neuroscientific knowledge to human beings [...] [whereas the latter studies] the impact of neuroscientific knowledge upon our understanding of ethics itself” (Levy 2007, p. 1). Furthermore:

the ethics of neuroscience can be roughly subdivided into [...] (1) the ethical issues and considerations that should be raised in the course of designing and executing neuroscientific studies and (2) evaluation of the ethical and social impact that the results of those studies might have, or ought to have, on existing social, ethical, and legal structures. (Roskies 2002, p. 21)

This top-down approach to NE emphasizes the philosophical challenges posed by neuroscience (Racine 2008, p. 34), for example, for “philosophical notions such as free-will, self-control, personal identity, and intention” (Roskies 2002, p. 22).

From a technology-driven perspective (Racine 2008, p. 33), Wolpe identifies NE with “both research and clinical applications of neurotechnology, as well as social and policy issues attendant to their use. [...] [Thus, it is] a content field, defined by the technologies it examines rather than any particular philosophical approach” (Wolpe 2004, p. 1894). This top-down approach to NE emphasizes the ethical challenges of using neurotechnology (Racine 2008, p. 33), for ex-

ample, in healthcare and social practices (Racine 2008, p. 32).

From a healthcare-driven perspective (Racine 2008, p. 33), Racine & Illes (2008) propose a definition of NE that “profiles the field as at the intersection of neuroscience and bioethics defined by a general practical goal, that of improving patient care for specific patient populations” (Racine 2008, p. 34). This top-down approach to NE emphasizes the field as “both a scholarly and practical endeavor, akin to medicine, which attempts to understand and intervene” (Racine 2008, p. 34).

In sum, each of the three top-down approaches to NE comprises (despite their convergences) different issues in different subject categories or topic prototypes with different relations to each other. Seemingly, there are as many top-down approaches to NE as philosophers in the field (e.g., Farah 2012⁷; Gazzaniga 2005;⁸ Giordano n. d.;⁹ Moreno 2003;¹⁰ Safire 2007¹¹) but probably even more.¹²

This unsystematic versatility is disadvantageous for any attempt at a precise localization of Churchland’s publication within the field because it suggests that the aforementioned top-down approaches to NE are necessarily incomplete or even inconsistent. Hence, their application can lead to unsatisfactory results—for example, a localization of the publication that depends more on a research agenda than on facts.¹³ The bottom-up approach to NE attempts to provide a solution to this problem.

⁷ Farah characterizes NE as “a broad range of ethical, legal, and social issues raised by progress in neuroscience” (2012, p. 572).

⁸ Gazzaniga understands NE as “the examination of how we want to deal with the social issues of disease, normality, mortality, lifestyle, and the philosophy of living, informed by our understanding of underlying brain mechanisms” (2005, p. xv).

⁹ Giordano identifies NE with “(1) the study of neurological bases of moral cognition, sense and action[,] (2) the field of study that addresses the moral issues that arise in and from neuroscientific research and the clinical practices and social effects/implications that evolve from these investigations[, and] (3) the reciprocal interaction(s) between neurological research/clinical practices and other ethically relevant areas of biomedical sciences” (Giordano n. d.).

¹⁰ Moreno argues that NE “is in some ways old wine in a new bottle” (2003, p. 153).

¹¹ Safire defines NE as “the examination of what is right and wrong, good and bad about the treatment of, perfection of, and welcome invasion or worrisome manipulation of the human brain” (2007, p. 8).

¹² Buniak et al. “provide an iterative, four-part document that affords a repository of international papers, books, and chapters that address the field in overview, and present discussion(s) of more particular aspects and topics of neuroethics” (2014, p. 3).

3 A bottom-up approach to neuroethics

The bottom-up approach to NE is a quantitative approach (based on scientometric methods) that, among other things, allows us to outline the field from 1995 until 2012 through the development of subject categories or topic prototypes.¹⁴ Although similar work has been done before, for example, by Gooray & Ferguson (2013), Garnet et al. (2011), or Seixas & Basto (2008), no bottom-up approach to NE based on such a comprehensive database as that of Hildt et al. (forthcoming) has yet been attempted.¹⁵ To be more precise, they use the Mainz NE bibliography.¹⁶

The Mainz bibliography (launched in 2006) is an open-access online bibliography compiled and provided by the Mainz Research Group on Neuroethics/Neurophilosophy.¹⁷ Currently, the bibliography, as a multimodal compilation of NE publications (e.g., anthologies, edited volumes, journal articles, and monographs), contains about 4095 entries produced between 1949 and mid-2014. On the one hand, the bibliography is based on regular scans of relevant journals from neuroscience and medicine (e.g., *Cortex*, *Der Nervenarzt*, *EMBO Reports*, *Journal of Neurology*, *Journal of the American Medical Association*, *Nature*, *Nature Neuroscience*, *Nature Reviews Neuroscience*, *Neurocritical Care*, *NeuroImage*, *Neurology*, *Neuropsychology Review*, *Psychopharmacology*, *Science*, and *Trends in Cognitive Sciences*),

philosophy (e.g., *American Journal of Bioethics Neuroscience*, *American Journal of Bioethics Bioethics*, *Cambridge Quarterly of Healthcare Ethics*, *Consciousness and Cognition*, *Journal of Applied Philosophy*, *Journal of Medical Ethics*, *Medicine, Health Care and Philosophy*, *Neuroethics*, *Philosophy*, *Psychiatry*, & *Psychology*, *Science and Engineering Ethics*, *Hastings Center Report*, *The Journal of Law, Medicine & Ethics*, and *Theoretical Medicine and Bioethics*), the humanities, and social sciences.¹⁸ On the other hand, the bibliography is based on regular searches of both relevant citation (meta-)databases such as *Web of Science*,¹⁹ *PubMed*,²⁰ and *Scopus*,²¹ and relevant bibliographies such as the *Brainstorm*²² newsletter of the Canadian Neuroethics and Mental Health Interest Group. The bibliography also incorporates irregular additions of relevant publications (mainly anthologies, edited volumes, and monographs) as soon as the Research Group on Neuroethics/Neurophilosophy becomes aware of them. Regarding the selection criteria for publications from the various sources, publications from neuroscience or medicine are selected if they refer to the philosophical, ethical, anthropological, or socio-cultural impact of the presented results,

¹³ For example, facts that are necessary for an adequate mapping of the field may have been (un-)intentionally overlooked.

¹⁴ In Hildt et al. (forthcoming), the developed subject categories or topic prototypes form the basis for further scientometric analysis of the data. For example, the subject categories or topic prototypes allow us to examine the development and institutionalization of NE (e.g., temporal development, structure and disciplinary institutionalization, and reciprocal shaping of NE and related disciplines).

¹⁵ For example, Gooray & Ferguson's (2013) database contains about 205 entries dating from 2000 to 2012. The database is based on books and articles from the following twelve journals: *Neuroethics*, *American Journal of Bioethics Neuroscience*, *Nature Reviews Neuroscience*, *Annual Review of Neuroscience*, *Behavioral and Brain Sciences*, *Molecular Psychiatry*, *Nature Neuroscience*, *Neuron*, *Trends in Neurosciences*, *Frontiers in Neuroendocrinology*, *Annals of Neurology*, and *Progress in Neurobiology*. In contrast, Hildt et al.'s (forthcoming) database contains about 2296 entries dating from 1995 to 2012. It is based on books and articles from more than 700 journals.

¹⁶ <https://teamweb.uni-mainz.de/fb05/Neuroethics/SitePages/Home.aspx>

¹⁷ <http://www.blogs.uni-mainz.de/fb05philosophieengl/further-institutions/research-group-on-neuroethics-and-neurophilosophy/>

¹⁸ The aforementioned selection of twenty-nine journals comprises those journals that had added at least twenty publications to the Mainz NE bibliography before mid-2014. The number of publications ranges from (at least) 352 publications (*American Journal of Bioethics Neuroscience*), 298 publications (*American Journal of Bioethics*), 211 publications (*Neuroethics*), 91 publications (*Nature Reviews Neuroscience*), 68 publications (*Der Nervenarzt*), 61 publications (*Nature Neuroscience*), 58 publications (*Journal of Medical Ethics*), 57 publications (*Journal of Neurology*), 54 publications (*Nature and Neurology*), 46 publications (*Bioethics*), 40 publications (*NeuroImage and Science and Engineering Ethics*), 37 publications (*Trends in Cognitive Sciences*), 35 publications (*Hastings Center Report*), 31 publications (*Journal of the American Medical Association*, *Medicine, Health Care and Philosophy*, and *Philosophy, Psychiatry, & Psychology*), 28 publications (*Science*), 26 publications (*Cortex and EMBO Reports*), 23 publications (*Neurocritical Care and Neuropsychology Review*), 22 publications (*Cambridge Quarterly of Healthcare Ethics*, *Journal of Applied Philosophy*, and *Psychopharmacology*), 21 publications (*The Journal of Law, Medicine & Ethics*) to 20 publications (*Consciousness and Cognition* and *Theoretical Medicine and Bioethics*). This selection of twenty-nine journals could be a fruitful starting point for future scientometric research related to NE. Besides this, the Mainz NE bibliography comprises journals that have added less than twenty publications (e.g., *Behavioral and Brain Sciences* and *Philosophical Psychology*).

¹⁹ <http://www.webofknowledge.com>

²⁰ <http://www.ncbi.nlm.nih.gov/pubmed>

²¹ <http://www.scopus.com>

²² <http://www.ircm.qc.ca/LARECHERCHE/AXES/NEURO/NEURO-ETHIQUE/PAGES/GROUPE.ASPX?PFLG=1033&lan=1033>

whereas publications from philosophy, the humanities, or social sciences are selected if they refer to empirical results from neuroscience or medicine. Moreover, non-transdisciplinary publications are selected if the Research Group on Neuroethics/Neurophilosophy considers them to be relevant to NE.²³

Subsequently, Hildt et al. (forthcoming) use a bibliometric analysis of the Mainz NE bibliography from 1995 until 2012 to develop, among other things, fifteen subject categories or topic prototypes on content-based criteria. Thereby, each subject category or topic prototype is defined by up to thirty-one keywords that appear frequently in the abstracts and titles of the publications. These fifteen subject categories or topic prototypes are *Addiction*, *Brain Death and Severe Disorders of Consciousness*, *Brain Stimulation*, *Enhancement*, *Legal Studies*, *(Medical) Research and Medicine*, *Molecular Neurobiology and Genetics*, *Moral Theory*, *Neuroimaging*, *Neuroscience and Society*, *Neurosurgery*, *Philosophy of Mind and Consciousness*, *Psychiatric and Neurodegenerative Diseases and Disorders*, *Psychopharmacology*, and *Social and Economic Neuroscience*. Each subject category or topic prototype represents certain issues discussed in NE²⁴ and, taken together, they outline the field.²⁵ Importantly, Hildt et al. (forthcoming) also determine, among other things, the connection strengths²⁶ between the subject categories or topic prototypes within NE. Due to the content-based development of the subject categories or topic prototypes, a keyword-based search of the abstract and title of any publication in NE allows us to

assimilate it to (at least) one subject category or topic prototype²⁷ and, thereby, localize it within NE.

In the following, I apply the bottom-up approach to NE to Churchland's publication and present my case study results. I thereby attempt to achieve the first part of my epistemic goal, which is to localize Churchland's publication within NE.

4 Case study results

The keyword-based search of the abstract and title of Churchland's publication reveals that it can be assimilated to the subject category or topic prototype *Moral Theory*, that is, a subject category or topic prototype that comprises publications on the psychology and neurobiology of moral-decision making, publications on determinism, free-will, and the function of moral theory in the neurosciences, and publications on challenges to established interpretations of morally significant concepts such as autonomy, responsibility, and human nature.

This subject category or topic prototype has strong connections to the subject categories or topic prototypes *Neuroimaging*, *Philosophy of Mind and Consciousness*, and *Social and Economic Neuroscience*, and weak connections to the subject categories or topic prototypes *Addiction*, *Brain Death and Severe Disorders of Consciousness*, *Brain Stimulation*, *Enhancement*, *Legal Studies*, *(Medical) Research and Medicine*, *Molecular Neurobiology and Genetics*, *Neuroscience and Society*, *Neurosurgery*, *Psychiatric and Neurodegenerative Diseases and Disorders*, and *Psychopharmacology*. The strong connections can be explained by a high number of shared publications, that is, a high number of publications that can be assimilated to both the subject category or topic prototype *Moral Theory* and the subject category or topic prototype *Neuroimaging*, *Philosophy of Mind and Consciousness*, or *Social and Economic Neuros-*

²³ For example, a publication in medicine on the effects of neuroleptics, antidepressants, stimulants, or tranquilizers is selected if it could offer a contribution to the interdisciplinary debate on psychopharmacological cognitive enhancement.

²⁴ Combinations of the subject categories or topic prototypes are able to represent almost every issue discussed in NE.

²⁵ Bottom-up approaches to NE attempt to provide maximally parsimonious bottom-up descriptions of their target phenomenon (e.g., NE as a dynamical publication state-space). If the top-down descriptions of NE, provided by the top-down approaches to NE, are neither identical with nor reducible to the bottom-up descriptions of NE, then, using a superficial analogy to Churchland's eliminative materialism (1981), an interesting question is whether or not (and, if so, which of) the top-down descriptions of NE can be eliminated.

²⁶ The connection strength between two subject categories or topic prototypes depends upon the number of shared publications, that is, the number of publications that can be assimilated to both subject categories or topic prototypes.

²⁷ A publication can be assimilated to a subject category or topic prototype if its abstract and title contain (at least) one of the keywords that define the subject category or topic prototype. As such, less than ten percent of the total publications could not be assimilated to a subject category or topic prototype. An interesting question is whether or not (and, if so, how) those publications can still be regarded as belonging to NE.

cience. The weak connections can be explained by a low number of shared publications, that is, a low number of publications that can be assimilated to both the subject category or topic prototype *Moral Theory* and the subject category or topic prototype *Addiction, Brain Death and Severe Disorders of Consciousness, Brain Stimulation, Enhancement, Legal Studies, (Medical) Research and Medicine, Molecular Neurobiology and Genetics, Neuroscience and Society, Neurosurgery, Psychiatric and Neurodegenerative Diseases and Disorders, or Psychopharmacology* (Hildt et al. forthcoming).

In the following, I analyze my results. I thereby attempt to achieve the second part of my epistemic goal, which is to reveal the degrees of relevance of Churchland's publication to neuroethical research; as well as my argumentative goal, which is to demonstrate that applied metascience of NE can optimize NE itself and, hence, improve our pursuit of moral understanding.

5 Analysis

First of all, the degrees of relevance of publications to neuroethical research are measured by the connection strengths between the subject categories or topic prototypes. The connection strengths between subject categories or topic prototypes depend upon the numbers of shared publications. The numbers of shared publications can be explained by the degrees of overlap of content, methodology, or both. The degrees of overlap of content, methodology, or both, in turn, indicate the probabilities that publications will prove fruitful for neuroethical research. In short, the degrees of relevance of publications to neuroethical research, as measured by the connection strengths between subject categories or topic prototypes, indicate the probabilities that publications will prove fruitful for neuroethical research.

Based on my results, Churchland's publication has high degrees of relevance to research that can be assimilated to the subject categories or topic prototypes *Moral Theory, Neuroimaging, Philosophy of Mind and Consciousness*, or *Social and Economic Neuroscience* because of

the strong connections between the subject category or topic prototype *Moral Theory* and the subject categories or topic prototypes *Neuroimaging, Philosophy of Mind and Consciousness*, and *Social and Economic Neuroscience*. The strong connections can be explained by the high numbers of shared publications. The high numbers of shared publications can be explained by the high degrees of overlap of either content, methodology, or both.²⁸ This, in turn, indicates high probabilities that Churchland's publication will prove fruitful for research that can be assimilated to the aforementioned subject categories or topic prototypes. Conversely, Churchland's publication has low degrees of relevance to research that can be assimilated to the subject categories or topic prototypes *Addiction, Brain Death and Severe Disorders of Consciousness, Brain Stimulation, Enhancement, Legal Studies, (Medical) Research and Medicine, Molecular Neurobiology and Genetics, Neuroscience and Society, Neurosurgery, Psychiatric and Neurodegenerative Diseases and Disorders*, or *Psychopharmacology* because of the weak connections between the subject category or topic prototype *Moral Theory* and the aforementioned subject categories or topic prototypes. Here are some brief theoretical considerations.

Churchland's publication is highly relevant to research that can be assimilated to the subject category or topic prototype *Economic and Social Neuroscience*, suggesting that his idea of reconceiving moral decision-making in terms of PDP could prove fruitful for neuroethical research that refers to the underlying physiology of economic or social decision-making. This application might show that moral, economic, and social decision-making share important properties but differ in others. This possible result could then be fed back into neuroethical research.

Churchland's publication is also highly relevant to research that can be assimilated to the subject category or topic prototype *Neuroima-*

²⁸ Accordingly, publications that can be assimilated to the subject category or topic prototype *Moral Theory, Neuroimaging, Philosophy of Mind and Consciousness*, or *Social and Economic Neuroscience* are highly relevant to the subject of Churchland's publication.

ging, suggesting that his idea of reconceiving moral decision-making in terms of PDP could prove fruitful for neuroethical research that refers to imaging techniques that visualize the brain, such as cranial computed tomography (CCT), electroencephalography (EEG), magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET) (Hildt 2012, p. 11). For example, it could be used to reconceive the classic distinction between off-track and truth-tracking processes in genealogical debunking arguments²⁹ that refer to fMRI research (e.g., Greene 2008 and Singer 2005). This application might show that the classic distinction is neurobiologically implausible, which would mean that arguments relying on this distinction are implausible as well. This possible result could then be fed back into neuroethical research.

Moreover, the possible (yet unrecognized) relevance of Churchland's publication to research that can be assimilated to the subject categories or topic prototypes *Addiction*, *Brain Death and Severe Disorders of Consciousness*, *Brain Stimulation*, *Enhancement*, *Legal Studies*, *(Medical) Research and Medicine*, *Molecular Neurobiology and Genetics*, *Neuroscience and Society*, *Neurosurgery*, *Psychiatric and Neurodegenerative Diseases and Disorders*, and *Psychopharmacology* could have been emphasized more strongly by including keywords in the abstract and title that define the aforementioned subject categories or topic prototypes, which, in turn, could have increased the connection strengths between those subject categories or topic prototypes and the subject category or topic prototype *Moral Theory*. A possible outcome of this could have been the revelation of a systematic overlap of content, methodology, or both that has been neglected so far. And this possible result could then have been fed back into neuroethical research.³⁰

This feedback process, in turn, can optimize NE itself and, hence, improve our pursuit of moral understanding because it can help to “produce better ethical theories [...] and contribute toward the great project of better understanding ourselves” (Levy 2011, p. 8). Apparently, a recurring pattern emerges: the bottom-up approach to NE can be applied to neuroethical research, which, in turn, can lead to such results that can be fed back into it, which, in turn, can optimize NE itself and, hence, improve our pursuit of moral understanding.

6 Concluding remarks

In this commentary, I applied the bottom-up approach to NE to Churchland's publication. I thereby attempted to localize the publication within NE and reveal its degrees of relevance to neuroethical research, and to demonstrate that applied metascience of NE can optimize NE itself and, hence, improve our pursuit of moral understanding.

Assuming that I have achieved the former, which was my epistemic goal, the first and more specific take-home message is that potential follow-up studies on Churchland's publication should consider my case study results and analysis, that is, they should both bring together research that can be assimilated to the subject categories or topic prototypes *Moral Theory*, *Neuroimaging*, *Philosophy of Mind and Consciousness*, and *Social and Economic Neuroscience*, and build bridges to research that can be assimilated to the subject categories or topic prototypes *Addiction*, *Brain Death and Severe Disorders of Consciousness*, *Brain Stimulation*, *Enhancement*, *Legal Studies*, *(Medical) Research and Medicine*, *Molecular Neurobiology and Genetics*, *Neuroscience and Society*, *Neurosurgery*, *Psychiatric and Neurodegenerative Diseases and Disorders*, and *Psychopharmacology*. Assuming that I have achieved the latter, which was my argumentative goal, the more general take-home message is that future neuroethical research should be more careful to take applied metascience of NE into account because it can optimize NE itself and, hence, improve our pursuit of moral understanding.

²⁹ According to Kahane, the general form of a genealogical debunking argument is the following: S's belief that p is explained by x. But, x is an off-track process, that is, not a truth-tracking process, with respect to p. Therefore, S's belief that p is unjustified (Kahane 2011, p. 106).

³⁰ Of course, this theoretical consideration is not meant to be a serious criticism of Churchland's publication, because the bottom-up approach to NE was not available to him at the time of writing. It rather shows that applied metascience of NE can help us discover new pathways and directions for future neuroethical research.

In the case of the bottom-up approach to NE, this can be done at different stages of research. First, while seeking inspiration for research, researchers and students can bypass well-trodden paths in NE and identify (as yet) unorthodox ones from the very beginning. Second, while pursuing these (or already well-trodden) paths, scholars can optimize the efficiency of their own research. Third, while preparing their research for publication, they can prepare abstracts and titles in such a manner as to optimally reflect the publications' (real or intended) degrees of relevance to specific subject categories or topic prototypes. Fourth and finally, when taking it into account, they shape NE in such a way that it provides input for more fine-grained follow-up models in the metascience of NE.

If this general idea is on the right track, then applied metascience of NE is complementary to (and perhaps even extends) Churchland's argument, only on a different level: "knowing how the brain works to generate and constantly improve our moral understanding will not obviate the need to keep it working towards that worthy end" (Churchland this collection, p. 13; emphasis omitted), just as knowing how to optimize NE will not do this either, though both "may help us to improve our pursuit thereof" (Churchland this collection, p. 13). Only time will tell.

My thanks to Boelsen for his penetrating understanding of my modest contribution to this collection, and for placing its significance in a much broader context, namely, the context of the full range of scientific and philosophical research to which it might be *relevant*. Indeed, his principal topic is the emerging internet mechanism for evaluating the relevance of *any* publication to the research interests of scholars in general, a mechanism that allows a specific scholar to identify, from among the teeming multitude, exactly those published papers most likely to be of interest to him or her. Its brief application to my own paper in this collection is just one illustration of its wide-ranging *possible* applications.

The mechanism he describes – namely, the calculation of “connections strengths” between the prototype topics and the key words found in the abstracts of any arbitrarily chosen pair of publications – is an interesting elaboration of the simpler “key words” convention already in widespread use in modern journals, a convention that has already proven to be very useful to scholars all across the academic spectrum, as we all know. Taking the variable “connection strengths” – as defined by Boelsen – between those already-salient indexes into account, and making them systematically available also, would seem only to enhance the usefulness of the mechanisms already in play.

And no doubt it would. However, and its undoubted advantages conceded, there is an unfortunate limit on the usefulness of such a mechanism, a limit already familiar to us from our experience with the existing conventions of abstracts and key words. They are intellectually useful only if, and only to the extent that, one *already understands* the “key words” involved, and the research areas that they name. Otherwise, the mechanism here at issue does no more than *cluster together* distinct publications as having “the same”, or “closely similar”, intellectual concerns. That is, it does provide a map of the “topical concentrations” at the presumptive current “ceiling” of academic understanding, but it does not itself raise the “level” of that ceiling. By itself, it provides no novel or additional understanding of the various topics themselves displayed in its many lists. *That* sort of achievement, if it is realized at all, must be made by those occasional thinkers who actually *read* the papers thus clustered together, and subsequently manage to *solve* one or more of the problems that they still leave open, by using the quite different mechanisms that reside within the human *brain*.

In sum, the mechanism described by Boelsen will certainly help aspiring scholars to *catch up* on the already existing research that is relevant to their own research interests, and may thereby stimulate further research. But any intellectual or theoretical novelties will have to come from the subsequent researches of those aspiring scholars themselves, and not from the mechanism described by Boelsen. That said, in constructing “key-word lists” for my own papers in the future, I will keep the mechanism described by Boelsen firmly in mind. And for a reason that would not have occurred to me, save for Boelsen’s commentary. In constructing the abstract and key-words list for my own paper in this collection, I did not pay special attention to the possible *novel uses* to which its contents might be put, and the possible *novel topics* for which it might provide enlightenment. To illustrate this point, I would now include the key words *moral pathology*, *moral character*, *moral reasoning*, *moral development*, and *moral conflict* in such a list. For this belated oppor-

tunity, here on this page, I am once again in Boelsen’s debt.

Embodied Prediction

Andy Clark

Versions of the “predictive brain” hypothesis rank among the most promising and the most conceptually challenging visions ever to emerge from computational and cognitive neuroscience. In this paper, I briefly introduce (section 1) the most radical and comprehensive of these visions—the account of “active inference”, or “action-oriented predictive processing” (Clark 2013a), developed by Karl Friston and colleagues. In section 2, I isolate and discuss four of the framework’s most provocative claims: (i) that the core flow of information is top-down, not bottom-up, with the forward flow of sensory information replaced by the forward flow of prediction error; (ii) that motor control is just more top-down sensory prediction; (iii) that efference copies, and distinct “controllers”, can be replaced by top-down predictions; and (iv) that cost functions can fruitfully be replaced by predictions. Working together, these four claims offer a tantalizing glimpse of a new, integrated framework for understanding perception, action, embodiment, and the nature of human experience. I end (section 3) by sketching what may be the most important aspect of the emerging view: its ability to embed the use of fast and frugal solutions (as highlighted by much work in robotics and embodied cognition) within an over-arching scheme that includes more structured, knowledge-intensive strategies, combining these fluently and continuously as task and context dictate.

1 Mind turned upside down?

PP (Predictive processing; for this terminology, see Clark 2013a) turns a traditional picture of perception on its head. According to that once-standard picture (Marr 1982), perceptual processing is dominated by the forward flow of information transduced from various sensory receptors. As information flows forward, a progressively richer picture of the real-world scene is constructed. The process of construction would involve the use of stored knowledge of various kinds, and the forward flow of information was subject to modulation and nuancing by top-down (mostly attentional) effects. But the basic picture remained one in which perception was fundamentally a process of “bottom-up feature detection”. In Marr’s theory of vision, detected intensities (arising from surface discon-

tinuities and other factors) gave way to detected features such as blobs, edges, bars, “zero-crossings”, and lines, which in turn gave way to detected surface orientations leading ultimately (though this step was always going to be problematic) to a three-dimensional model of the visual scene. Early perception is here seen as building towards a complex world model by a feedforward process of evidence accumulation. Traditional perceptual neuroscience followed suit, with visual cortex (the most-studied example) being “traditionally viewed as a hierarchy of neural feature detectors, with neural population responses being driven by bottom-up stimulus features” (Egner et al. 2010, p. 16601). This was a view of the perceiving brain as passive and stimulus-driven, taking energetic inputs

from the senses and turning them into a coherent percept by a kind of step-wise build-up moving from the simplest features to the more complex: from simple intensities up to lines and edges and on to complex meaningful shapes, accumulating structure and complexity along the way in a kind of Lego-block fashion.

Such views may be contrasted with the increasingly active views that have been pursued over the past several decades of neuroscientific and computational research. These views (Ballard 1991; Churchland et al. 1994; Ballard et al. 1997) stress the active search for task-relevant information just-in-time for use. In addition, huge industries of work on intrinsic neural activity, the “resting state” and the “default mode” (for a review, see Raichle & Snyder 2007) have drawn our attention to the ceaseless buzz of neural activity that takes place even in the absence of ongoing task-specific stimulation, suggesting that much of the brain’s work and activity is in some way ongoing and endogenously generated.

Predictive processing plausibly represents the last and most radical step in this retreat from the passive, input-dominated view of the flow of neural processing. According to this emerging class of models, naturally intelligent systems (humans and other animals) do not passively await sensory stimulation. Instead, they are constantly active, trying to predict the streams of sensory stimulation before they arrive. Before an “input” arrives on the scene, these pro-active cognitive systems are already busy predicting its most probable shape and implications. Systems like this are already (and almost constantly) poised to act, and all they need to process are any sensed deviations from the predicted state. It is these calculated deviations from predicted states (known as *prediction errors*) that thus bear much of the information-processing burden, informing us of what is salient and newsworthy within the dense sensory barrage. The extensive use of top-down probabilistic prediction here provides an effective means of avoiding the kinds of “representational bottleneck” feared by early opponents (e.g., Brooks 1991) of representation-heavy—but feed-forward dominated—forms of pro-

cessing. Instead, the downward flow of prediction now does most of the computational “heavy-lifting”, allowing moment-by-moment processing to focus only on the newsworthy departures signified by salient (that is, high-precision—see section 3) prediction errors. Such economy and preparedness is biologically attractive, and neatly sidesteps the many processing bottlenecks associated with more passive models of the flow of information.

Action itself (more on this shortly) then needs to be reconceived. Action is not so much a response to an input as a neat and efficient way of selecting the next “input”, and thereby driving a rolling cycle. These hyperactive systems are constantly predicting their own upcoming states, and actively moving so as to bring some of them into being. We thus act so as to bring forth the evolving streams of sensory information that keep us viable (keeping us fed, warm, and watered) and that serve our increasingly recondite ends. PP thus implements a comprehensive reversal of the traditional (bottom-up, forward-flowing) schema. The largest contributor to ongoing neural response, if PP is correct, is the ceaseless anticipatory buzz of downwards-flowing neural prediction that drives both perception and action. Incoming sensory information is just one further factor perturbing those restless pro-active seas. Within those seas, percepts and actions emerge via a recurrent cascade of sub-personal predictions forged (see below) from unconscious expectations spanning multiple spatial and temporal scales.

Conceptually, this implies a striking reversal, in that the driving sensory signal is really just providing corrective feedback on the emerging top-down predictions.¹ As ever-active prediction engines, these kinds of minds are not, fundamentally, in the business of solving puzzles given to them as inputs. Rather, they are in the business of keeping us one step ahead of the game, poised to act and actively eliciting the sensory flows that keep us viable and fulfilled. If this is on track, then just about every aspect of the passive forward-flowing model is false. We are not passive cognitive couch potatoes so

¹ For this observation, see Friston (2005), p. 825, and the discussion in Hohwy (2013).

much as proactive predictors, forever trying to stay one step ahead of the incoming waves of sensory stimulation.

2 Radical predictive processing

Such models involve a number of quite radical claims. In the present treatment, I propose focusing upon just four:

1. The core flow of information is top-down, not bottom-up, and the forward flow of sensory information is replaced by the forward flow of prediction error.
2. Motor control is just more top-down sensory prediction.
3. Efference copies, and distinct “controllers” (inverse models) are replaced by top-down predictions.
4. Cost functions are absorbed into predictions.

One thing I shan’t try to do here is rehearse the empirical evidence for the framework. That evidence (which is substantial but importantly incomplete) is rehearsed in [Clark \(2013a\)](#) and [Hohwy \(2013, this collection\)](#). For a recent attempt to specify a neural implementation, see [Bastos et al. \(2012\)](#). I now look at each of these points in turn:

2.1 The core flow of information is top-down, not bottom-up, and the forward flow of sensory information is replaced by the forward flow of prediction error

This is the heart and soul of the radical vision. Incoming sensory information, if PP is correct, is constantly met with a cascade of top-down prediction, whose job is to predict the incoming signal across multiple temporal and spatial scales.

To see how this works in practice, consider a seminal proof-of-concept by [Rao & Ballard \(1999\)](#). In this work, prediction-based learning targets image patches drawn from natural scenes using a multi-layer artificial neural network. The network had no pre-set task apart from that of using the downwards connections

to match input samples with successful predictions. Instead, visual signals were processed via a hierarchical system in which each level tried (in the way just sketched) to predict activity at the level below it using recurrent (feedback) connections. If the feedback successfully predicted the lower-level activity, no further action was required. Failures to predict enabled tuning and revision of the model (initially, just a random set of connection weights) generating the predictions, thus slowly delivering knowledge of the regularities governing the domain. In this architecture, forward connections between levels carried only the “residual errors” ([Rao & Ballard 1999](#), p. 79) between top-down predictions and actual lower level activity, while backward or recurrent connections carried the predictions themselves.

After training, the network developed a nested structure of units with simple-cell-like receptive fields and captured a variety of important, empirically-observed effects. One such effect was “end-stopping”. This is a “non-classical receptive field” effect in which a neuron responds strongly to a short line falling within its classical receptive field but (surprisingly) shows diminishing response as the line gets longer. Such effects (and with them, a whole panoply of “context effects”) emerge naturally from the use of hierarchical predictive processing. The response tails off as the line gets longer, because longer lines and edges were the statistical norm in the natural scenes to which the network was exposed in training. After training, longer lines are thus what is first predicted (and fed back, as a hypothesis) by the level-two network. The strong firing of some level-one “edge cells”, when they are driven by shorter lines, thus reflects not successful feature detection by those cells but rather error or mismatch, since the short segment was not initially predicted by the higher-level network. This example neatly illustrates the dangers of thinking in terms of a simple cumulative flow of feature-detection, and also shows the advantages of re-thinking the flow of processing as a mixture of top-down prediction and bottom-up error correction.² In ad-

² This does not mean that there are no cells in v1 or elsewhere whose responses match the classical profile. PP claims that each neural area

dition it highlights the way these learning routines latch on to the world in a manner specified by the training data. End-stopped cells are simply a response to the structure of the natural scenes used in training, and reflect the typical length of the lines and edges in these natural scenes. In a very different world (such as the underwater world of some sea-creatures) such cells would learn very different responses.

These were early and relatively low-level results, but the predictive processing model itself has proven rich and (as we shall see) widely applicable. It assumes only that the environment generates sensory signals by means of nested interacting causes and that the task of the perceptual system is to invert this structure by learning and applying a structured internal model—so as to predict the unfolding sensory stream. Routines of this kind have recently been successfully applied in many domains, including speech perception, reading, and recognizing the actions of oneself and of other agents (see [Poepel & Monahan 2011](#); [Price & Devlin 2011](#); [Friston et al. 2011](#)). This is not surprising, since the underlying rationale is quite general. If you want to predict the way some set of sensory signals will change and evolve over time, a good thing to do is to learn how those sensory signals are determined by interacting external causes. And a good way to learn about those interacting causes is to try to predict how the sensory signal will change and evolve over time.

Now try to imagine this this on a very grand scale. To predict the visually presented scene, the system must learn about edges, blobs, line segments, shapes, forms, and (ultimately) objects. To predict text, it must learn about interacting “hidden” causes in the linguistic domain: causes such as sentences, words, and letters. To predict all of our rich multimodal plays of sensory data, across many scales of space and time, it must learn about interacting hidden causes such as tables, chairs, cats, faces, people, hurricanes, football games, goals,

contains two kinds of cell, or at least supports two functionally distinct response profiles, such that one functionality encodes error and the other current best-guess content. This means that there can indeed be (as single cell recordings amply demonstrate) recognition cells in each area, along with the classical response profiles. For more on this important topic, see [Clark \(2013a\)](#).

meanings, and intentions. The structured world of human experience, if this is correct, comes into view only when all manner of top-down predictions meet (and “explain away”) the incoming waves of sensory information. What propagates forwards (through the brain, away from the sensory peripheries) is then only the mismatches, at every level, with predicted activity.

This makes functional sense. Given that the brain is ever-active, busily predicting its own states at many levels, all that matters (that is, all that is newsworthy, and thus ought to drive further processing) are the incoming surprises: unexpected deviations from what is predicted. Such deviations result in prediction errors reflecting residual differences, at every level and stage of processing, between the actual current signal and the predicted one. These error signals are used to refine the prediction until the sensory signal is best accommodated.

Prediction error thus “carries the news”, and is pretty much the hero (or anti-hero) of this whole family of models. So much so, that it is sometimes said that:

In predictive coding schemes, sensory data are replaced by prediction error, because that is the only sensory information that has yet to be explained. ([Feldman & Friston 2010](#), p. 2)

We can now savor the radicalism. Where traditional, feed-forward-based views see a progressive (though top-down modulated) flow of complex feature-detection, the new view depicts a progressive, complex flow of feature prediction. The top-down flow is not mere attentional modulation. It is the core flow of structured content itself. The forward-flowing signal, by contrast, has now morphed into a stream of residual error. I want to suggest, however, that we treat this apparently radical inversion with some caution. There are two reasons for this—one conceptual, and one empirical.

The first (conceptual) reason for caution is that the “error signal” in a trained-up predictive coding scheme is highly informative. Prediction error signals carry detailed information

about the mismatched content itself. Prediction errors are thus as structured and nuanced in their implications as the model-based predictions relative to which they are computed. This means that, in a very real sense, the prediction error signal is not a mere proxy for incoming sensory information – it *is* sensory information. Thus, suppose you and I play a game in which I (the “higher, predicting level”) try to describe to you (the “lower level”) the scene in front of your eyes. I can’t see the scene directly, but you can. I do, however, believe that you are in some specific room (the living room in my house, say) that I have seen in the past. Recalling that room as best I can, I say to you “there’s a vase of yellow flowers on a table in front of you”. The game then continues like this. If you are silent, I take that as your agreeing to my description. But if I get anything that matters wrong, you must tell me what I got wrong. You might say “the flowers are yellow”. You thus provide an error signal that invites me to try again in a rather specific fashion—that is, to try again with respect to the colour of the flowers in the vase. The next most probable colour, I conjecture, is red. I now describe the scene in the same way but with red flowers. Silence. We have settled into a mutually agreeable description.³

The point to note is that your “error signal” carried some quite specific information. In the pragmatic context of your silence regarding all other matters, the content might be glossed as “there is indeed a vase of flowers on the table in front of me but they are not yellow”. This is a pretty rich message. Indeed, it does not (content-wise) seem different in kind to the down-

ward-flowing predictions themselves. Prediction error signals are thus richly informative, and as such (I would argue) not radically different to sensory information itself. This is unsurprising, since mathematically (as Karl Friston has pointed out⁴) sensory information and prediction error are informationally identical, except that the latter are centred on the predictions. To see this, reflect on the fact that prediction error is just the original information minus the prediction. It follows that the original information is given by the prediction error plus the prediction. Prediction error is simply error relative to some specific prediction and as such it flags the sensory information that is as yet unexplained. The forward flow of prediction error thus constitutes a *forward flow of sensory information relative to specific predictions*.

There is more to the story at this point, since the (complex, non-linear) ways in which downward-flowing predictions interact are importantly different to the (simple, linear) effects of upward-flowing error signals. Non-linearities characterize the multi-level construction of the predictions, which do the “heavy lifting”, while the prediction error signals are free to behave additively (since all the complex webs of linkage are already in place). But the bottom line is that prediction error does not replace sensory information in any mysterious or conceptually challenging fashion, since prediction error is nothing other than that sensory information that has yet to be explained.

The second (empirical) reason for caution is that it is, in any case, only one specific implementation of the predictive brain story depicts the forward-flow as consisting solely of prediction error. An alternative implementation (due to Spratling 2008 and 2010—and see discussion in Spratling 2013) implements the same key principles using a different flow of prediction and error, and described by a variant mathematical framework. This illustrates the urgent need to explore multiple variant architectures for prediction error minimization. In fact, the PP schema occupies just one point in a large and complex space of probabilistic generative-

³ To complete the image using this parlour game, we’d need to add a little more structure to reflect the hierarchical nature of the message-passing scheme. We might thus imagine many even-higher-level “prediction agents” working together to predict which room (house, world, etc.) the layers below are currently responding to. Should sufficient prediction error signals accrue, this ensemble might abandon the hypothesis that signals are coming in from the living room, suggesting instead that they are from the boudoir, or the attic. In this grander version (which recalls the “mixtures of experts” model in machine learning—see Jordan & Jacobs 1994)—there are teams (and teams of teams) of specialist prediction agents, all trying (guided top-down by the other prediction agents, and bottom-up by prediction errors from the level below) to decide which specialists should handle the current sensory barrage. Each higher-level “prediction agent”, in this multi-level version, treats activity at the level below as sensory information, to be explained by the discovery of apt top-down predictions.

⁴ Personal communication.

model-based approaches, and there are many possible architectures and possible ways of combining top-down predictions and bottom-up sensory information in this general vicinity. These include foundational work by Hinton and colleagues on deep belief networks (Hinton & Salakhutdinov 2006; Hinton et al. 2006), work that shares a core emphasis on the use of prediction and probabilistic multi-level generative models, as well as recent work combining connectionist principles with Bayesian angles (see McClelland 2013 and Zorzi et al. 2013). Meanwhile, roboticists such as Tani (2007), Saegusa et al. (2008), Park et al. (2012), Pezzulo (2008), and Mohan et al. (2010) explore the use of a variety of prediction-based learning routines as a means of grounding higher cognitive functions in the solid bedrock of sensorimotor engagements with the world. Only by considering the full space of possible prediction-and-generative-model-based architectures and strategies can we start to ask truly pointed experimental questions about the brain and about biological organisms; questions that might one day favor one of these models (or, more likely, one coherent sub-set of models⁵) over the rest, or else may reveal deep faults and failings among their substantial common foundations.

2.2 Motor control is just more top-down sensory prediction

I shall, however, continue to concentrate upon the specific explanatory schema implied by PP, as this represents (it seems to me) the most comprehensive and neuroscientifically well-grounded vision of the predictive mind currently available. What makes PP especially interesting—and conceptually challenging—is the seamless integration of perception and action achieved under the rubric of “active inference”.

To understand this, consider the motor system. The motor system (like the visual cortex) displays a complex hierarchical structure.⁶

Such a structure allows complex behaviors to be specified, at higher levels, in compact ways, the implications of which can be progressively unpacked at the lower levels. The traditional way of conceptualizing the difference, however, is that in the case of motor control we imagine a downwards flow of information, whereas in the case of the visual cortex we imagine an upwards flow. Descending pathways in the motor cortex, this traditional picture suggests, should correspond functionally to ascending pathways in the visual cortex. This is not, however, the case. Within the motor cortex the downwards connections (descending projections) are “anatomically and physiologically more like backwards connections in the visual cortex than the corresponding forward connections” (Adams et al. 2013, p. 1).

This is suggestive. Where we might have imagined the functional anatomy of a hierarchical motor system to be some kind of inverted image of that of the perceptual system, instead the two seem fundamentally alike.⁷ The explanation, PP suggests, is that the downwards connections, in both cases, take care of essentially the same kind of business—namely the business of predicting sensory stimulation. Predictive processing models subvert, we saw, the traditional picture with respect to perception. In PP, compact higher-level encodings are part of an apparatus that tries to predict the play of energy across the sensory surfaces. The same story applies, recent extensions (see below) of PP suggest, to the motor case. The difference is that motor control is, in a certain sense, subjunctive. It involves predicting the non-actual sensory trajectories that *would* ensue *were* we performing some desired action. Reducing prediction er-

archy is fluid in that the information-flows it supports are reconfigurable moment-by-moment (by, for example, changing β and theta band oscillations —see Bastos et al. 2015). In addition, PP dispenses entirely with the traditional idea (nicely reviewed, and roundly rejected, in Churchland et al. 1994) that earlier levels must complete their tasks before passing information “up” the hierarchy. The upshot is that the PP models are much closer to dynamical systems accounts than to traditional, feed forward, hierarchical ones.

⁷ For the full story, see Adams et al. (2013). In short: “[t]he descending projections from motor cortex share many features with top-down or backward connections in visual cortex; for example, corticospinal projections originate in infragranular layers, are highly divergent and (along with descending cortico-cortical projections) target cells expressing NMDA receptors” (Adams et al. 2013, p. 1).

⁵ One such subset is, of course, the set of hierarchical dynamic models (see Friston 2008).

⁶ The appeal to hierarchical structure in PP, it should be noted, is substantially different to that familiar from treatments such as Felleman & Van Essen (1991). Although I cannot argue for this here (for more on this see Clark 2013b; *in press*) the PP hier-

rors calculated against these non-actual states then serves (in ways we are about to explore) to make them actual. We predict the sensory consequences of our own action and this brings the actions about.

The upshot is that the downwards connections, in both the motor and the sensory cortex, carry complex predictions, and the upwards connections carry prediction errors. This explains the otherwise “paradoxical” (Shipp et al. 2013, p. 1) fact that the functional circuitry of the motor cortex does not seem to be inverted with respect to that of the sensory cortex. Instead, the very distinction between the motor and the sensory cortex is now eroded—both are in the business of top-down prediction, though the kind of thing they predict is (of course) different. The motor cortex here emerges, ultimately, as a multimodal sensorimotor area issuing predictions in both proprioceptive and other modalities.

In this way, PP models have been extended (under the umbrella of “active inference”—see Friston 2009; Friston et al. 2011) to include the control of action. This is accomplished by predicting the flow of sensation (especially that of proprioception) that would occur were some target action to be performed. The resulting cascade of prediction error is then quashed by moving the bodily plant so as to bring the action about. Action thus results from our own predictions concerning the flow of sensation—a version of the “ideomotor” theory of James (1890) and Lotze (1852), according to which the very idea of moving, when unimpeded by other factors, is what brings the moving about. The resulting schema is one in which:

The perceptual and motor systems should not be regarded as separate but instead as a single active inference machine that tries to predict its sensory input in all domains: visual, auditory, somatosensory, interoceptive and, in the case of the motor system, proprioceptive. (Adams et al. 2013, p. 4)

In the case of motor behaviors, the key driving predictions, Friston and colleagues suggest, are

predictions of the proprioceptive patterns⁸ that would ensue were the action to be performed (see Friston et al. 2010). To make an action come about, the motor plant responds so as to cancel out proprioceptive prediction errors. In this way, predictions of the unfolding proprioceptive patterns that would be associated with the performance of some action serve to bring that action about. Proprioceptive predictions directly elicit motor actions (so traditional motor commands are simply replaced by those proprioceptive predictions).

This erases any fundamental computational line between perception and the control of action. There remains, to be sure, an obvious (and important) difference in direction of fit. Perception here matches neural hypotheses to sensory inputs, and involves “predicting the present”; while action brings unfolding proprioceptive inputs into line with neural predictions. The difference, as Elizabeth Anscombe (1957) famously remarked,⁹ is akin to that between consulting a shopping list to select which items to purchase (thus letting the list determine the contents of the shopping basket) and listing some actually purchased items (thus letting the contents of the shopping basket determine the list). But despite this difference in direction of fit, the underlying form of the neural computations is now revealed to be the same. Indeed, the main difference between the motor and the visual cortex, on this account, lies more in what kind of thing (for example, the proprioceptive consequences of a trajectory of motion) is predicted, rather than in how it is predicted. The upshot is that:

The primary motor cortex is no more or less a motor cortical area than striate (visual) cortex. The only difference

⁸ Proprioception is the “inner” sense that informs us about the relative locations of our bodily parts and the forces and efforts that are being applied. It is to be distinguished from exteroceptive (i.e., standard perceptual) channels such as vision and audition, and from interoceptive channels informing us of hunger, thirst, and states of the viscera. Predictions concerning the latter may (see Seth 2013 and Pezzulo 2014) play a large role in the construction of feelings and emotions.

⁹ Anscombe’s target was the distinction between desire and belief, but her observations about direction of fit generalize (as Shea 2013 notes) to the case of actions, here conceived as the motoric outcomes of certain forms of desire.

between the motor cortex and visual cortex is that one predicts retinotopic input while the other predicts proprioceptive input from the motor plant. (Friston et al. 2011, p. 138)

Perception and action here follow the same basic logic and are implemented using the same computational strategy. In each case, the systemic imperative remains the same: the reduction of ongoing prediction error. This view has two rather radical consequences, to which we shall now turn.

2.3 Efference copies and distinct “controllers” are replaced by top-down predictions

A long tradition in the study of motor control invokes a “forward model” of the likely sensory consequences of our own motor commands. In this work, a copy of the motor command (known as the “efference copy”; Von Holst 1954) is processed using the forward model. This model captures (or “emulates”—see Grush 2004) the relevant biodynamics of the motor plant, enabling (for example) a rapid prediction of the likely feedback from the sensory peripheries. It does this by encoding the relationship between motor commands and predicted sensory outcomes. The motor command is thus captured using the efference copy which, fed to the forward model, yields a prediction of the sensory outcome (this is sometimes called the “corollary discharge”). Comparisons between the actual and the predicted sensory input are thus enabled.

But motor control, in the leading versions of this kind of account, requires in addition the development and use of a so-called “inverse model” (see e.g., Kawato 1999; Franklin & Wolpert 2011). Where the forward model maps current motor commands in order to predicted sensory effects, the inverse model (also known as a controller) “performs the opposite transformation [...] determining the motor command required to achieve some desired outcome” (Wolpert et al. 2003, p. 595). Learning and deploying an inverse model appropriate to some

task is, however, generally much more demanding than learning the forward model, and requires solving a complex mapping problem (linking the desired end-state to a nested cascade of non-linearly interacting motor commands) while effecting transformations between varying co-ordinate schemes (e.g., visual to muscular or proprioceptive—see e.g., Wolpert et al. 2003, pp. 594–596).

PP (the full “action-inclusive” version just described) shares many key insights with this work. They have common a core emphasis on the prediction-based learning of a forward (generative) model, which is able to anticipate the sensory consequences of action. But active inference, as defended by Friston and others—see e.g., Friston (2011); Friston et al. (2012)—dispenses with the inverse model or controller, and along with it the need for efference copy of the motor command. To see how this works, consider that action is here reconceived as a direct consequence of predictions (spanning multiple temporal and spatial scales) about trajectories of motion. Of special importance here are predictions about proprioceptive consequences that implicitly minimize various energetic costs. Subject to the full cascade of hierarchical top-down processing, a simple motor command now unfolds into a complex set of predictions concerning both proprioceptive and exteroceptive effects. The proprioceptive predictions then drive behavior, causing us to sample the world in the ways that the current winning hypothesis dictates.¹⁰

Such predictions can be couched, at the higher levels, in terms of desired states or trajectories specified using extrinsic (world-centered, limb-centered) co-ordinates. This is possible because the required translation into intrinsic (muscle-based) co-ordinates is then devolved to what are essentially classical reflex arcs set up to quash proprioceptive prediction errors. Thus:

if motor neurons are wired to suppress proprioceptive prediction errors in the dorsal horn of the spinal cord, they effect-

¹⁰ For a simulation-based demonstration of the overall shape of the PP account, see Friston et al. (2012). These simulations, as the authors note, turn out to implement the kind of “active vision” account put forward in Wurtz et al. (2011).

ively implement an inverse model, mapping from desired sensory consequences to causes in intrinsic (muscle-based) coordinates. In this simplification of conventional schemes, descending motor commands become topdown predictions of proprioceptive sensations conveyed by primary and secondary sensory afferents. (Friston 2011, p. 491)

The need (prominent in approaches such as Kawato 1999; Wolpert et al. 2003; and Franklin & Wolpert 2011) for a distinct inverse model/optimal control calculation has now disappeared. In its place we find a more complex forward model mapping prior beliefs about desired trajectories to sensory consequences, some of which (the “bottom level” proprioceptive ones) are automatically fulfilled.

The need for efference copy has also disappeared. This is because descending signals are already (just as in the perceptual case) in the business of predicting sensory (both proprioceptive and exteroceptive) consequences. By contrast, so-called “corollary discharge” (encoding predicted sensory outcomes) is now endemic and pervades the downwards cascade, since:

[...] every backward connection in the brain (that conveys topdown predictions) can be regarded as corollary discharge, reporting the predictions of some sensorimotor construct. (Friston 2011, p. 492)

This proposal may, on first encounter, strike the reader as quite implausible and indeed too radical. Isn’t an account of the functional significance and neurophysiological reality of efference copy one of the major success stories of contemporary cognitive and computational neuroscience? In fact, most (perhaps all) of the evidence often assumed to favour that account is, on closer examination, simply evidence of the pervasive and crucial role of forward models and corollary discharge—it is evidence, that is to say, for just those parts of the traditional story that are preserved (and made even more central) by PP. For example, Sommer & (Wurtz’s influential (2008) review paper makes very little

mention of efference copy as such, but makes widespread use of the more general concept of corollary discharge—though as those authors note, the two terms are often used interchangeably in the literature. A more recent paper, Wurtz et al. (2011), mentions efference copy only once, and does so only to merge it with discussions of corollary discharge (which then occur 114 times in the text). Similarly, there is ample reason to believe that the cerebellum plays a special role here, and that that role involves making or optimizing perceptual predictions about upcoming sensory events (Bastian 2006; Roth et al. 2013). But such a role is, of course, entirely consistent with the PP picture. This shows, I suggest, that it is the general concept of forward models (as used by e.g., Miall & Wolpert 1996) and corollary discharge, rather than the more specific concept of efference copy as we defined it above, that enjoys the clearest support from both experimental and cognitive neuroscience.

Efference copy figures prominently, of course, in one particular set of computational proposals. These proposals concern (in essence) the positioning of forward models and corollary discharges within a putative larger cognitive architecture involving multiple paired forward and inverse models. In these “paired forward inverse model” architectures (see e.g., Wolpert & Kawato 1998; Haruno et al. 2003) motor commands are copied to a stack of separate forward models that are used to predict the sensory consequences of actions. But acquiring and deploying such an architecture, as even its strongest advocates concede, poses a variety of extremely hard computational challenges (see Franklin & Wolpert 2011). The PP alternative neatly sidesteps many of these problems—as we shall see in section 2.4. The heavy lifting that is usually done by traditional efference copy, inverse models, and optimal controllers is now shifted to the acquisition and use of the predictive (generative) model—i.e., the right set of prior probabilistic “beliefs”. This is potentially advantageous if (but only if) we can reasonably assume that these beliefs “emerge naturally as top-down or empirical priors during hierarchical perceptual inference” (Friston 2011, p. 492).

The deeper reason that efference copy may be said to have disappeared in PP is thus that the whole (problematic) structure of paired forward and inverse models is absent. It is not needed, because some of the predicted sensory consequences (the predicted proprioceptive trajectories) act as motor commands already. As a result, there are no distinct motor commands to copy, and (obviously) no efference copies as such. But one could equally well describe the forward-model-based predictions of proprioceptive trajectories as “minimal motor commands”: motor commands that operate (in essence) by specifying results rather than by exerting fine-grained limb and joint control. These minimal motor commands (proprioceptive predictions) clearly influence the even wider range of predictions concerning the exteroceptive sensory consequences of upcoming actions. The core functionality that is normally attributed to the action of efference copy is thus preserved in PP, as is the forward-model-based explanation of core phenomena, such as the finessing of time-delays (Bastian 2006) and the stability of the visual world despite eye-movements (Sommer & Wurtz 2006; 2008).

2.4 Cost functions are absorbed by predictions.

Active inference also sidesteps the need for explicit cost or value functions as a means of selecting and sculpting motor response. It does this (Friston 2011; Friston et al. 2012) by, in essence, building these in to the generative model whose probabilistic predictions combine with sensory inputs in order to yield behaviors. Simple examples of cost or value functions (that might be applied to sculpt and select motor behaviors) include minimizing “jerk” (the rate of change of acceleration of a limb during some behavior) and minimizing rate of change of torque (for these examples see Flash & Hogan 1985 and Uno et al. 1989 respectively). Recent work on “optimal feedback control” minimizes more complex “mixed cost functions” that address not just bodily dynamics but also systemic noise and the required accuracy of outcomes (see Todorov 2004; Todorov & Jordan 2002).

Such cost functions (as Friston 2011, p. 496 observes) resolve the many-one mapping problem that afflicts classical approaches to motor control. There are many ways of using one’s body to achieve a certain goal, but the action system has to choose one way from the many available. Such devices are not, however, needed within the framework on offer, since:

In active inference, these problems are resolved by prior beliefs about the trajectory (that may include minimal jerk) that uniquely determine the (intrinsic) consequences of (extrinsic) movements. (Friston 2011, p. 496)

Simple cost functions are thus folded into the expectations that determine trajectories of motion. But the story does not stop there. For the very same strategy applies to the notion of desired consequences and rewards at all levels. Thus we read that:

Crucially, active inference does not invoke any “desired consequences”. It rests only on experience-dependent learning and inference: experience induces prior expectations, which guide perceptual inference and action. (Friston et al. 2011, p. 157)

Notice that there is no *overall* computational advantage to be gained by this reallocation of duties. Indeed, Friston himself is clear that:

[...] there is no free lunch when replacing cost functions with prior beliefs [since] it is well-known [Littman et al. (2001)] that the computational complexity of a problem is not reduced when formulating it as an inference problem. (2011, p. 492)

Nonetheless, it may well be that this reallocation (in which cost functions are treated as priors) has conceptually and strategically important consequences. It is easy, for example, to specify whole paths or trajectories using prior beliefs about (you guessed it) paths and trajectories! Scalar reward functions, by contrast, specify points or peaks. The upshot is that everything

that can be specified by a cost function can be specified by some prior over trajectories, but not vice versa.

Related concerns have led many working roboticists to argue that explicit cost-function-based solutions are inflexible and biologically unrealistic, and should be replaced by approaches that entrain actions in ways that implicitly exploit the complex attractor dynamics of embodied agents (see e.g., [Thelen & Smith 1994](#); [Mohan & Morasso 2011](#); [Feldman 2009](#)). One way to imagine this broad class of solutions (for a longer discussion, see [Clark 2008](#), Ch. 1) is by thinking of the way you might control a wooden marionette simply by moving the strings attached to specific body parts. In such cases:

The distribution of motion among the joints is the “passive” consequence of the [...] forces applied to the end-effectors and the “compliance” of different joints. ([Mohan & Morasso 2011](#), p. 5)

Solutions such as these, which make maximal use of learnt or inbuilt “synergies” and the complex bio-mechanics of the bodily plant, can be very fluently implemented (see [Friston 2011](#); [Yamashita & Tani 2008](#)) using the resources of active inference and (attractor-based) generative models. For example, [Namikawa et al. \(2011\)](#) show how a generative model with multi-timescale dynamics enables a fluent and decomposable (see also [Namikawa & Tani 2010](#)) set of motor behaviors. In these simulations:

Action per se, was a result of movements that conformed to the proprioceptive predictions of [...] joint angles [and] perception and action were both trying to minimize prediction errors throughout the hierarchy, where movement minimized the prediction errors at the level of proprioceptive sensations. ([Namikawa et al. 2011](#), p. 4)

Another example (which we briefly encountered in the previous section) is the use of downward-flowing prediction to side-step the need to transform desired movement trajectories from

extrinsic (task-centered) to intrinsic (e.g., muscle-centered) co-ordinates: an “inverse problem” that is said to be both complex and ill-posed ([Feldman 2009](#); [Adams et al. 2013](#), p. 8). In active inference the prior beliefs that guide motor action already map predictions couched (at high levels) in extrinsic frames of reference onto proprioceptive effects defined over muscles and effectors, simply as part and parcel of ordinary online control.

By re-conceiving cost functions as implicit in bodies of expectations concerning trajectories of motion, PP-style solutions sidestep the need to solve difficult (often intractable) optimality equations during online processing (see [Friston 2011](#); [Mohan & Morasso 2011](#)) and—courtesy of the complex generative model—fluidly accommodate signaling delays, sensory noise, and the many-one mapping between goals and motor programs. Alternatives requiring the distinct and explicit computation of costs and values thus arguably make unrealistic demands on online processing, fail to exploit the helpful characteristics of the physical system, and lack biologically plausible means of implementation.

These various advantages come, however, at a price. For the full PP story now shifts much of the burden onto the acquisition of those prior “beliefs”—the multi-level, multi-modal webs of probabilistic expectation that together drive perception and action. This may turn out to be a better trade than it at first appears, since (see [Clark in press](#)) PP describes a biologically plausible architecture that is just about maximally well-suited to installing the requisite suites of prediction, through embodied interactions with the training environments that we encounter, perturb, and—at several slower timescales—actively construct.

3 Putting predictive processing, body, and world together again

An important feature of the full PP account (see [Friston 2009](#); [Hohwy 2013](#); [Clark in press](#)) is that the impact of specific prediction error signals can be systematically varied according to their estimated certainty or “precision”. The precision of a specific prediction error is

its inverse variance—the size (if you like) of its error bars. Precision estimation thus has a kind of meta-representational feel, since we are, in effect, estimating the uncertainty of our own representations of the world. These ongoing (task and context-varying) estimates alter the weighting (the gain or volume, to use the standard auditory analogy) on select prediction error units, so as to increase the impact of task-relevant, reliable information. One key effect of this is to allow the brain to vary the balance between sensory inputs and prior expectations at different levels (see [Friston 2009](#), p. 299) in ways sensitive to task and context.¹¹ High-precision prediction errors have greater gain, and thus play a larger role in driving processing and response. More generally, variable precision-weighting may be seen as the PP mechanism for implementing a wide range of attentional effects (see [Feldman & Friston 2010](#)).

Subtle applications of this strategy, as we shall shortly see, allow PP to nest simple (“quick and dirty”) solutions within the larger context of a fluid, re-configurable inner economy; an economy in which rich, knowledge-based strategies and fast, frugal solutions are now merely different expressions of a unified underlying web of processing. Within that web, changing ensembles of inner resources are repeatedly recruited, forming and dissolving in ways determined by external context, current needs, and (importantly) by flexible precision-weighting reflecting ongoing estimations of our own uncertainty. This process of inner recruitment is itself constantly modulated, courtesy of the complex circular causal dance of sensorimotor engagement, by the evolving state of the external environment. In this way (as I shall now argue) many key insights from work on embodiment and situated, world-exploiting action may be comfortably accommodated within the emerging PP framework.

¹¹ Malfunctions of this precision-weighting apparatus have recently been implicated in a number of fascinating proposals concerning the origins and persistence of various forms of mental disturbance, including the emergence of delusions and hallucinations in schizophrenia, “functional motor and sensory symptoms”, Parkinson’s disease, and autism—see [Fletcher & Frith \(2009\)](#), [Frith & Friston \(2012\)](#), [Adams et al. \(2012\)](#), [Brown et al. \(2013\)](#), [Edwards et al. \(2012\)](#), and [Pellicano & Burr \(2012\)](#).

3.1 Nesting simplicity within complexity

Consider the well-known “outfielder’s problem”: running to catch a fly ball in baseball. Giving perception its standard role, we might assume that the job of the visual system is to transduce information about the current position of the ball so as to allow a distinct “reasoning system” to project its future trajectory. Nature, however, seems to have found a more elegant and efficient solution. The solution, a version of which was first proposed in [Chapman \(1968\)](#), involves running in a way that seems to keep the ball moving at a constant speed through the visual field. As long as the fielder’s own movements cancel any apparent changes in the ball’s optical acceleration, she will end up in the location where the ball hits the ground. This solution, OAC (Optical Acceleration Cancellation), explains why fielders, when asked to stand still and simply predict where the ball will land, typically do rather badly. They are unable to predict the landing spot because OAC is a strategy that works by means of moment-by-moment self-corrections that, crucially, involve the agent’s own movements. The suggestion that we rely on such a strategy is also confirmed by some interesting virtual reality experiments in which the ball’s trajectory is suddenly altered in flight, in ways that could not happen in the real world—see [Fink et al. 2009](#)). OAC is a succinct case of fast, economical problem-solving. The canny use of data available in the optic flow enables the catcher to sidestep the need to deploy a rich inner model to calculate the forward trajectory of the ball.¹²

Such strategies are suggestive (see also [Maturana & Varela 1980](#)) of a very different role of the perceptual coupling itself. Instead of using sensing to get enough information inside, past the visual bottleneck, so as to allow the reasoning system to “throw away the world” and solve the problem wholly internally, such strategies use the sensor as *an open conduit allowing environmental magnitudes to exert a constant influence on behavior*. Sensing is here

¹² There are related accounts of how dogs catch Frisbees—a rather more demanding task due to occasional dramatic fluctuations in the flight path (see [Shaffer et al. 2004](#)).

depicted as the opening of a channel, with successful whole-system behavior emerging when activity in this channel is kept within a certain range. In such cases:

[T]he focus shifts from accurately representing an environment to continuously engaging that environment with a body so as to stabilize appropriate co-ordinated patterns of behaviour. (Beer 2000, p. 97)

These focal shifts may be fluidly accommodated within the PP framework. To see how, recall that “precision weighting” alters the gain on specific prediction error units, and thus provides a means of systematically varying the relative influence of different neural populations. The most familiar role of such manipulations is to vary the balance of influence between bottom-up sensory information and top-down model-based expectation. But another important role is the implementation of fluid and flexible forms of large-scale “gating” among neural populations. This works because very low-precision prediction errors will have little or no influence upon ongoing processing, and will fail to recruit or nuance higher-level representations. Altering the distribution of precision weightings thus amounts, as we saw above, to altering the “simplest circuit diagram” (Aertsen & Preißl 1991) for current processing. When combined with the complex, cascading forms of influence made available by the apparatus of top-down prediction, the result is an inner processing economy that is (see Clark in press) “maximally context-sensitive”.

This suggests a new angle upon the outfielder’s problem. Here too, already-active neural predictions and simple, rapidly-processed perceptual cues must work together (if PP is correct) to determine a pattern of precision-weightings for different prediction-error signals. This creates a pattern of effective connectivity (a temporary distributed circuit) and, within that circuit, it sets the balance between top-down and bottom-up modes of influence. In the case at hand, however, efficiency demands selecting a circuit in which visual sensing is used to cancel the optical acceleration of the fly ball.

This means giving high weighting to the prediction errors associated with cancelling the vertical acceleration of the ball’s optical projection, and (to put it bluntly) not caring very much about anything else. Apt precision weightings here function to select *what to predict* at any given moment. They may thus select a pre-learned, fast, low-cost strategy for solving a problem, as task and context dictate. Contextually-recruited patterns of precision weighting thus accomplish a form of set-selection or strategy switching—an effect already demonstrated in some simple simulations of cued reaching under the influence of changing tonic levels of dopamine firing—see Friston et al. (2012).

Fast, efficient solutions have also been proposed in the context of reasoning and choice. In an extensive literature concerning choice and decision-making, it has been common to distinguish between “model-based” and “model-free” approaches (see e.g., Dayan & Daw 2008; Dayan 2012; Wolpert et al. 2003). Model-based strategies rely, as their name suggests, on a model of the domain that includes information about how various states (worldly situations) are connected, thus allowing a kind of principled estimation (given some cost function) of the value of a putative action. Such approaches involve the acquisition and the (computationally challenging) deployment of fairly rich bodies of information concerning the structure of the task-domain. Model-free strategies, by contrast, are said to “learn action values directly, by trial and error, without building an explicit model of the environment, and thus retain no explicit estimate of the probabilities that govern state transitions” (Gläscher et al. 2010, p. 585). Such approaches implement “policies” that typically exploit simple cues and regularities while nonetheless delivering fluent, often rapid, response.

The model-based/model-free distinction is intuitive, and resonates with old (but increasingly discredited) dichotomies between reason and habit, and between analytic evaluation and emotion. But it seems likely that the image of parallel, functionally independent, neural subsystems will not stand the test of time. For example, a recent functional Magnetic Resonance Imaging (fMRI) study (Daw et al. 2011) sug-

gests that rather than thinking in terms of distinct (functionally isolated) model-based and model-free learning systems, we may need to posit a single “more integrated computational architecture” (Daw et al. 2011, p. 1204), in which the different brain areas most commonly associated with model-based and model-free learning (pre-frontal cortex and dorsolateral striatum, respectively) *each* trade in both model-free and model-based modes of evaluations and do so “in proportions matching those that determine choice behavior” (Daw et al. 2011, p. 1209). Top-down information, (Daw et al. (2011) suggest, might then control the way different strategies are combined in differing contexts for action and choice. Within the PP framework, this would follow from the embedding of shallow “model-free” responses within a deeper hierarchical generative model. By thus combining the two modes within an overarching model-based economy, inferential machinery can, by and large, identify the appropriate contexts in which to deploy the model-free (“habitual”) schemes. “Model-based” and “model-free” modes of valuation and response, if this is correct, name extremes along a single continuum, and may appear in many mixtures and combinations determined by the task at hand.

This suggests a possible reworking of the popular suggestion (Kahneman 2011) that human reasoning involves the operation of two functionally distinct systems: one for fast, automatic, “habitual” response, and the other dedicated to slow, effortful, deliberative reasoning. Instead of a truly dichotomous inner organization, we may benefit from a richer form of organization in which fast, habitual, or heuristically-based modes of response are often the default, but within which a large variety of possible strategies may be available. Humans and other animals would thus deploy multiple—rich, frugal and all points in between—strategies defined across a fundamentally unified web of neural resources (for some preliminary exploration of this kind of more integrated space, see Pezzulo et al. 2013). Some of those strategies will involve the canny use of environmental structure – efficient embodied prediction machines, that is to say, will often deploy minimal

neural models that benefit from repeated calls to world-altering action (as when we use a few taps of the smartphone to carry out a complex calculation).

Nor, finally, is there any fixed limit to the complexities of the possible strategic embeddings that might occur even within a single more integrated system. We might, for example, use some quick-and-dirty heuristic strategy to identify a context in which to use a richer one, or use intensive model-exploring strategies to identify a context in which a simpler one will do. From this emerging vantage point the very distinction between model-based and model-free response (and indeed between System 1 and System 2) looks increasingly shallow. These are now just convenient labels for different admixtures of resource and influence, each of which is recruited in the same general way as circumstances dictate.¹³

3.2 Being human

There is nothing specifically human, however, about the suite of mechanisms explored above. The basic elements of the predictive processing story, as Roepstorff (2013, p. 45) correctly notes, may be found in many types of organism and model-system. The neocortex (the layered structure housing cortical columns that provides the most compelling neural implementation for predictive processing machinery) displays some dramatic variations in size but is common to all mammals. What, then, makes us (superficially at least) so very different? What is it that allows us—unlike dogs, chimps, or dolphins—to latch on to distal hidden causes that include not just food, mates, and relative social rankings, but also neurons, predictive processing, Higgs bosons, and black holes?

One possibility (Conway & Christiansen 2001) is that adaptations of the human neural apparatus have somehow conspired to create, in us, an even more complex and context-flexible

¹³ Current thinking about switching between model-free and model-based strategies places them squarely in the context of hierarchical inference, through the use of “Bayesian parameter averaging”. This essentially associates model-free schemes with simpler (less complex) lower levels of the hierarchy that may, at times, need to be contextualized by (more complex) higher levels.

hierarchical learning system than is found in other animals. Insofar as the predictive processing framework allows for rampant context-dependent influence within the distributed hierarchy, the same basic operating principles might (given a few new opportunities for routing and influence) result in the emergence of qualitatively novel forms of behavior and control. Such changes might explain why human agents display what [Spivey \(2007, p. 169\)](#) describes as an “exceptional sensitivity to hierarchical structure in *any* time-dependent signal”.

Another (possibly linked, and certainly highly complementary) possibility involves a potent complex of features of human life, in particular our ability to engage in temporally coordinated social interaction (see [Roepstorff et al. 2010](#)) and our ability to construct artifacts and design environments. Some of these ingredients have emerged in other species too. But in the human case the whole mosaic comes together under the influence of flexible and structured symbolic language (this was the target of the Conway and Christiansen paper mentioned above) and an almost obsessive drive ([Tommasello et al. 2005](#)) to engage in shared cultural practices. We are thus able to redeploy our core cognitive skills in the transformative context of exposure to what [Roepstorff et al. \(2010\)](#) call “patterned sociocultural practices”. These include the use of symbolic codes (encountered as “material symbols” ([Clark 2006](#)) and complex social routines ([Hutchins 1995, 2014](#))—and more general, all the various plays and strategies known as “cognitive niche construction” (see [Clark 2008](#)).

A simple example is the way that learning to perform mental arithmetic has been scaffolded, in some cultures, by the deliberate use of an abacus. Experience with patterns thus made available helps to install appreciation of many complex arithmetical operations and relations (for discussion of this, see [Stigler 1984](#)). The specific example does not matter very much, to be sure, but the general strategy does. In such cases, we structure (and repeatedly re-structure) our physical and social environments in ways that make available new knowledge and skills—see [Landy & Goldstone \(2005\)](#). Prediction-hungry brains, ex-

posed in the course of embodied action to novel patterns of sensory stimulation, may thus acquire forms of knowledge that were genuinely out-of-reach prior to such physical-manipulation-based re-tuning of the generative model. Action and perception thus work together to reduce prediction error against the more slowly evolving backdrop of a culturally distributed process that spawns a succession of designed environments whose impact on the development (e.g., [Smith & Gasser 2005](#)) and unfolding ([Hutchins 2014](#)) of human thought and reason can hardly be overestimated.

To further appreciate the power and scope of such re-shaping, recall that the predictive brain is not doomed to deploy high-cost, model-rich strategies moment-by-moment in a demanding and time-pressured world. Instead, that very same apparatus supports the learning and contextually-determined deployment of low-cost strategies that make the most of body, world, and action. A maximally simple example is painting white lines along the edges of a winding cliff-top road. Such environmental alterations allow the driver to solve the complex problem of keeping the car on the road by (in part) predicting the ebb and flow of various simpler optical features and cues (see e.g., [Land 2001](#)). In such cases, we are building a better world in which to predict, while simultaneously structuring the world to cue the low-cost strategy at the right time.

3.3 Extending the predictive mind

All this suggests a very natural model of “extended cognition” ([Clark & Chalmers 1998; Clark 2008](#)), where this is simply the idea that bio-external structures and operations may sometimes form integral parts of an agent’s cognitive routines. Nothing in the PP framework materially alters, as far as I can tell, the arguments previously presented, both pro and con, regarding the possibility and actuality of genuinely extended cognitive systems.¹⁴ What PP

¹⁴ For a thorough rehearsal of the positive arguments, see [Clark \(2008\)](#). For critiques, see [Rupert \(2004, 2009\)](#), [Adams & Aizawa \(2001\)](#), and [Adams & Aizawa \(2008\)](#). For a rich sampling of the ongoing debate, see the essays in [Menary \(2010\)](#) and [Estany & Sturm \(2014\)](#).

does offer, however, is a specific and highly “extension-friendly” proposal concerning the shape of the specifically neural contribution to cognitive success. To see this, reflect on the fact that known external (e.g., environmental) operations provide—by partly constituting—additional strategies apt for the kind of “meta-model-based” selection described above. This is because actions that engage and exploit specific external resources will now be selected in just the same manner as the inner coalitions of neural resources themselves. Minimal internal models that involve calls to world-recruiting actions may thus be selected in the same way as a purely internal model. The availability of such strategies (of trading inner complexity against real-world action) is the hallmark of embodied prediction machines.

As a simple illustration, consider the work undertaken by [Pezzulo et al. \(2013\)](#). Here, a so-called “Mixed Instrumental Controller” determines whether to choose an action based upon a set of simple, pre-computed (“cached”) values, or by running a mental simulation enabling a more flexible, model-based assessment of the desirability, or otherwise, of actually performing the action. The mixed controller computes the “value of information”, selecting the more informative (but costly) model-based option only when that value is sufficiently high. Mental simulation, in such cases, then produces new reward expectancies that can determine current action by updating the values used to determine choice. We can think of this as a mechanism that, moment-by-moment, determines (as discussed in previous sections) whether to exploit simple, already-cached routines or to explore a richer set of possibilities using some form of mental simulation. It is easy to imagine a version of the mixed controller that determines (on the basis of past experience) the value of the information that it believes would be made available by some kind of cognitive extension, such as the manipulation of an abacus, an iPhone, or a physical model. Deciding when to rest, content with a simple cached strategy, when to deploy a more costly mental simulation, and when to exploit the environment itself as a cognitive resource are thus all options apt for the same

kind of “meta-Bayesian” model-based resolution.

Seen from this perspective, the selection of task-specific inner *neural* coalitions within an interaction-dominated PP economy is entirely on a par with the selection of task-specific *neural-bodily-worldly* ensembles. The recruitment and use of extended (brain-body-world) problem-solving ensembles now turns out to obey many of the same basic rules, and reflects many of the same basic normative principles (balancing efficacy and efficiency, and reflecting complex precision estimations) as does the recruitment of temporary inner coalitions bound by effective connectivity. In each case, what is selected is a temporary problem-solving ensemble (a “temporary task-specific device”—see [Anderson et al. 2012](#)) recruited as a function of context-varying estimations of uncertainty.

4 Conclusion: Towards a mature science of the embodied mind

By self-organizing around prediction error, and by learning a generative rather than a merely discriminative (i.e., pattern-classifying) model, these approaches realize many of the goals of previous work in artificial neural networks, robotics, dynamical systems theory, and classical cognitive science. They self-organize around prediction error signals, perform unsupervised learning using a multi-level architecture, and acquire a satisfying grip—courtesy of the problem decompositions enabled by their hierarchical form—upon structural relations within a domain. They do this, moreover, in ways that are firmly grounded in the patterns of sensorimotor experience that structure learning, using continuous, non-linguaform, inner encodings (probability density functions and probabilistic inference). Precision-based restructuring of patterns of effective connectivity then allow us to nest simplicity within complexity, and to make as much (or as little) use of body and world as task and context dictate.

This is encouraging. It might even be that models in this broad ballpark offer us a first glimpse of the shape of a fundamental and unified science of the embodied mind.

Extending the Explanandum for Predictive Processing

A Commentary on Andy Clark

Michael Madary

In this commentary, I suggest that the predictive processing framework (PP) might be applicable to areas beyond those identified by Clark. In particular, PP may be relevant for our understanding of perceptual content, consciousness, and for applied cognitive neuroscience. My main claim for each area is as follows:

- 1) PP urges an organism-relative conception of perceptual content.
- 2) Historical *a priori* accounts of the structure of perceptual experience converge with results from PP.
- 3) There are a number of areas in which PP can find important practical applications, including education, public policy, and social interaction.

1 Introduction

An understandable reaction to the predictive processing framework (PP) is to think that it is too ambitious ([Hohwy this collection](#)). My suggestion in this commentary is the opposite. I will argue that PP can be fruitfully applied to areas of inquiry that have so far received little, if any, attention from the proponents of PP. Perhaps we can extend the explanandum even further than Andy Clark has recommended.

There is a certain rhetorical danger to the position I am urging. One should not oversell

one's case. I hope to avoid this danger by being clear upfront that my goal is not to convince the skeptic of the attraction of PP. I cannot improve on Clark (and others, see below) in that regard. Instead, I investigate the following question: if some version of PP (again, see below) is true, then what are the larger implications for human self-understanding? My answer to this question covers three topics. First I will engage with Clark's discussion of perceptual processing from sections 1 and 2.1 of his article. There I

will sketch how PP's reversal of the traditional model of perceptual processing may have significant implications for the way in which we understand perceptual content, which is a core issue in the philosophy of psychology. In the [second](#) section I will turn to another area of philosophical concern: consciousness. Historically, consciousness research has had a rocky relationship with the sciences of the mind. I hope to point towards the possibility of a rapprochement. In the final section of the commentary, I will quickly touch on some practical matters. If PP is true, then there are important consequences for the way in which we approach topics in education, public policy, and social interaction.

My goal is to indicate possible areas in which Clark's article (and related themes) might serve as a foundation for future directions of research. My main claims are as follows, numbered according to each section:

1. PP urges an organism-relative conception of perceptual content.
2. Historical *a priori* accounts of the structure of perceptual experience converge with results from PP.
3. There are a number of areas in which PP can find important practical applications.

Before entering into the specific issues, I should add a note about what I mean by PP. Here I am following the general theoretical framework expressed in Clark's article as well as in a number of other publications ([Clark 2013](#); [Hohwy 2013](#)). The approach has a number of intellectual roots, including [Hermann von Helmholtz \(1867\)](#) and [Richard Gregory \(1980\)](#). The main contemporary expression of PP perhaps owes the most to [Karl Friston \(2005, 2008, 2010\)](#) and his collaborators, also with important developments of the generative model by [Geoffrey Hinton \(2007\)](#). By referring to PP as one general framework, I do not mean to imply that there are no outstanding issues of disagreement or open questions within PP. As Clark indicates, citing [Spratling \(2013\)](#), there are a number of options being developed as to the specific implementation of PP. Also, in the philosophical lit-

erature there is an emerging question about whether to understand PP as internalist or externalist regarding the vehicles of mental states ([Hohwy 2014](#))—I take no position either way here, but see footnote 2. Overall, my remarks are motivated by Clark's exposition of PP, but they should be applicable to other approaches and interpretations as well.

2 A new conception of perceptual content

Clark has emphasized the way in which PP departs from the standard picture in perceptual psychology, and from [David Marr's \(1982\)](#) model of visual processing in particular (pp. 1–5). According to the standard account, the flow of information is “bottom-up,” as perceptual systems construct increasingly sophisticated representations based on the information transduced at the periphery. According to PP, perception involves the active prediction of the upcoming sensory input, “top-down.” Deviation from what is predicted, known as the prediction error, propagates upwards through the hierarchy until it is explained away by the Bayesian generative model.

Now I would like to add that the standard picture in perceptual psychology has been widely regarded as complementary to the standard picture in the philosophy of perception (see [Tye 2000](#), for example). One central question in the philosophy of perception is the following: what is the *content* of perceptual states? Or, what does perception *represent*? The standard answer, in tune with Marr's approach, is that perceptual systems represent the external world, more or less as it really is. As [Marr](#) puts it, the purpose of vision is “to know what is where by looking” ([1982](#)). This way of thinking about perceptual content is almost a commonplace in the philosophical literature ([Lewis 1980](#), p. 239; [Fodor 1987](#), Ch. 4; [Dretske 1995](#), Ch. 1). [Kathleen Akins](#) has described how the orthodox conception regards the senses as “servile” in that they report on the environmental stimulus “without fiction or embellishment” ([1996](#), pp. 350–351).

Since PP overturns the reigning model in perceptual psychology, one might now ask

whether it also overturns the reigning model in the philosophy of perception. Here are two initial reasons to think that it does. First, according to PP, there is always an active contribution from the organism, or at least from a part of the organism. Perceptual states are generated internally and spontaneously by the ongoing dynamics of the generative model. Those states are *constrained* by perceptual sampling of the world, not driven by input from the world. Perceptual states are driven by the endogenous activity of the predictive brain. The relevant causal history of these states begins, if you will, within the brain, rather than from the outside. Each organism's generative model is unique in that it has been formed and continuously revised according to the particular trajectory of that organism's cycle of action and perception. As Clark himself puts it, the forward flow of sensory information is always "*relative to specific predictions*" (p. 6). These considerations make it clear that there can be variation in perceptual content for identical environmental conditions. Perceivers with different histories will have different predictions (Madary 2013, pp. 342–345). The degree of variation is an open question, but it is reasonable to expect variation.

A second reason to think that PP motivates a richer conception of perceptual content is that perception, according to PP, is not simply in the service of informing the organism "what is where." One main feature of PP is that perception and action work together in the service of minimizing prediction error. Clark explains that in "active inference [...]" the agent moves its sensors in ways that amount to actively seeking or generating the sensory consequences that they [...] expect" (2013, p. 6, also see his discussion on page 16). If this is right, then perception does not serve the purpose of simply reporting on the state of the environment. Instead, perception is guided by expectation. While the received view of perceptual content answers the question of "what is out there?", PP suggests that perceptual content answers the question of "is this what I expected and tested via active inference?" In a way, PP simplifies perceptual content by replacing the goal

of representing the world with the single guiding principle of error minimization.

These two points suggest an understanding of perceptual content as something that is deeply informed by the specific history and embodiment of the organism. The content of perception is a complex interplay between particular organisms and their particular environments. At least on the face of it, this way of considering perception suggests new challenges and interesting new theoretical options for philosophers interested in describing perceptual content. For one thing, it suggests that propositional content as expressed using natural language (Searle 1983, p. 40) may be ill-suited for the task of describing perceptual content. Natural language does not typically include reports about prediction-error minimization, nor does it capture the fine-grained differences in perceptual content that will arise due to slight variations in the predictions made by different organisms. The traditional account of perceptual content, following Marr, does not include such differences, and is thus better disposed to expression using natural language.

These new challenges for understanding perceptual content may offer at the same time a general lesson for understanding all mental content in a naturalistic manner. Let me explain. One of the main goals in the philosophy of psychology has been to naturalize intentionality, to give an account of the content of mental states in terms of the natural sciences (in non-mentalistic terms). Well-known attempts include causal co-variation (Fodor 1987, Ch. 4) and teleosemantics (Millikan 1984, 2004). All attempts have met with compelling counterexamples.¹ Importantly, one implicit presupposition in the debate is that mental content should be conceived along the lines of the traditional view of perceptual content sketched above. That is, mental states are thought to be about bits of the objective world considered independently of the particular organism who possesses those mental states. To use a standard example, my belief that there is milk in the refrigerator is true if and only if there is milk in the refriger-

¹ For an overview of the major theories and their challenges, see Jacob (2010, section 9) and the references therein.

ator. This belief is about bits of the objective world: milk and the refrigerator in particular. Nothing else about my mind is deemed relevant for understanding the content of that belief. To use the familiar phrase, beliefs have a mind-to-world direction of fit (based on [Anscombe 1957](#), §32).

If my reading of PP is right, and perceptual content turns out to be a matter of the complex interaction between particular organisms and their environments, then the comfortable pre-theoretical mind/world distinction might need revision.² Recall the discussion above, in which I claimed that, on the new PP-inspired understanding of perception the question is about whether sensory stimulation fulfils the expectations of particular organisms. All perceptual states are thereby colored, as it were, by the mental lives of the organisms having those states. Organisms are not interested in what the world is like. Organisms are interested in sustaining their integrity and physical existence; they are interested in what the world is like *relative to their own particular sensorimotor trajectory through the world*, a trajectory that is partly determined by their phenotype ([Friston et al. 2006](#)). This refashioning of the mind/world relationship is unorthodox, but it is hardly new. Similar ideas can be found in [von Uexküll's Umwelt \(1934\)](#), [Merleau-Ponty's](#) discussion of sensory stimuli (1962, p. 79), [Milikan's](#) “pushmi-pullyu” representations (1995), [Akins' narcissistic sensory systems \(1996\)](#), [Clark's](#) earlier work (1997, Ch. 1), and in [Metzinger's](#) ego tunnel (2009, pp. 8–9).

Now return to the problem of naturalizing intentionality. If we replace the notion of a purely world-directed mental state with a world-relative-to-the-organism-directed mental state, then naturalizing intentionality must somehow incorporate the relationship between

the organism and its world. One way to pursue this project is to make it a matter of biology and physics. All living organisms keep themselves far from thermodynamic equilibrium by continuously exchanging matter and energy with their environment ([Haynie 2008](#)). Perhaps intentionality can be recast in terms of the organism's ongoing struggle to maintain itself as a living entity. This line of thought is central to the enactivist “sense-making” of [Maturana, Varela, and Thompson \(Maturana & Varela 1980; Thompson 2007\)](#). Crucially, it is also a central feature of [Friston's](#) version of PP. According to [Friston](#), prediction error minimization is a kind of functional description for the physical process of the organism's minimizing free energy in its effort to maintain itself far from thermodynamic equilibrium (2013). Naturalizing intentionality may be just a matter of physics (see [Dixon et al. 2014](#) for an implementation of this strategy for problem-solving tasks).

Before moving on to the next section, I should add two qualifications. First, the idea of perceptual content being partly determined by the particular history of the perceiver should not be misunderstood as some kind of radical relativism with regard to perceptual content. Even if perceptual content is *partly* determined by the details of the organism, it is also partly determined by the world itself. As proponents of PP frequently claim, our generative models mirror the causal structure of the world ([Hohwy 2013](#), Ch. 1). The point I am emphasizing here is that the causal structure of the world that is extracted is a structure relative to the embodiment (see [Clark this collection](#), section 2.4)—and perceptual history—of the perceiver. The causal structure mirrored by a chimpanzee's generative model is, in important ways, unlike the causal structure mirrored by that of a catfish.

The second qualification has to do with my remark that naturalizing intentionality may be just a matter of physics. Even if one allows that the approach I sketched shows promise, it is important to emphasize the explanatory gulf that remains. The intentionality-as-physics approach might succeed in explaining a bacterium's intentional directedness towards a

² One possibility here has been explored recently by Karl Friston using the concept of a Markov blanket, which produces a kind of partition between information states. As I read Friston, he advocates a pluralism about Markov blankets. On this view, there is not one boundary between mind and world, but instead there are a number of salient boundaries within, and perhaps around, living organisms. [Friston](#) writes that “... a system can have a multitude of partitions and Markov blankets ... the Markov blanket of an animal encloses the Markov blankets of its organs, which enclose Markov blankets of cells, which enclose Markov blankets of nuclei ...” (2013, p. 10).

sugar gradient (Thompson 2007, p. 74–75), but it is far from clear how it would apply to my belief that P—say, for example, that California Chrome won the Kentucky Derby in 2014.

The main argument of this section has been that PP motivates an understanding of perceptual content that is always organism-relative. Clark’s version of PP, while not in conflict with this idea, has not addressed it explicitly, especially as it relates to the philosophy of perception. My goal here has been to do just that.

3 Consciousness

In this section I would like to consider how conscious experience might relate to the PP framework. In particular, I suggest that there is a convergence between *a priori* descriptions of consciousness, on one hand, and the structure of information processing according to PP on the other.³ I will not remark on the way in which PP relates to some well-known issues in the study of consciousness, such as the hard problem or the explanatory gap. It is not clear to me that PP has anything new to contribute to these topics. Nor will I make any claims about which existing theories of the neural basis of consciousness fit best with PP, although I suspect there is some interesting work there to be done.

My main concern here is in the *structure* of conscious experience, of visual experience in particular. Here I adopt a strategy recommended by Thomas Nagel (1974), and David Chalmers (1996, pp. 224–225). Nagel puts the idea nicely, “[...] structural features of perception might be more accessible to objective description, even though something would be left out” (1974, p. 449, cited in Chalmers 1996, pp. 382 f.). The strategy has been implemented, in fact, using Marr’s theory of vision—the theory that, as Clark puts it, PP turns upside down. Ray Jackendoff (1987, p. 178) and Jesse Prinz (2012, p. 52) have both emphasized the structural similarities between conscious visual experience and Marr’s 2.5 dimensional sketch.

³ For a theoretical treatment of the functional significance of this convergence, see Metzinger & Gallese (2003).

Visual phenomenology is not a flat two-dimensional surface, because we see depth. But neither is visual phenomenology fully three-dimensional, because we cannot see the hidden sides of objects. Marr’s 2.5 dimensional representation captures the level in-between two and three dimensional representation that seems to correspond to our visual phenomenology; it captures Hume’s insight that visual experience is perspectival: “The table, which we see, seems to diminish, as we remove farther from it [...]” (1993, p. 104).

As Hume emphasized the perspectival nature of visual experience, Kant famously emphasized the temporal nature of experience in the second section of the *Transcendental Aesthetic*: “Time is a necessary representation (*Vorstellung*), which lays at the foundation of all intuitions” (1781/1887/1998, A31). In an elegant synthesis of these two features of visual experience, Edmund Husserl suggested that the general structure of visual experience is one of anticipation and fulfillment:

Every percept, and every perceptual context, reveals itself, on closer analysis, as made up of components which are to be understood as ranged under two stand-points of intention and (actual or possible) fulfillment. (*Logical Investigation*, VI §10 1900, Findlay trans., 1970)

In this passage from his early work, Husserl writes of “intention and fulfillment,” but he later replaced “intention” with “anticipation” when dealing with perception.⁴

The main point is fairly straightforward: we perceive properties by implicitly anticipating how the appearances of those properties will

⁴ When first developing the framework, he used the more general term “intention” because he was dealing with linguistic meaning, not perception. When applying the framework to perception one can be more precise about the nature of the empty perceptual intentions: they are anticipatory. In his later work, his *Analyses of Passive Synthesis* from the 1920s, Husserl ties in perceptual intentions with his work on time consciousness (1969) and refers to them as protentions (*Protentionen*; Husserl 1966, p. 7). In the same work, he refers to perceptual protentions as anticipations (*Erwartungen*, 1966, p. 13, and *antizipiert*, 1966, p. 7). See Madary (2012a) for a discussion of how Husserl’s framework can be situated relative to contemporary philosophy of perception. Also see Bernet et al. (1993, p. 128) and Hopp (2011).

change as we move (or as the objects move). Husserl's proposal accommodates the perspectival character of experience because it addresses the question of how we perceive objective properties despite being constrained to one perspective at a time. And it accommodates the temporal nature of experience because anticipation is always future-directed.

Here is not the place to enter into the details of the thesis that the general structure of conscious experience is one of anticipation and fulfillment (see my 2013 for some of these details), but I should add one more point. As both Husserl (1973, p. 294) and Daniel Dennett (1991, Ch. 3) have noted, peripheral vision is highly indeterminate.⁵ Also, as we explore our environment we experience a continuous trade off between determinacy and indeterminacy. As I lean in for a closer look at one object, the other objects in my visual field fade into indeterminacy. In order to account for this feature of experience, we can note that visual anticipations have various degrees of determinacy.⁶

Now let us return to PP. *If Hume provides the philosophy of perception for Marr's theory of vision, then Husserl provides the philosophy of perception for PP.* The structural similarities should be apparent. The predictive brain underlies the essentially anticipatory structure of perceptual awareness. Degrees of determinacy are encoded probabilistically in our generative models (Clark 2013; Madary 2012b). Action and perception are tightly linked (Clark this collection, p. 9) as self-generated movements stir up new perceptual anticipations.

Many readers will see a connection between the thesis of anticipation and fulfillment, on one hand, and the sensorimotor approach to perception (O'Regan & Noë 2001; Noë 2004) on the other. Overall, there is significant thematic overlap between the two (Madary 2012a, p. 149). As Seth (2014) has argued, many of the central claims of the sensorimotor approach can be incorporated into the PP framework.⁷ This synthesis offers impressive explanatory power, bringing the standard sensorimotor experimental evidence (reversing

goggles, change blindness, selective rearing) together with the theoretical neuroscience of PP. The explanatory power is even more impressive if I am correct that PP reflects the general structure of visual phenomenology, where predictive processing corresponds to perceptual anticipations and probabilistic coding corresponds to experienced indeterminacy.

4 Applied cognitive neuroscience

I would like to begin this section with some general comments about new opportunities for human self-understanding, about extending the explanandum. Academic disciplines are standardly divided into the sciences and the humanities, and some have expressed discomfort about the distance between the two modes of inquiry, or between the two cultures, as Snow (1959) famously put it (also see Brockman 1996). There is an immediate appeal to Metzinger's assertion that "Epistemic progress in the real world is something that is achieved by all disciplines together" (2003, p. 4). *If my claims from the previous section are on the right track, then we have a convergence of results between the two independent modes of inquiry, between the empirical sciences and the humanities.* It is tempting to hope that this convergence signals the beginning of a rapprochement between the sciences and the humanities. Perhaps we are at the threshold of a new science of the mind (Rowlands 2010), a science that finds natural and fruitful connections with the world of human experience. In this section, I will explore possible connections with education, public policy, and social interaction.

Clark makes two main claims in the final sections of his article that serve for the basis of my comments here. First, he suggests that PP motivates an understanding of cognitive processing as "maximally context sensitive" (p. 16), which follows from the property of PP systems being highly flexible in setting precision weightings for the incoming prediction errors. Flexibility in weighting precision enables flexibility in the deployment of processing resources. Thus there may be a wide variety of cognitive strategies at our disposal, with a continuous in-

⁵ For impressive empirical work on this theme, see Freeman & Simoncelli (2011).

terplay between more costly and less costly strategies. Second, he addresses the challenge of explaining why humans have unique cognitive powers unavailable to non-human animals who have the same fundamental PP architecture. In response to this challenge, Clark suggests that our abilities may be due to our patterns of social interaction as well as our construction of artifacts and “designer environments” (p. 19). Taken together, these two claims can be used to inform practical decisions in a number of ways.

Begin with education. Educational psychology is a broad and important area of research. PP suggests new ways of approaching human learning, ways that might depart from the received views that have guided educational psychology. I cannot begin to engage with this huge issue here, but I would like to offer one quick example. One fairly well-known application of educational psychology is in the concept of scaffolded learning, which is built on work by Lev Vygotsky and Jerome Bruner. As it is used now, scaffolded learning involves providing the student with helpful aids at particular stages of the learning process. These aids could include having a teacher present to give helpful hints, working in small groups, and various artifacts designed with the intention of anticipating stages at which the student will need help, such as visual aids, models, or tools. Clark himself mentions the abacus, which is central example of scaffolded learning (p. 19). More generally, scaffolded learning is a good example of what Richard Menary has called “cognitive practices,” which he defines as “manipulations of an external representation to complete a cognitive task” (2010, p. 238).

If PP is right, then the learning process could be optimized by designing environments in order to provide the cycle of action and perception with precisely controlled feedback (prediction error). With the growing commercial availability of immersive virtual reality equipment, educators could design learning environments (or help students design their own environments) without the messy constraints of the physical world. PP may give us a framework with which to understand—and predict—the detailed bodily movements of subjects as they

attempt to minimize their own prediction error. Using this framework, we can design systems that would optimize skill acquisition by efficiently predicting the errors that learners will make. This method could be fruitfully applied in the abstract (mathematics), the concrete (skiing), and in-between (foreign languages). Along these lines, the insights of PP, together with emerging technology, can lead to powerful new educational techniques.

Psychology is also applied in some areas of public policy. Clark mentions that PP challenges Kahneman’s well-known model of human thinking as consisting of a fast automatic system and a slower deliberative system (p. 18). Kahneman’s model has been applied as a basis for influential recommendations about laws and public policy in the United States (Thaler & Sunstein 2008; Sunstein 2014). If PP homes in on a more accurate model of the thinking process, then we ought to use it, rather than (or as a complement to?) the dual systems model as a basis for policy making. Clark’s interpretation of PP suggests that we have a highly flexible range of cognitive systems, not limited to Kahneman’s two.

For example, one application of Kahneman’s model might involve the installation of environmental elements meant to appeal to the fast thinking system, to “nudge” agents towards making decisions in their best interest. If Clark is correct, we might consider even more sophisticated environmental features that have the goal of helping agents to deploy their range of cognitive strategies more efficiently. Clark’s ideas of context sensitivity and designer environments are both relevant here. As a society we may wish somehow to create environments and contexts that take advantage of the large repertoire of cognitive strategies available to us, according to Clark’s version of PP (see Levy 2012, for example).

The final topic I’d like to mention in this section is what is best described in general terms as social interaction. I mean to indicate a number of related topics here, but the main issue is how PP might relate to the well-known philosophical topic of the way in which we understand and explain our behavior to one an-

other. Recall, for instance, [Donald Davidson's](#) (1963) claim that our explanation of our behavior in terms of reasons is a kind of causal explanation—reasons as causes. On his influential view, the connection between reason and actions is a causal connection. In contrast, recall [Paul Churchland's](#) envisioning of the golden age of psychology in which we dispose of folk psychological reason-giving in favor of more precise neurophysiological explanations of behavior (1981). According to Churchland's radical alternative, the causes of actions are not reasons as expressed using natural language. Instead, our actions are caused by patterns of neurons firing, patterns that can be described using mathematical tools such as a multidimensional state space. In opposition to Churchland's grand vision, we have [Jerry Fodor's](#) claim that the realization of such a vision would be “the greatest intellectual catastrophe in the history of our species” (1987, p. xii). Is PP the beginning of Churchland's grand vision coming to pass? Is a great intellectual catastrophe looming?

On one hand, PP seems like an obvious departure from folk psychology: Try explaining your X-ing to someone by claiming that you X-ed in order to minimize prediction error! One big issue here will be the way in which we think about agency itself. It seems mistaken to say that minimizing prediction error is something done by an agent. Such a process seems to be better described as occurring sub-personally. On the other hand, it is not inconceivable that propositional attitudes can capture the dynamics of prediction error minimization on a suitably coarse-grained level, perhaps along the lines suggested using symbolic dynamics ([Dale & Spivey 2005](#); [Atmanspacher & beim Graben 2007](#); [Spivey 2007](#), Ch. 10). I suggest that these fascinating issues warrant further investigation. In particular, further investigation ought to incorporate Clark's ideas of maximal context sensitivity and the importance of designer environments.

The way in which we understand each other's behavior is also directly relevant for moral responsibility. Following Peter Strawson's seminal “[Freedom and Resentment](#)” (1962),

philosophers have started thinking about moral responsibility in terms of our reactions to one another, reactions that involve holding each other accountable. On one influential view, we hold each other accountable when our actions issue from our own reasons-responsive mechanisms ([Fischer & Ravizza 1998](#)). On a more recent proposal, holding each other accountable is best modeled as a kind of conversation ([McKenna 2012](#)). These proposals depend, in important ways, on assumptions about human psychology. In particular, they depend on our practice of giving reasons for behavior. As PP suggests a new fundamental underlying principle of behavior, our practices of holding each other accountable may be approached from a new perspective. The new challenge in this area will be to reconcile (if possible) the practice of giving reasons, on one hand, with PP's account of behavior in terms of error minimization on the other.

5 Conclusion

The main theme of my commentary might appear to be driven by an overexcited optimism for the new theory. To be clear, I have not claimed that PP is correct. Even its main proponents are quick to point out that important open issues remain. My claim is that it is worthwhile to consider the full implications of PP, given the convincing evidence presented so far. In this commentary, I have tried to suggest some of the implications that have not yet been mentioned—implications for perceptual content, consciousness, and applied cognitive neuroscience. These implications can be summarized as follows:

1. PP urges an organism-relative conception of perceptual content.
2. Historical *a priori* accounts of the structure of perceptual experience converge with results from PP.
3. There are a number of areas in which PP can find important practical applications.

The final section includes some challenges for future research. The main challenge is one that

has been familiar in one form or another for several decades in the philosophy of mind. This challenge is to address the tension between the way in which we understand and explain our behavior using natural language, on one hand, and our best theory of human behavior from cognitive neuroscience, which, arguably, is PP, on the other hand. In closing I should note that even if key elements of PP are eventually rejected, it might still turn out that our best model of the mind supports some of the themes I have been discussing.

Acknowledgments

I thank Thomas Metzinger and Jennifer Windt for helpful detailed comments on an earlier draft. This research was supported by the EC Project VERE, funded under the EU 7th Framework Program, Future and Emerging Technologies (Grant 257695).

Predicting Peace: The End of the Representation Wars

A Reply to Michael Madary

Andy Clark

Michael Madary's visionary and incisive commentary brings into clear and productive focus some of the deepest, potentially most transformative, implications of the Predictive Processing (PP) framework. A key thread running through the commentary concerns the active and "organism-relative" nature of the inner states underlying perception and action. In this Reply, I pick up this thread, expanding upon some additional features that extend and underline Madary's point. I then ask, What remains of the bedrock picture of inner states bearing familiar representational contents? The answer is not clear-cut. I end by suggesting that we have here moved so far from a once-standard complex of ideas concerning the nature and role of the inner states underlying perception and action that stale old debates concerning the existence, nature, and role of "internal representations" should now be abandoned and peace declared.

Keywords

Action | Action-oriented perception | Content | Enaction | Intentionality | Perception | Perceptual content | Predictive coding | Predictive processing | Representation

1 Organism-relative content

I'm hugely indebted to Michael Madary for his visionary and incisive commentary. The commentary covers three topics – the nature of perceptual content, the structure of experience, and some practical implications of the PP (Predictive Processing) framework. Each one deserves a full-length paper in reply, but I will restrict these brief comments to the first topic – the nature of perceptual content. Should the PP vision prove correct, Madary suggests, this would transform our understanding of the nature and role of perceptual content, with potential consequences for the larger project of naturalizing mental content.

Driving such sweeping and radical reform is (Madary argues) the PP emphasis upon the active contribution of the organism to the generation of perceptual states. There is an active contribution, Madary ([this collection](#), section 2) suggests, insofar as PP depicts perceptual states as "generated internally and spontaneously by the internal dynamics of the generative model" (p. 3).

Such a claim clearly requires careful handling. For even the most staunchly feedforward model of perception requires a substantial contribution from the organism. It is thus the nature, not the existence, of that contribution

that must make the difference. Elaborating upon this, Madary notes that ongoing endogenous activity plays a leading role in the PP story. One might say: the organism's generative model (more on which later) is already active, attempting to predict the incoming sensory flow. The flow of incoming information is thus rapidly flipped into a flow tracking "unexpected salient deviation". Identical inputs may thus result in very different perceptual states as predictions alter and evolve. An important consequence, highlighted by Madary, is that different histories of interaction will thus result in different perceptual contents being computed for the very same inputs. Different species, different niches, differences of bodily form, and differences of proximal goals and of personal history are all thus apt (to varying degrees) to transform what is being predicted, and hence the contents properly delivered by the perceptual process.

Those contents are further transformed by a second feature of the PP account: the active selection of perceptual inputs. For at the most fundamental level, the PP story does not depict perception as a process of building a representation of the external world at all. Instead, it depicts perception as just one part of a cohesive strategy for keeping an organism within a kind of "window of viability". To this end the active organism both predicts *and selects* the evolving sensory flow, moving its body and sensory organs so as to expose itself to the sensory stimulations that it predicts. In this way, some of our predictions act as self-fulfilling prophecies, enabling us to harvest the predicted sensory streams. These two features (endogenous activity and the self-selection of the sensory flow) place PP just about maximally distant from traditional, passive "feedforward hierarchy" stories. They are rather (as Mike Anderson once commented to me) the ultimate expression of the "active perception" program.

Here too, though, we should be careful to nuance our story correctly. For part of maintaining ourselves in a long-term window of viability may involve not just seeking out the sensory flows we predict, but the active elicitation of many that we don't! PP may, in fact, man-

date all manner of short-term explorations and self-destabilizations. But such delicacies (though critically important- see [Clark \(in press\)](#) chapters 8 and 9) may safely be left for another day. The present upshot ([Madary this collection](#), section 2) is simply that PP, instead of depicting perception as a mechanism for revealing "what is where" in the external world, turns out to be a mechanism for engaging the external world in ways that say as much about the organism (and its own history) as they do about the world outside. To naturalize intentionality, then, "all" we need do is display the mechanisms by which such ongoing viability-preserving engagements are enabled, and make intelligible that such mechanisms can deliver the rich and varied grip upon the world that we humans enjoy. This, of course, is exactly what PP sets out to achieve.

2 Structural coupling and the bringing forth of worlds¹

Madary notes, more or less in passing, that the PP vision of "organism-relative perceptual content" bears a close resemblance to views that have been defended under the broad banner of "enactivism". I want to pick up on this hint, and suggest that the PP account actually sets the scene for peace to be declared between the once-warring camps of representationalism and enactivism. Thus consider the mysterious-sounding notion of "enacting a world", as that notion appears in [Varela et al. \(1991\)](#)². [Varela et al.](#) write that:

The overall concern of an enactive approach to perception is not to determine how some perceiver-independent world is to be recovered; it is, rather, to determine the common principles or lawful linkages between sensory and motor systems that explain how

1 Parts of this section condense and draw upon materials from [Clark \(in press\)](#).

2 There is now a large, and not altogether unified, literature on enaction. For our purposes, however, it will suffice to consider only the classic statement by [Varela et al. \(1991\)](#). Important contributions to the larger space of enactivist, and enactivist-inspired, theorizing include [Noë \(2004, 2010, this collection\)](#), [Thompson \(2010\)](#), and [Froese & Di Paolo \(2011\)](#). The edited volume by [Stewart et al. \(2010\)](#) provides an excellent window onto much of this larger space.

action can be perceptually-guided in a perceiver-dependent world. (1991, p. 173)

This kind of relation is described by Varela et al. as one of “structural coupling” in which “the species brings forth and specifies its own domain of problems” (1991, p. 198) and in that sense “enacts” or brings forth (1991, p. 205) its own world. In discussing these matters, Varela et al. are also concerned to stress that the relevant histories of structural coupling may select what they describe as “non-optimal” features, traits, and behaviors: ones that involve “satisficing” (see Simon 1956) where that means settling for whatever “good enough” solution or structure “has sufficient integrity to persist” (Varela et al. 1991, p. 196). PP, I will now suggest, has the resources to cash these enactivist cheques, depicting the organism and the organism-salient world as bound together in a process of mutual specification in which the simplest approximations apt to support a history of viable interaction are the ones that are learnt, selected, and maintained.

The simplest way in which a PP-style organism might be said to actively construct its world is by sampling. Action, as Madary noted, serves perception by moving the body and sense-organs around in ways that aim to “serve up” predicted sequences of high-reliability, task-relevant information. In this way, different organisms and individuals may selectively sample in ways that both actively construct and continuously confirm the existence of different “worlds”. It is in this sense that, as Friston, Adams, and Montague (Friston et al. 2012, p. 22) comment, our implicit and explicit models might be said to “create their own data”.³ Fur-

thermore, the PP framework depicts perception and action as a single (neurally distributed) process whose goal is the reduction of salient prediction-error. To be sure, “sensory” and “motor” systems specialize in different predictions. But the old image of sensory information IN and motor output OUT is here abandoned. Instead, there is a unified sensorimotor system aiming to predict the full range of sensory inputs – inputs that are often at least partially self-selected and that include exteroceptive, proprioceptive (action-determining), and interoceptive elements. Nor is it just the sensorimotor system that is here in play. Instead, the whole embodied organism (as Madary notes) is treated as a prediction-error minimizing device.

The task of the generative model in all these settings is (as noted in Clark this collection) to capture the simplest approximations that will support the actions required to do the job. And that means taking into account whatever work can be done by a creature’s morphology, physical actions, and socio-technological surroundings. Such approximations are constrained to “provide the simplest (most parsimonious) explanations for sampled outcomes” (Friston et al. 2012, p. 22). This respects the enactivist’s stress on biological frugality, satisficing, and the ubiquity of simple but adequate solutions that make the most of brain, body, and world. At this point, all the positive enactivist cheques mentioned above have been cashed.

But one outstanding debt remains. To broker real and lasting peace, we must tiptoe bravely back into some muddy and contested territory: the smoking battleground of the Representation wars.

3 Representations: What are they good for?

PP, Madary suggests, provides a new kind of lever for naturalizing intentionality and mental content. Might it also offer a new perspective upon the vexed topic of internal representation? Varela et al. are explicit that, on the enactivist conception “cognition is no longer seen as problem solving on the basis of representations”

³ Such a process repeats at several organizational scales. Thus we humans do not merely sample some natural environment. We also structure that environment by building material artifacts (from homes to highways), creating cultural practices and institutions, and trading in all manner of symbolic and notational props, aids, and scaffoldings. Some of our practices and institutions are also designed to *train us to sample* our human-built environment more effectively – examples would include sports practice, training in the use of specific tools and software, learning to speed-read, and many, many more. Finally, some of our technological infrastructure is now self-altering in ways that are designed to reduce the load on the predictive agent, learning from our past behaviors and searches so as to serve up the right options at the right time. In all these ways, and at all these interacting scales of space and time, we build and selectively sample the very worlds that – in iterated bouts of statistically-sensitive interaction – install the generative models that we bring to bear upon them.

(1991, p. 205). PP, however, deals extensively in internal models – models that may (see [Clark this collection](#)) be rich, frugal, and all points in-between. The role of such models is to control action by predicting and bringing about complex plays of sensory data. This, the enactivist might fear, is where our promising story about neural processing goes conceptually astray. Why not simply ditch the talk of inner models and internal representations and stay on the true path of enactivist virtue?

This issue requires a lot more discussion than I can attempt here.⁴ Nonetheless, the remaining distance between PP and the enactivist may not be as great as that bald opposition suggests. We can begin by reminding ourselves that PP, although it openly trades in talk of inner models and representations, invokes representations that are action-oriented through and through. These are representations that are fundamentally in the business of serving up actions within the context of rolling sensorimotor cycles. Such representations aim to *engage* the world, rather than to depict it in some action-neutral fashion, and they are firmly rooted in the history of organism-environment interactions that served up the sensory stimulations that installed the probabilistic generative model. What is on offer is thus just about maximally distant from a passive (“mirror of nature” – see [Rorty 1979](#)) story about the possible fit between model and world. For the test of a good model is how well it enables the organism to engage the world in a rolling cycle of actions that maintain it within a window of viability. The better the engagements, the lower the information-theoretic free energy (this is intuitive, since more of the system’s resources are being put to “effective work” in engaging the world). Prediction error reports this information-theoretic free energy, which is mathematically constructed so as always to be greater than “surprisal” (where this names the sub-personally computed implausibility of some sensory state given a model of the world – see [Tribus 1961](#)). Notice also that the prediction task uses only information *clearly*

available to the organism, and is ultimately defined over the energies that impinge on the organism’s sensory surfaces. But finding the best ways to predict those energetic impacts can (as substantial bodies of work in machine learning amply demonstrate⁵) yield a structured grip upon a world of interacting causes.

This notion of a *structured* grip is important. Early connectionist networks were famously challenged ([Fodor & Pylyshyn 1988](#)) by the need to deal with structure – they were unable to capture part-whole hierarchies, or complex nested structures in which larger wholes embed smaller components, each of which may itself be some kind of structured entity. For example, a city scene may consist of a street populated by shops and cars and people, each of which is also a structured whole in its own right. Classical approaches benefitted from an easy way of dealing with such issues. There, digital objects (symbol strings) could be composed of other symbols, and equipped with pointers to further bodies of information. This apparatus was (and remains) extremely biologically suspect, but it enabled nesting, sharing, and recombination on a grand scale – see [Hinton \(1990\)](#) for discussion. Such systems could easily capture structured (nested, often hierarchical) relationships in a manner that allowed for easy sharing and recombination of elements. But they proved brittle and inflexible in other ways, failing to display fluid context-sensitive responsiveness, and floundering when required to guide behavior in time-pressured real-world settings.⁶

Connectionist research has since spawned a variety of methods – some more successful than others – for dealing with structure in various domains. At the same time, work in robotics and in embodied and situated cognitive science has explored the many ways in which structure in the environment (including the highly structured artificial environments of text and external symbol systems) could be exploited so as to reap some of the benefits associated with classical forms of in-

⁴ I have engaged such arguments at length elsewhere – see [Clark \(1989, 1997, 2008, 2012\)](#). For sustained arguments *against* the explanatory appeal to internal representation, see [Ramsey \(2007\)](#), [Chemero \(2009\)](#), [Hutto & Myin \(2013\)](#). For some useful discussion, see [Sprevak \(2010, 2013\)](#), [Gallagher et al. \(2013\)](#).

⁵ For reviews and discussions, see [Bengio \(2009\)](#), [Huang & Rao \(2011\)](#), [Hinton \(2007\)](#), and [Clark \(in press\)](#).

⁶ For a sustained discussion of these failings, and the attractions of connectionist (and post-connectionist) alternatives, see [Clark \(1989, 1993, 2014\)](#), [Bechtel & Abrahamsen \(2002\)](#), [Pfeifer & Bongard \(2007\)](#).

ner encoding, without (it was hoped) the associated costs of biological implausibility – see, for example, Pfeifer & Bongard (2007). Perhaps the combination of a few technical patches and a much richer reliance upon the use of structured external resources would address the worries about dealing with structure? Such was the hope of many, myself included.

On this project, the jury is still out. But PP can embrace these insights and economies while providing a more powerful overall solution. For it offers a biologically plausible means, consistent (we saw) with as much reliance on external scaffolding as possible, of internally encoding and deploying richly structured bodies of information. This is because each PP level (perhaps these correspond to cortical columns – this is an open question) treats activity at the level below as if it were sensory data, and learns compressed methods to predict those unfolding patterns. This results in a very natural extraction of nested structure in the causes of the input signal, as different levels are progressively exposed to different re-codings, and re-re-codings of the original sensory information. These re-re-codings (I think of them as representational re-descriptions in much the sense of Karmiloff-Smith 1992) enable us, as agents, to lock us onto worldly causes that are ever more recondite, capturing regularities visible only in patterns spread far in space and time. Patterns such as weather fronts, persons, elections, marriages, promises, and soccer games. Such patterns are the stuff of which human lives, and human mental lives, are made. What locks the *agent* on to these familiar patterns is, however, the whole multi-level processing device (sometimes, it is the whole machine in action). That machine works (if PP is correct) because each level is driven to try to find a compressed way to predict activity at the level below, all the way out to the sensory peripheries. These nested compressions, discovered and annealed in the furnace of action, are what I (following Hinton 1990) would like to call “internal representations”.

What are the *contents* of the many states governed by the resulting structured, multi-level, action-oriented probabilistic generative models? The generative model issues predictions that estimate various identifiable worldly states (includ-

ing states of the body, and the mental states of other agents).⁷ But it is also necessary, as we saw in Clark (this collection) to estimate the context-variable reliability (precision) of the neural estimations themselves. It is these precision-weighted estimates that drive action, and it is action that then samples the scene, delivering percepts that select more actions. Such looping complexities exacerbate an important consequence that Madary nicely notes. They make it even harder (perhaps impossible) adequately to capture the contents or the cognitive roles of many key inner states and processes using the terms and vocabulary of ordinary daily speech. That vocabulary is “designed” for communication, and (perhaps) for various forms of cognitive self-stimulation (see Clark 2008). The probabilistic generative model, by contrast, is designed to engage the world in rolling, uncertainty-modulated, cycles of perception and action. Nonetheless, high-level states of the generative model will target large-scale, increasingly invariant patterns in space and time, corresponding to (and allowing us to keep track of) specific individuals, properties, and events despite large moment-by-moment variations in the stream of sensory stimulation. Unpacked via cascades of descending prediction, such higher-level states simultaneously inform both perception and action, locking them into continuous circular causal flows. Instead of simply describing “how the world is”, these models – even when considered at those “higher” more abstract levels – are geared to engaging those aspects of the world that matter to us. They are delivering a grip on the *patterns that matter* for the *interactions that matter*.

Could we perhaps (especially given the likely difficulties in specifying intermediate-level contents in natural-language terms) have told our story in entirely non-representational terms, without invoking the concept of a hierarchical probabilistic generative *model* at all? One should always beware of sweeping assertions about what might, one day, be explanatorily possible! But as things stand, I simply don’t see how this is to be achieved. For it is surely that very model-invoking

⁷ Bayesian perceptual and sensorimotor psychology (see for example, Rescorla 2013; Körding & Wolpert 2006) already has much to say about just what worldly and bodily states these may be.

schema that allows us to understand how it is that these looping dynamical regimes arise and enable such spectacular results. The regimes arise and succeed because the system self-organizes around prediction-error so as to capture organism-salient patterns, at various scales of space and time, in the (partially self-created) input stream. These patterns specify complex, inter-animated structures of bodily and worldly causes. Subtract this guiding vision and what remains is just the picture of complex looping dynamics spanning brain, body, and world. Consider those same looping dynamics from the multi-level model-invoking explanatory perspective afforded by PP, however, and many things fall naturally into place. We see how statistically-driven learning can unearth interacting distal and bodily causes in the first place, revealing a structured world of human-sized opportunities for action; we see why, and exactly how, perception and action can be co-constructed and co-determining; and we unravel the precise (and happily un-mysterious) sense in which organisms may be said to bring forth their worlds.

4 Predicting peace: An end to the war over internal representation

Dynamically speaking, the whole embodied, active system here self-organizes around the organismically-computable quantity “prediction error”. This is what delivers that multi-level, multi-area, grip on the evolving sensory barrage – a grip that must span multiple spatial and temporal scales. Such a grip simultaneously determines perception and action, and it selects (enacts) the ongoing stream of sensory bombardment itself. The generative model that here issues sensory predictions is thus nothing but that multi-level, multi-area⁸, multi-scale, body-and-action involving grip on the unfolding sensory stream. To achieve that grip is

⁸ The point about multiple areas (not just multiple levels within areas) is important, but it is often overlooked in philosophical discussions of predictive processing. Different neural areas are best-suited – by location, inputs, structure, and/or cell-type – to different kinds of prediction. So the same overarching PP strategy will yield a complex economy in which higher-levels predict lower levels, but different areas learn to trade in very different kinds of prediction. This adds great dynamical complexity to the picture, and requires some means for sculpting the flow of information among areas. I touch on these issues in Clark (this collection). But for a much fuller exploration, see Clark (in press).

to know the structured and meaningful world that we encounter in experience and action.

Is this an inner economy bloated with representations, detached from the world? Not at all. This is an inner economy geared for action, whose inner states bear contents in virtue of the way they lock embodied agents onto properties and features of their worlds. But it is simultaneously a structured economy built of nested systems, whose communal project is both to model and engage the (organism-relative) world.

Levels

Carl F. Craver

The levels metaphor is commonly used to describe science, its theories, and the world. Yet the metaphor means different things in different contexts, inviting equivocation. These distinct applications of the metaphor can be distinguished by the relata they relate, the relation between levels that they assert, and the rule by which they locate items at a level. I discuss these many applications of the levels metaphor with an eye to developing a descriptively adequate account of one particular application: levels of mechanisms. I argue that this application of the metaphor is central to the explanatory practices of the special sciences and defensible as a metaphysical picture of how phenomena studied in the special sciences are constituted.

1 Introduction

The levels metaphor is ubiquitous in our descriptions of science and the world. So simple and elegant, the metaphor takes an apparently heterogeneous collection of objects and arranges them in space from bottom to top. The metaphor works in so many contexts because it leaves open just what kinds of object are to be arranged, what distinguishes top from bottom, and what it means to say that an object is at some levels and not others. This flexibility explains the metaphor's fecundity, but it also helps to obscure the fact that it is used in many different ways in many different contexts.

A survey of kinds of levels drawn from science and philosophy would have to include levels of abstraction (Floridi 2008), aggregation (Wimsatt 1997), analysis (Shepherd 1994;

Churchland & Sejnowski 1992), causation and explanation (Kim 1998), implementation (Marr 1982), organization (Churchland & Sejnowski 1992), processing (Craik & Lockhart 1972), realization (Gillett 2002), sizes (Wimsatt 1976), sciences, theories, and explanations (Oppenheim & Putnam 1958). Many of these familiar applications of the levels metaphor are distinct from but also clearly related to one another. And when they are related, they often have rather indirect and reticulate connections. The level metaphors thus takes subtly different forms when applied in neighboring contexts, and this obscures the extent to which features of one application of the metaphor do and do not transfer from one context to the next. My first thesis, then, is that our ways of describing sci-

ence and the world contain many distinct, legitimate applications of the levels metaphor that are either unrelated or that have only indirect relations with one another.¹

This *descriptive pluralism* about the levels metaphor is directly opposed to eliminativism about levels (Fehr 2004; Machamer & Sullivan 2001; Thalos 2013). The suggestion that we might be better off abandoning the levels metaphor is about as likely to win converts as the suggestion that we should abandon metaphors involving weight or spatial inclusion. These metaphors are too basic to how we organize the world to seriously recommend that they could or should be stricken from thought and expression. Yet, descriptive pluralism about the levels metaphor is consistent with the thought that some applications of the metaphor distort the structure of the world or represent it as having conceptually incoherent structures. I discuss some examples below. The central message of this paper is that there can be no single verdict concerning the utility or conceptual soundness of the levels metaphor *simpliciter*. The metaphor must be evaluated and used with caution, especially when it is called on to settle disputes about the character of science and the metaphysical structure of the world.

As some motivation for adopting this proposal, and as a step toward a more positive thesis, I show that we can avoid some simple confusion by separating the different applications of the metaphor. To make this case, I build slowly toward a particular application of the metaphor that, as I have argued elsewhere (Craver 2001, 2007), is central to explanatory practices in neuroscience and across the special sciences: levels of mechanisms. This application of the levels metaphor is metaphysically plausible and, so far as I can tell, more or less innocuous; that is part of its virtue. Yet this simple and useful application of the metaphor can begin to appear problematic when it is inappropriately assimilated to other applications that

serve altogether different purposes in our thinking about science and the world.

My point is not to defend levels of mechanisms as the one true application of the levels metaphor (that would be as pointless as eliminativism). Rather, my first positive goal is to provide a reasonably clear account of levels of mechanisms and to show that this application is metaphysically benign yet exceptionally important for doing science. Levels of mechanisms are, as would be expected, richly but indirectly connected with many other applications of the metaphor. My second goal is to highlight and disentangle some of the confusions that arise from failing to keep levels of mechanisms distinct from other senses of levels. In particular, I show that commitment to the existence of levels of mechanisms entails no commitment to: a) monolithic levels in nature, b) the stratification of sciences by levels, or c) a tidy hierarchy of theories among the sciences. I will also show why levels of mechanisms are d) distinct from Marr's views about levels of abstraction and e) distinct from levels of realization more generally. I argue that f) the idea of interlevel causation is conceptually awkward within levels of mechanisms (but not to levels of size, for example). Furthermore, g) the idea of levels of mechanisms nicely expresses the idea of emergence as a kind of non-aggregativity while providing no support to those who seek evidence in biology for a more robust kind of emergence. The failure to disambiguate altogether separate applications of the levels metaphor creates a conceptual malaise for which levels of mechanisms are at least a partial cure.

2 Refining the levels metaphor: Three defining questions

In its barest of forms, the levels metaphor demands little of its object; it requires only a set of items and some criterion for ranking them as higher or lower than one another in some respect. Seniors are at a higher level in the American high school system than juniors, poetry is at a higher level than pushpin, lust is at a higher (and lower) level than like, and cells are at a higher level than molecules. In these ex-

¹ Standard etymologies trace the term “level” to the balance and from there to the idea of a flat, horizontal landing, as in the stories of a building. From there, it is easy to see how the metaphor might be extended to the kinds of hierarchy discussed in this paper.

amples, it is obvious that different kinds of thing are related by entirely distinct kinds of relation. In subtler cases, the equivocation is less noticeable, and for that, all the more misleading.

Three defining questions can be used to explicate how the levels metaphor is applied in a given context:

The Relata Question: What kinds of item are being sorted into levels?

The Relations Question: In virtue of what are two items at different levels?

The Placement Question: In virtue of what are two items at the same level?

The Relata Question provides an important clue about the intended sense of levels. The flexibility of the metaphor allows it to be applied to *abstracta*, such as branches of mathematics and ethical principles, or to *concreta*, such as astronomical objects and stereo equipment. The metaphor can be applied to types, such as sergeants and corporals, or to tokens, such as the relationship between Colonel Blake and Corporal O'Reilly. It can be applied to objects such as cats and mountains, to activities such as releasing neurotransmitters and making decisions, and to properties such as excitability or charge. Within the neurosciences, the levels metaphor is applied fluidly to causes, descriptions, developmental stages, events, explanations, scientific fields, objects, properties, techniques, and theories. Confusion arises when we assume that each application is the same.

The Relations Question concerns the ordering relationship by which items are said to be at a higher or a lower level than one another. A theory, for example, might be said to be at a higher level than a second if the first is derivable from the second (and not vice versa); the lowest-level theories are in this sense “fundamental.” Poetry might be said to be higher than pushpin in the sense that it requires greater intellectual skill and training to take pleasure in the former than to take pleasure in the latter. A technique might be said to be at a lower level than another because it detects phenomena at a smaller size scale. Some applications of the levels metaphor are discrete in the sense that there is a gap between things at lower and high

levels; other applications are continuous, as when one uses the metaphor to describe size. We are unlikely to confuse such wildly different kinds of relationship. However, as we will see, the metaphor is used in other contexts where it is beguilingly difficult to keep them distinct, even for those who know better.

The Placement Question asks for the principle by which different items are located on the same level. Many uses of the levels metaphor rely at heart on an answer to the placement question. When the metaphor is used to describe size scales, for example, puffins and porcupines are at roughly the same level, vasopressin and oxytocin are at roughly the same level, and hydrogen and oxygen atoms are together at a lower level still. Juniors are all juniors because they are in their third year of American high school. For Marr, computational level questions are directed at what is computed and why it is computed that way (Shagrir 2010; Bechtel & Shagrir 2013).² Not every account of levels requires an answer to the placement question affirmatively. Indeed, it is of central importance that the idea of levels of mechanisms articulated here entails no positive story about what it means to be at a level, only a negative story about when things are not at different levels.

3 From gesture to prototype

Perhaps the most common application of the levels metaphor is to gesture loosely at the relationship between different fields of scientific research, *levels of science*.³ In neuroscience, for example, some researchers work at “the molecular level,” doing things such as sequencing channel proteins, studying enzyme kinetics, or manipulating genes. Others work at the cellular level, doing things such as staining cells, recording action potentials, or studying neural migration. Others study brain regions, characterizing

² One consequence of the following discussion is that not every account of levels must offer a unique answer to the placement question. Levels of mechanisms are defined by their distinctive relata and relations; these constraints, by themselves, offer no unique answer to the placement question. This is why levels of mechanisms are, as I will argue, local rather than monolithic.

³ For the relevant sense of a scientific “field”, see Darden & Maul (1977) and Darden (1992).

their anatomical features or, studying the propagation of neural signals within them. Still others work at the level of systems, using functional magnetic resonance imaging (fMRI), transcranial magnetic stimulation (TMS), and cognitive tasks to find large-scale cognitive systems in the mind-brain. One could perhaps insinuate other levels between these, and one could certainly extend the hierarchy further down or higher up. But the central idea is that the *scientific fields* can be ordered as higher or lower than one another.

Scientific fields are individuated in part by their theories (Darden 1992). The gestural sense of levels, then, can seem to carry the implication that scientific *theories* are or will someday be ordered more or less clearly into levels. Oppenheim & Putnam's (1958) influential view of the unity of science is based on a rough correspondence between levels of science, levels of theory, and levels of parts and wholes (see Table 1). They divide the world into six ontological strata (societies, organisms, cells, molecules, atoms, and elementary particles). These strata are defined by mereological relationships among types: elementary particles are the parts of atoms, atoms are the parts of molecules, molecules are parts of cells, and so on. Each of these strata is assigned a distinct science: economics and the social sciences at the top, particle physics at the bottom. Each science develops its theory more or less autonomously from the others, so the theories developed by these sciences can themselves be ordered, like the layers of a cake, from top to bottom. The unity of science, for Oppenheim and Putnam, is to be achieved by explaining phenomena in the domain of a higher-level science, as described in the theory of that science, in terms of the items in the domain of the more fundamental science, as described in the theories of that science. (Levels of mechanisms, as defined below, involve a kind of part-whole relation as well but without any commitment to the idea that such type-level part-whole relationships correspond in even a rough way to the structure of the sciences or to the structures of their theories.)

Wimsatt's detailed and influential exploration of the levels metaphor confronts Oppen-

heim and Putnam with the complexity of the levels found in many areas of contemporary science (Wimsatt 1976). Against Oppenheim and Putnam's six-layer model, Wimsatt's "Reductionist Illustrative" (Figure 1) represents multiple branches of levels fanning out from the lowest level in subatomic particles to cosmological objects, the sociocultural world (e.g., economic and political phenomena), and the socioecological world (e.g., evolution).

Wimsatt's tree diagram, however, represents only one aspect of his *prototype account* of levels that encompasses many more features than Oppenheim and Putnam's layer-cake mapping in Table 1. The core features in Wimsatt's prototype are:

- **Size.** Higher-level items are larger than lower-level items.
- **Composition.** Higher-level items are made up of lower-level objects and processes.
- **Laws.** Laws of nature hold only or mostly between items at the same level.
- **Forces.** Distinct forces operate at different levels.
- **Predictability.** Levels are local maxima of regularity and predictability that appear at different size scales.
- **Detection.** Items at a given level tend to be detected or detectable primarily by other items at that level.
- **Causes.** Causal relationships hold only or mostly between items at the same level.
- **Theories.** Scientific theories describe phenomena exclusively or mostly at a single level.
- **Techniques.** Different techniques and instruments detect items at different levels.
- **Disciplines.** Different disciplines of science direct their attention at different levels.

Wimsatt's view is a prototype view in the sense that it characterizes the levels metaphor in terms of a core set of features, not all of which must be present in order for the metaphor to apply. Insofar as Wimsatt embraces a prototype model, he can be seen as embracing descriptive pluralism while, at the same time, holding that there is a sufficiently strong family resemblance

(h) A reductionistic (?) illustrative*
phylogenetic ontology of our world as we see it.

[letters in parentheses refer to local character of network around that node]

* A diagram like this is obviously highly tentative. Although it has been constructed with many specific relations in mind, I would claim accuracy only of a general qualitative sort – i.e., for the rough general distribution of network properties, as indicated, e.g., by the distribution of letters.

W.C. Wimsatt 1973

Figure 1: Wimsatt's tree of levels branches to preserve compositional relationships among levels (1976).

among the plurality of applications of the levels metaphor to warrant their inclusion in a single prototype.

Is the levels metaphor sufficiently unified across these different applications to warrant a single prototype? My remarks on the relation, and placement questions should already indicate that it is not—that different features in Wimsatt's list are at best indirectly related and

so fail to map to one another in any tidy way. While the prototype approach usefully highlights the complexity of the levels metaphor, it also obscures the extent to which the different features in the prototype are features of different applications of that metaphor.⁴

⁴ Wimsatt's diagram in Figure 1 reflects this. The branching tree structure is ordered by compositional relations. Wimsatt's view of levels as dissipating waves (see Figure 3 below) flouts that relation.

Table 1: Oppenheim and Putnam's layer-cake sketch of the levels of mereology (left), sciences (middle), and theories (right).

Mereological level	Sciences	Theories
Societies	Economics	Classical Economics
Organisms	Psychology	Law of Effect
Cells	Cytology	The Neuron Doctrine
Molecules	Chemistry	The Central Dogma
Atoms	Physics	The Bohr Model
Sub-Atomic Particles	Quantum Mechanics	Schrödinger Equation

4 Levels of sciences and theories

Wimsatt, Oppenheim, and Putnam all include within their analysis of levels the gestural idea that different fields or disciplines of science are arranged by the sizes of the objects they study. Wimsatt's branching hierarchies depict a more ornate structure. Within that structure, it seems inappropriate to say that astrophysics is at a higher level than biology or economics, though astrophysicists typically deal with things that are orders of magnitude larger than the things biologists and economists study. The gestural sense of levels doesn't seem to branch that way.

When we apply the levels metaphor to *sciences*, the relata are units of scientific organization (such as fields, research programs, or disciplines). Answers to the relations and placement questions are more difficult to discern and are likely impossible to express both accurately and concisely for this application. Size seems to be relevant, but we have just seen that it cannot be the whole story. The branches in Wimsatt's diagram follow, in addition to size relationships, relationships of composition. The things studied by economists (groups) are composed of things studied

by psychologists (organisms), which are composed of things studied by physiologists (physiological systems), and so on. The things studied by Darwin are composed of the things studied by zoologists, which are composed of the things studied by cytologists. The point of these examples is not to get the branches in Wimsatt's hierarchy exactly right; any proposed hierarchy of the sciences and the items in their domains is bound to be historically contingent and provisional at best.

In fact, many sciences appear to resist tidy compartmentalization within levels. Neuroscience, especially cognitive neuroscience, is a paradigm of multilevel science, encompassing the study of ions, ion channels, cells, populations of cells, brain regions, and behaviors of whole organisms. No competent evolutionary biologist can avoid knowing something about genes, physiological systems, organisms, populations, and environments. Many sciences, in short, contain items within their domain that stand in compositional relations to one another. Such sciences often construct multilevel theories that integrate findings across multiple levels of organization. This is one reason why the relationship between levels of science and part-whole levels is indirect.

Another reason is that, in many cases, more than one science is dedicated to studying items at the same mereological or size level. Cytologists, anatomists, and electrophysiologists all study aspects of cells with different tools. The ethologist and the experimental psychologist study animal behavior, but they approach that behavior with different assumptions, methods, and theories. Economists, ecologists, epidemiologists, and organizational psychologists study populations of organisms. The relationship between levels of science and the ontological levels that Oppenheim and Putnam presume is many to many.

For this reason, it is unlikely that any precise answer to the placement question will correctly express the application of the levels metaphor to sciences. One might say that two sciences are on the same level when they pertain to items at the same compositional level. Perhaps it makes sense to say that Camillo Golgi was investigating the same level when he stained Purkinje cells with silver nitrate that Alan Hodgkin was investigating when he used his voltage clamp to study the action potential of the squid giant axon. They were both studying cells, but they studied different phenomena and used different techniques. If we focus now on the parts of these wholes, we see that these different scientists are not even on the same branches of a Wimsatt diagram, and the levels metaphor begins to break down. Ask Golgi about the relevant parts of the cell, and he will tell you about its gross morphological features and its organs. Ask Hodgkin and Huxley about the relevant parts of the squid giant axon, and they will tell you about membranes, axon hillocks, ionic conductances, and voltage gradients. An epidemiologist might talk about nodes and networks and hubs in a model of contagion. Economists will talk about producers and consumers. Differences in scientific interests often entail differences in the relevant ontology for the science; and the same thing can be carved into parts in many ways depending on what one is interested in describing or explaining (Kauffman 1971; Wimsatt 1972).

The take-home lesson: the application of the levels metaphor to fields of science yields a

notion of levels only indirectly related to ontological levels (as understood in a roughly compositional, part-whole sense). The idealized, Oppenheim-Putnam correspondence between levels of science, levels of theory, and levels of mereology breaks down in the face of this many-many mapping. And the compositional aspect in Wimsatt's prototype appears to be only loosely related to the application of the levels metaphor to fields of science. These are, in short, distinct applications of the metaphor, offering different answers to the relata, relations, and placement questions. As a result, an understanding of how sciences can be organized loosely into levels provides no direct insight into ontological levels. This will come as no surprise to those who study intellectual history, or to those who have witnessed for themselves how fields of science change their boundaries over time. Our age, perhaps more than any other, has witnessed an explosion of hybrid fields (neuroeconomics, behavioral genetics, cognitive ethology) that cross levels, combine approaches, and attempt to feed off insights shared between distant scientific neighbors. The historical relativity of disciplinary boundaries makes them unreliable guides to ontology.

The same considerations suggest that *levels of scientific theory* will also have a many-many relationship with ontological levels. In this application of the metaphor, the relata are theories or models. And the relationship is typically construed as a kind of subsumption, e.g., deductive subsumption (Hempel 1965; Schaffner 1993; Kitcher 1989), or some kind of similarity or inclusion (Bickle 1998). The disciplinary hodgepodge of the special sciences fails to match this philosophical reconstruction. Single theories, such as the theory explaining spatial memory in terms of memory systems, grid cell organization, synaptic plasticity, and changes in ionic conductances through a membrane (see Moser 2008), often reach across many different part-whole levels (Darden & Maul 1977; Bechtel 1988; Craver 2002, 2008). One and the same mereological unit (e.g., cells) can appear in many distinct theories (e.g., neurons play some role in most theories in neuroscience).

Figure 2: Churchland & Sejnowski's (1992) diagram of levels of organization in the central nervous system.

The multilevel structure of contemporary science emphasized in nearly every corner of the special sciences is not best understood as a hierarchy of theories. Nor is it a hierarchy of fields. Instead, there is an ontological hierarchy working behind the scenes. This background ontological assumption guides the development of theories, informs the criteria for evaluating explanations, and underlies the roughly hewn idea that sciences and theories are organized into levels. It is the expression of an ideal of explanation to understand how things work in terms of their component parts and to understand how those parts work in terms of still lower-level components. It is precisely because the world is presumed to have this kind of multilevel structure, of mechanisms within mechanisms, that the sciences investigating that world and the theories describing it are so reticulate that they can look like the “bio-psychological thicket” on the right side of Wimsatt’s tree. In the thicket, the orderly relationship among

levels breaks down and is replaced by a jumble. The image makes it hard to see any meaningful sense in which distinct items are at different levels. Perhaps this thought fuels eliminativism about levels.

The biological sciences are undeniably thicket-like. But this sociological fact is only indirectly related to the ontic structures presumed to lie behind and scaffold the development of these theories. From now on, then, I focus on applications of the levels metaphor to the world, not to sciences or theories.

5 Size levels

One ontological application of the levels metaphor emphasizes the relative sizes of objects at different levels. The relation in size levels are objects or kinds of object, and the interlevel relationship is relative size (larger, smaller). Things in the same size range are at the same level. Churchland and Sejnowski’s classic diagram of

Figure 3: Levels as local maxima of regularity and at different size scales (Wimsatt 1976).

levels in the neurosciences (Figure 2) is accompanied by size scales for each level, ranging from Angstrom units to meters.⁵

As noted above, Wimsatt's tree diagram branches precisely because it is tracking something stronger than size: some kind of compositional relation. In a second diagram (Figure 3), Wimsatt emphasizes size and abandons the compositional relationship implicit in Figure 1. The abscissa in Figure 3 represents a roughly logarithmic size scale, and yet the figure is not compositional. Large metazoan organisms are not generally composed of smaller metazoan organisms, and it would surely be a stretch to claim that these two are generally composed of unicellular organisms (though there might be some truth in that claim). The ordinate in this diagram is a measure of regularity and predictability. The figure is repeated three times, each

illustrating a different way the world might be organized with respect to size. At the top is an orderly world (despite impending doom on the right). Objects become more regular and predictable in their behavior, and to the same degree, at certain size scales. Beneath this is a world with no sharp peaks of regularity and predictability. As Wimsatt notes, scientists confronted by such a world might question whether they have chosen the right variables for their models. On the bottom is Wimsatt's conjecture for our world, where regularity is very high for single atoms but falls off at larger or smaller scales. This wave dissipates over time, peaking lower and spreading out over larger and larger size ranges as scale increases. Wimsatt's diagram thus represents an *empirical hypothesis* about how levels, as peaks of regularity and predictability, are in fact distributed across different size scales in our world. If his empirical hypothesis is correct, it calls out for explanation that our world is more like the first and third graphs than it is like the second.

⁵ One might, analogously, arrange a hierarchy of activities, with different activities occurring on different temporal scales. The idea of levels of mechanisms combines these two ideas; it is a hierarchy of doings framed by a relevance relationship between those at lower levels and those at higher levels.

Why does Wimsatt represent size as the determining factor in regularity and predictability? The answer turns on other features in his prototype account. For example, things of different sizes effect and are affected by different forces, and objects of different sizes act and interact with one another more than they interact with objects at other levels. Market forces run economies, cosmic objects move under gravitational forces, and hydrogen bonds hold molecules together. Regularity and predictability peak at different size scales because the forces act and the causal relationships occur mostly at those size scales.

Wimsatt's empirical hypothesis has not been tested.⁶ Despite its intuitive appeal, one can readily produce examples of causes, forces, and laws that operate promiscuously across a very wide range of size scales. Big things (even very big things) and little things (even very little things) routinely interact, as when planets attract molecules into atmospheres or when a five-millimeter louse attaches itself to a thirteen-meter gray whale. Forces also act at many scales. Gravitation affects the human species on an evolutionary scale just as much as it influences individual human actions and the otoliths in our vestibular system. The very existence of interlevel theories, bridging molecules to behaviors (for example), provides ample evidence that regularity and predictability often span size scales: facts about gasses can be predicted from facts about molecules, and facts about learning can be inferred from facts about molecules.

If we could find a way to test Wimsatt's hypothesis, it might turn out that causes, forces, and laws do tend to cluster around certain size scales. This would be a striking empirical fact about the world and would, again, call out for some kind of explanation. In contrast, Wimsatt raises no *principled* objections to interlevel causes, forces, or regularities; he offers an *empirical* hypothesis that interlevel causes, forces, and regularities tend to be less prevalent than those operating at a single level.

⁶ It is hard to say how it would be tested and, in particular, how predictability is to be measured. Surely items in the valleys of this diagram are not unpredictable, full stop. Rather, they are more difficult to predict for creatures *like us*, unaided by machines and programs. It is not clear why human cognitive abilities should have any further ontological significance.

There are, however, apparent principled, *conceptual* difficulties faced by the effort to describe *levels of realization* in terms of a causal relation. There are many notions of realization, often tailored to altogether distinct philosophical disputes (Craver & Wilson 2007). On most accounts, however, one and the same object or event has both the realized and the realizing property, and the object cannot differ with respect to the realized property without the realizing property being different in some way (supervenience). The relata here are properties. The interlevel relationship is or includes supervenience.⁷

Marr's levels, as I understand them, are levels of realization. The hardware realizes the algorithm, which, in the right context, realizes the computation. It is awkward at best to say that the algorithm causes the computation; rather, the algorithm implements the computation in context. Changing context can change the computation. For example, a subtraction algorithm can implement division; the log of a division is a difference of logs. Likewise, the function represented in the algorithm is not caused by the hardware; the hardware instantiates or implements the algorithm. Computation-, algorithm-, and hardware-level theories are all different ways of describing one and the same thing—different predicates applied to one and the same system as a whole in its working context.

The same holds for what we might call micro-realization: when some property of a whole is realized by the organized and interacting collection of parts that constitute the property of the whole. An early edition of the *Betty Crocker Cookbook* apparently contains an explanation of how the microwave heats the soup (Churchland 1995). According to this explanation, the molecules excited by the microwave rub against one another and heat the soup by friction. As Churchland points out, Betty misrepresents the relationship between the heat of a liquid and the kinetic energy of its constituent molecules. Temperature is not produced by the

⁷ Supplemental conditions might be added to make realization more demanding (e.g., Melnyk 2003; Haug forthcoming). The point I wish to make doesn't turn on this matter.

mean kinetic energy of component molecules in such cases; rather, temperature in such situations is constituted or realized by (Churchland would say identical to) the mean kinetic energy of the components. In the same way, one might think that the behavior of a mechanism as a whole is realized by, rather than caused by, the organized collection of its components. The beating of the heart is realized, not caused, by the choreographed movements of the auricles and ventricles. It is awkward and unnatural to assert otherwise.

The apparent awkwardness and unnaturalness of such ways of talking follows from many core principles that many (rightly or wrongly) embrace about the nature of causation. If one thinks that causes must precede their effects, and one understands the realization relationship as a synchronic relation, then levels of realization cannot be causally related. If one thinks of causation in terms of the intersection of processes and the exchange of marks or conserved quantities, then the relata in levels of realization do not *come to* intersect in space-time (they always and everywhere intersect), they do not carry their marks beyond the locus of the intersection (because they always and everywhere intersect), and they do not pass anything from one to the other. In short, the *intimacy* among levels of realization seemingly precludes any standard metaphor of production, or “oomph,” or expression of a disposition, or the exertion of a power. This intimacy stands in the way of anyone who believes that causes and effects must be altogether distinct from one another.⁸ So indistinct are levels of realization that many philosophers, Churchland included, prefer to speak of identity in such contexts (see Polger 2006). Finally, if one thinks of causation in terms of the ability to manipulate effects by intervening on causes, one will note that there is no way to intervene to change the properties of wholes without, at the same time, intervening to change the supervenience base of those properties.⁹

⁸ I discuss a representative quote from Lewis below when considering causal relations between levels of mechanisms.

⁹ One can, in cases of multiple realization, intervene into the parts and their organization without intervening to change the property of the whole, and this affords some measure of independence. Perhaps one can find room in this view for the idea of understanding bottom-up relations in a hierarchy of realization as causal (though, again, realization or token identity seem to be better ways of talking). But there

I raise these issues not to cement a case against the possibility of understanding realization and causation so as to leave conceptual space for causation between levels of realization. (For a fuller discussion, see Kim 2000; Craver & Bechtel 2006). I mention them only to point out that relations of size and realization have very different implications for the intelligibility of interlevel causation. No theory or principle of causation that I know places any metaphysical restrictions on causal relations among objects of different sizes. Many theories or principles of causation appear to rule out the possibility of causal relationships between levels of realization. The point is that Wimsatt’s empirical hypothesis that causes, laws, and regularities tend to be sequestered within size scales is altogether distinct from the claim that there is no conceptual room for causation between levels of realization. Interlevel causation is mysterious or not depending on which views of levels and causation one adopts.¹⁰

6 Parts and wholes

A distinct and indirectly related application of the levels metaphor in the neighborhood of

is no room in the view (no conceptual room) for causation to work from the top down in such levels. For a penetrating discussion of this matter and its implications for causation in a multilevel world, see Baumgartner 2010, 2013; Romero (forthcoming).

¹⁰ Levels of control and levels of processing, in contrast, are defined in terms of causal relations. In *levels of control*, the relata are agencies and the relation is dominance. Items at higher levels direct or regulate the activities of their underlings. Majors and corporals, queen bees and drones, bosses and workers occupy different levels of a control hierarchy. Analogous relations are sometimes found among physiological systems. When one speaks of “executive function” in cognition, one is describing levels of control.

The idea of control or dominance is a causal notion, and it is independent of matters of size (witness the sauropod brain). Contra Fehr (2004), the idea that the world is organized in levels of realization or organization (as defined below) is not an expression of patriarchy; it is an equivocation to characterize realization and organization as relations of dominance. In levels of control, the relata are logically independent and spatiotemporally distinct interactors. It is not at all implausible for one to control the other causally (more on this below).

In *levels of processing*, the relata are processing units of some sort (such as brain regions or computational modules), and they are related as “upstream” or “downstream” in the flow of information or the order of production. In the early visual system (neglecting feedback for the moment), one can describe visual information as passing from lowest- (shallowest-, earliest-) level processing in the retina to higher- (deeper-, later-) level processing in the Lateral geniculate nucleus (LGN) and the primary visual cortex. Levels of realization and organization are not earlier or later than one another. Craik and Lockhart define levels of processing in terms of depth of semantic or cognitive processing, not in terms of decomposition.

levels of realization invites a different kind of equivocation, this time concerning the existence of higher-level powers. This application involves not a whole-whole relationship but rather the relationship between the behavior or property of a whole and the behaviors or properties of one of its parts. The behavior of the whole does not (except in special cases) supervene on the operation of the individual parts. The grain of sand contributes to the mass of the sand pile. The kidney contributes to the capacity of creatures to maintain plasma osmolality. In each case, the property of the whole (the mass of the pile, the regulation of plasma osmolality) might differ even when the contribution of these singular parts remains the same. In *part-whole* levels, as opposed to levels of realization, the relationship is between parts and wholes, not between wholes and the corresponding organized collections of entities, properties, and activities. In this case, eliminativism about levels is a non-starter (whatever its metaphysical credentials); it is impossible to imagine neuroscience, biology generally, or indeed most special sciences without the idea that things have parts.

In applying the levels metaphor to this part-whole relation, one emphasizes the relations question over the placement question.¹¹ In levels of size, things are at a given level because they are similar in size. Levels, thus conceived, are *monolithic*: they reach across all of nature, embracing everything within a given size range. Oppenheim and Putnam's layered model of the world might be read as similarly monolithic. Wimsatt's tree diagram breaks with this monolithic view precisely because it emphasizes compositional relationships: different branching levels are required because different kinds of whole (cosmological objects, human societies) are composed in different ways. If one centers part-whole thinking in one's application of the levels metaphor, then the metaphor carries no particularly useful answer to the placement

question. One can offer only a necessary condition: two things are at the same level only if they are not related as part to whole. Given that most things are not related to one another as part to whole, the resulting idea of being "at" a part-whole level has little or no conceptual significance.

Levels of parts and wholes lack many of the features in Wimsatt's prototype of levels. Many of the features in that prototype appear to derive from the monolithic conception shown in Figure 3: causes, forces, and laws are most plausibly thought to cluster together on the assumption that size is relevant to which forces can act, that causal relations are expressions of forces acting, and that laws govern these interactions. But if one places the part-whole relation in the center of one's metaphor, then there is no reason to embrace an empirical association between being at a given level and having a proprietary set of causal interactions for that level. Levels of parts and wholes must also be correlated with size differences because parts can be no larger than the wholes they compose. But the size differences between levels of parts and wholes are an accidental consequence of the part-whole relationship itself, not part of defining what it is for things to be at different part-whole levels.

In the following subsections, my goal is to sketch some contours of the relevant notion of part and whole. I start with classical mereology only to make the point that this apparatus was not constructed with an eye to developing a descriptively adequate account of the levels described by science. The more we learn about the limits of these classical models for our present purposes, the more we place constraints on the relevant notion of levels that, as I and others have argued, is central to the explanatory structure of neuroscience and the special sciences generally: *levels of mechanisms* (Bechtel 1988; Bechtel & Richardson 1993; Craver 2001; Machamer et al. 2000).

6.1 Types and tokens of parts and wholes

The Gibson SG has two humbucker pickups. My Gibson SG has two humbucker pickups. Not all

¹¹ I am here using the terms "part" and "whole" in an intuitive and inclusive way. Much of the literature on the metaphysics of parthood is simply unrelated to the many senses of part and whole used in the theories of the special sciences. I am not thinking only of objects or sets, but also about events and temporal units. I sketch a more restrictive kind of part-whole relation below, but this remains an open question (see Sanford 1993).

Gibson SG's have two humbucker pickups. But that's the factory model, the central exemplar or prototype against which variations are evaluated as more or less "typical." Likewise, when we talk about *the* human brain or *the* frog kidney, we are talking about types: the human type of brain, the frog type of kidney. And we talk also about the parts these types of things typically have.

The monolithic, layer-cake image in the Oppenheim-Putnam hierarchy is a mereology of types: societies are formed of organisms, organisms of cells, cells of molecules, and so on. Wimsatt's tree also represents relationships between types. Crystals are made of crystalline solids, which are made of inorganic molecules, which are made of atoms. It is true, of course, that all cells are made of molecules and that all organs are made of cells. But is not true that all cells are at a higher level than molecules generally.

It seems natural and harmless enough to treat the part-whole relations among types as generalizations over relations between particular wholes and particular parts. When one says, "The human brain has two hemispheres and a corpus callosum," one asserts that having these parts is typical of human brains. One is warranted on the basis of such a claim (though not always correct) in asserting of a particular human brain that it has two hemispheres. That is, the relation among part and whole *types* derives from a more primitive, token relationship between particular parts and wholes. Type-level claims about part-whole relations assert that such part-whole relations regularly or typically hold in the individuals in the relevant reference class.

One of the many useful insights contained implicitly in the branching structure of Wimsatt's tree diagram (Figure 1) is that different types of wholes are made up of different types of parts and are naturally decomposed into different levels. Both the human brain and the frog kidney are organs, and both are made of cells, but the cells in each are different, and these cells are organized differently into higher-level components. If we look within the human brain, we find that different brain regions are composed of altogether different components

and exhibit more or less proprietary organization. Broadman mapped the brain by studying these differences in cytoarchitecture from one brain region to the next. The receptive field organization of the visual cortex has, to my knowledge, no companion in the organization of the amygdala or of the mammillary bodies. Different types of brain regions/systems are made up of different types of components: they have different part-whole levels.¹²

When we say that objects or processes of one type are parts of objects or processes of another type, we are asserting that *ceteris paribus* token objects of the one type are composed of token objects of the second type. Indeed, standard attempts to define the part-whole relationship with logical rigor are expressed in terms of relationships among token individuals (Varzi 2014).¹³

6.2 Mereology

Although Oppenheim and Putnam describe the layer-cake structure of science in terms of different types of objects, the mereological structure they use to support this picture is expressed in terms of tokens. Classical mereology provides a very general and content-neutral account of the part relation. It can be used equally well to express the sense in which

¹² Elephant hearts are parts of elephants, and puffin hearts are parts of puffins, and hearts are parts of organisms. Yet puffin hearts are not at a lower part-whole level than elephants, and elephant hearts are not at a lower part-whole level than puffins.

¹³ I shall not enter here into the difficult question of how token properties, processes, and objects are individuated in the biological sciences. Consider the spatial memory system in a rat. If we take this to be one thing over the life of the organism, then it will be composed of many different sets of parts over the course of its existence, like the ship of Theseus. If we take it instead to be the spatial memory system involved in learning the layout of one particular maze, which learning might be constituted by multiple trials and extended investigation, then again we will have a single higher-level system composed differently at different time slices. If we focus on a given instant in time, then no learning can occur; learning is a kind of change. For now, I simply note (along with Bechtel & Mundale 1999) that the appropriate mapping between such parts and wholes presupposes a criterion of individuation for the whole, and what counts or does not count as a part will be determined by whether it contributes to that whole, however specified. This is related to Marcus' (2006) thought that any token identity between levels presupposes a (non-dummy) sortal that fixes the individuation conditions of the relata in the same way. Carl Gillett (2013) has called attention to the need for different accounts of compositional relations for properties, processes, and objects. Here, I am glossing over these differences to keep the discussion simple.

the word apple has the letter “a” as a part, in which courage has judgment as a part, and in which apple pie has cinnamon as a part. Common axioms associated with classical mereology, including the mereology adopted by Oppenheim and Putnam (Rescher & Oppenheim 1955), include:

- 1) **Reflexivity:** Every object is a part of itself.
- 2) **Transitivity:** Every part of a part of an object is part of the object.
- 3) **Extensionality:** An object is completely determined by the set of its parts; i.e., for objects to be identical, it suffices that they have all and only the same parts.
- 4) **Summation:** Any pair of objects (x, y), is itself an object, z, which is their sum.

I list these constraints only to illustrate that classical mereology will take us only so far in the effort to characterize part-whole levels. This is a formal theory, abstracted entirely from the concerns of practicing scientists. This means that there are constraints in the scientific conception of parts and wholes that classical mereology need not honor. First, the levels that Churchland and Wimsatt describe are space-, structure-, and time-involving in ways that classical mereology need not be. The set of integers is part of the set of real numbers, and “Consider the Lobster” is part of Wallace’s corpus, but not in the same way that the glutamate receptor is part of the chemical synapse. The glutamate receptor takes up part of the space occupied by the synapse as a whole. Its opening is part of the extended process by which neurons communicate. None of this is expressed or intended to be expressed in the generic part-whole relation of classical mereology.¹⁴

¹⁴ Marr’s levels are not space-involving in this way. The algorithm is not located within the computation, it is not a substage of the computation, and it is not organized together with other parts in the service of the computation.

Second, although reflexivity is involved in certain theoretical applications of mereology, it has no application in thinking about such space-involving levels. It does no justice to the biological concept to assert that every hippocampus is a part of itself. If levels are defined as a relationship between a part and a whole, and everything is a part of itself, then everything is at both higher and lower levels than itself. The parts surely must be proper parts.¹⁵

Third, it has been noted that the transitivity axiom often fails to apply to functional parts of the sort that populate physiological and biological theories (Varzi 2014). Eric is part of the championship pool team, and Eric’s locks are part of Eric, but his locks are not part of the team. However, if one requires of a part (entity, property, or activity) that it must be *relevant* to the property or behavior of the whole, then one can retain the transitivity of this relation, at least in many contexts. *If we ask not about Eric, but about the motion of his arm as he wields his cue*, then his locks are clearly not relevant while the muscles gliding his arm steadily forward *are* relevant. So too are, in some sense, the molecules transmitted across the neuromuscular junction during his backstroke. When what counts as a part is filtered in each iteration by explanatory relevance relations (they are not mere spatial or temporal parts but working parts—parts that are involved in, contribute to, or make a difference to the property or activity of the whole), then the relationship is, in fact, transitive. The appearance of a failure of transitivity in functional systems trades, it seems, on failing to relativize the decomposition into parts by a highest-level target (explanandum) phenomenon; not all the spatiotemporal parts of an object or process are relevant to everything it does. It is only relative to a highest-level activity or property of the hierarchy under consideration that the lower level parts are visible as components—as working parts in the mechanism. *If we think not about the team, Eric, and his locks, but rather*

¹⁵ This is not a big departure from classical mereology; one could simply restrict one’s attention to proper parts. But the point underscores the fact that classical mereology was not developed with an eye toward understanding the sense in which pyramidal cells are parts of the hippocampus.

about the victory, the shot, and the muscular contraction, matters seem different.¹⁶ The contraction contributes to the shot, which contributes to the victory. The locks will not appear in this hierarchy, but the relevant parts will.¹⁷

The extensionality theorem holds that no two distinct objects share all and only their proper parts. A hippocampus and a bust of the Dalai Lama formed out of the same pyramidal cells, granule cells, etc. that compose the hippocampus are, according to classical mereology, one and the same object. But in biological systems, the organization of components is often (perhaps always) relevant to the properties and activities of the whole. Again, parts appear as parts only relative to a decomposition framed by reference to some highest-level property or activity. This is Kauffman's point, enshrined in Glennan's law: a mechanism is always a mechanism of a given phenomenon (Kauffman 1971; Glennan 1996). Thus Kauffman:

A view of what the system is doing sets the explanandum and also supplies criteria by which to decide whether or not a proposed portion of the system with some of its causal consequences is to count as a part and process of the system. Specifically, a proposed part will count as a part of the system if it, together with some of its causal consequences, will fit together with the other proposed parts and processes to cause the system to behave as described. (1971, p. 260)

The more general point is that there is an application of the levels metaphor that is not merely a part-whole relationship as specified in classical mereology, but one in which the parts are relevant (explanatorily and constitutively) to some property or activity of the whole.

One can make a similar point with respect to the summation axiom. This theorem allows

¹⁶ Clearly Eric's muscles are not part of the team, but this reflects only the fact that teams can have only certain kinds of part as members. If we look rather at an activity of the whole and ask what contributes to that, a different picture emerges.

¹⁷ Specific details about lower-level parts might be screened off in cases of multiple realization. Specific details about the parts might not be relevant. In that case, it would appear one must appeal to more abstract properties of the parts.

one to form arbitrarily many gerrymandered wholes out of disparate and unconnected parts with no spatial, temporal, causal, or functional unity. Lewis (1991) calls this "unrestricted composition": whenever there are some things, there is also a fusion of those things. The Yankees's starting rotation and the now disparate parts of my mother's old Chevy Vega together form a whole. This way of thinking about parts and wholes has little or no application in biology because such gerrymandered wholes don't do anything interesting (though such wholes will have aggregate properties of the sort discussed below). The whole in such gerrymandered collections typically doesn't play any explanatory role. And what goes for wholes goes for parts as well. According to this classical picture, it is perfectly legitimate to claim that my dog, Spike, has four parts: a front quarter, a hindquarter, and two midsections of approximately equal length. There is nothing to prevent this way of talking; but the parts revealed in this decomposition do not cut Spike at his joints. The biological decomposition finds joints at causal interfaces, and identifies parts with more or less isolable (nearly decomposable) subsystems (Simon 1962) that contribute to the behavior of the whole.

In short, many of the ideas central to classical mereology must be amended or restricted if they are to apply to the part-whole levels distinctive of biology, neuroscience, and the special sciences generally. At least some of the work can be done by restricting the part-whole relation by a *relevance condition* on biological part-whole: all the lower-level properties, activities, and organizational features of the parts are relevant to—contribute to—the property or activity of the whole.

6.3 Levels of organization: Aggregates and mechanisms

So let us focus on an application of the levels metaphor that is a part-whole relation and a (constitutive) relevance relation. I will not dwell here on the appropriate notion of relevance (see Craver 2007, see also Harinen 2014). For now, we can work with the idea that each part in

such a hierarchy (in addition to being spatially and/or temporally contained within the whole) plays a necessary but insufficient role within a collection of parts that are jointly sufficient (but possibly redundant) for a given explanandum phenomenon (Couch 2011). That is, relevant parts might usefully be thought of as constitutive insufficient, but necessary part of an unnecessary but sufficient condition (I) for the behavior of the mechanism as a whole (Mackie 1973).¹⁸

Again following Wimsatt (1997), we can distinguish two ways that spatiotemporal parts contribute to a property or activity of a whole: *aggregation* and *organization*. An aggregate property is literally a sum of the properties or activities of the parts. The current flowing through an ion channel, for example, is a sum of the charges carried by individual ions. The concentration of a volume of a fluid is a sum of the number of particles in that unit volume. Aggregative properties change linearly with the addition and removal of parts. And aggregative properties do not change as the parts are inter-substituted with one another. Some properties of the hippocampus, such as its mass, remain the same when the cellular constituents of the hippocampus are reorganized to represent His Holiness. Other properties of the hippocampus, such as its information processing capacities, are destroyed. For truly aggregative properties, spatial, temporal, and causal organization among the components is irrelevant.

¹⁸ Once we have made this adjustment, the *relata* in this relevance-merology are no longer objects but rather properties, activities/processes, or (as is more common in philosophical parlance) events. One does not explain the elephant; one explains why the elephant has large ears or how the elephant circulates its blood. One does not explain gasses; one explains their temperature and pressure. This point marks a significant departure from the mereological views of levels discussed above. Each of those applications of the levels metaphor focuses on objects or types of objects (societies, organisms, cells, and so on) as the *relata*, not on their properties, activities, and aspects of their organization. In many cases, the components picked out in a mechanistic decomposition fail to correspond to paradigmatic objects with clear spatial boundaries. The synapse, for instance, is composed of part of a presynaptic cell (the axon terminal), part of a postsynaptic cell (the dendrite or bouton), and a gap between them. What unifies these items into an object is their organized behavior: the pre-synaptic cell releases transmitters that traverse the cleft and act on the postsynaptic cell. Synapses are not cells or parts of cells, nor are they composed of cells. Rather, they are objects unified by their relevance to a given activity of the whole, such as chemical transmission.

Aggregates are rare. The masses of the individual grains in a sand pile do, in fact, depend on the spatial distribution of the other grains (if one takes relativity seriously). What is presumed to be a homogeneous concentration of a liquid can in fact have local concentration differences depending on how the ions are organized in different parts of the fluid. In the case of non-aggregates, the activity or property of the whole is not a simple sum of the properties of the individuals. Adding or removing parts (e.g., the human heart) can lead to dramatic changes in how the system (e.g., the body) works. And rearranging the parts and their activities in space and time can eliminate the explanandum phenomenon entirely (as would happen if one randomly swapped parts of the circulatory system for one another). This is all true because spatial, temporal, and causal organization are relevant to (make a difference to, partly constitute) the property of the whole.

I use the term “mechanism” permissively to describe non-aggregative compositional systems in which the parts interact and collectively realize the behavior or property of the whole. Mechanisms are by definition more than the sums of their parts: they have properties their parts do not have, and they engage in activities that their parts cannot accomplish on their own.

Most mechanisms with which I am familiar involve myriad part-whole relations, some of which are more aggregative in nature, and some of which are less so. Many things brains do, for example, involve the flux of ions across a membrane, which flux is closer to the aggregative than the mechanistic end of the organizational spectrum. Other things brains do (such as the developing grid cells in the entorhinal cortex) require precisely organized relations among the activities of cells in and around the entorhinal cortex. This organizational spectrum from aggregate to mechanism covers all the relations that go into levels of organization, the superordinate class.¹⁹

In levels of mechanisms, the *relata* are some activity or property of a mechanism as a

¹⁹ Levy (2013) calls attention to the fact that biological systems typically involve both aggregation and organization.

whole,²⁰ and the activities, properties, or organizational features of its components (its relevant parts and organization). Some component, X's φ -ing, is at a lower mechanistic level than S's ψ -ing if and only if X's φ -ing is a component in S's ψ -ing, that is, if and only if X's φ -ing is a relevant spatiotemporal part of S's ψ -ing. In levels of mechanisms (as opposed to aggregates) lower-level components are organized together to make up some behavior or property of the whole; in aggregates, the properties of the parts are summed.

Levels of mechanisms are represented in Figure 4. At the top is the activity of some mechanism as a whole (S's ψ -ing). S's ψ -ing is a behaving mechanism. Although one can speak of the mechanism and its activity separately (as when a mechanism stands inactive but ready to act), such separation in thought is artificial. Even the static mechanism is defined and sub-divided by reference to what it does. ψ is the topping-off activity of the mechanism for which all lower-level components are relevant. It can be idealized as an input-output relation, though this is an impoverished way of understanding phenomena (see Craver 2007). One level down are the activities and components, the X's φ -ing, which compose and are organized together to constitute S's ψ -ing.²¹ Below that is another iteration of levels: the ρ -ings of Ps organized such that one of the Xs φ s as it does. By organization, I mean that the parts have spatial (e.g., location, size, shape, and motion), temporal (e.g., order, rate, and duration), and active (e.g., feedback or other motifs of organization;

see Levy & Bechtel 2014) relations with one another by which they work together to do something they cannot do on their own. As noted above, the relationship between levels is a part-whole relationship filtered further by constitutive relevance (Craver 2005; Harinen forthcoming). In levels of mechanisms, parts are made into higher-level components by being organized spatially, temporally, and actively into something. In more aggregate compositional relationships, they are summed into higher levels.

Figure 4: An abstract diagram of levels of mechanisms.

Contemporary theories of learning and memory provide a compelling example of levels of mechanisms (see Craver & Darden 2001; Craver 2002). The top level is a mechanism as a whole engaged in a spatial memory task, such as learning to run efficiently through a maze. One component in that mechanism, and so one level down in this description, is the hippocampus, a region of the brain thought to form a “map” of locations and orientations within the maze. The capacity of the hippocampus to acquire such an internal map of local spaces is thought to be explained, in part, by changes in synapses between pyramidal cells, specifically by a process known as Long-Term Potentiation (LTP). And it is now known that n-methyl d-aspartate (NMDA) receptors (n-methyl d-aspartate is a pharmacological agonist that binds these receptors preferentially), contribute to LTP. This story could continue downward, looking

²⁰ These might be understood as the obtaining of a property or the unfolding of a process over time. What counts as a static property often depends on one's temporal resolution.

²¹ I have not always chosen my language in a way that comports with common usage among metaphysicians, preferring to follow Salmon (1984). In this paper, I have tried to make it clear that I am interested in components. Components, as the name suggests, compose behavior of the higher-level mechanism when organized together. All of the component entities and activities organized together, it now seems appropriate to say, jointly constitute the behavior of the whole. That is, I am now using componency to talk about relationships between wholes and parts, and I am using “constitution” to talk about levels of micro-realization. I am not especially interested in the relationship between statues and lumps of clay. I am interested in how parts are organized and interact so that together they exhibit higher-level behaviors. I know of no metaphysician who has developed an adequate notion to express this, so perhaps I will be forgiven for appropriating these words for new uses.

into aspects of protein chemistry and the structural changes thought to underlie channel functioning.

6.3.1 Levels of mechanisms are local

Levels of mechanisms are of entirely local significance. The levels in our example are defined by reference to a topping-off point, spatial memory, contribution to which determines whether or not a spatiotemporal part of the system is in fact relevant—whether it is a component in the mechanism *for S's ψ -ing*. The hierarchy in Figure 4 and the levels of spatial memory as I have described them follow only a single (local) strand of embedding: from the behavior of the mechanism as a whole, to the behaviors of its components, on to the behaviors of *one* of these components, and so on.

Levels of mechanisms, like part-whole levels generally, are not monolithic divisions in the furniture of the world. Levels of mechanisms are defined only within a given part-whole hierarchy. There are different levels of mechanisms in the spatial memory system, in the circulatory system, in the osmoregulatory system, and in the visual system; the levels in each need not map onto one another. How many levels there are, and which levels are included, must be determined on a case-by-case basis by discovering which sorts of components are explanatorily relevant for a given phenomenon. Levels of mechanisms cannot be read off a menu of levels in advance.

If we apply the levels metaphor only locally, then it makes no sense to ask whether the hippocampus is at a higher or lower level than the nephra in the kidney. The nephra are not part of the hippocampus, and they are not relevant to the functioning of the hippocampus. Neither similarities of size nor similarities in kinds of part are definitive of levels of mechanisms. Rather, levels of mechanisms are defined relative to one another within a hierarchically organized mechanism.

The idea that levels of mechanisms retain some hint of the layer-cake model can sneak its way back into one's application of the metaphor

if one slides unknowingly between tokens and types of parts and wholes. Compare the following three sentences:

- a) This pyramidal cell is at a lower level of mechanisms than this hippocampus.
- b) Pyramidal cells are at a lower level of mechanisms than hippocampi.
- c) Cells are at a lower level of mechanisms than organs.

Statement (a) expresses a mechanistic notion of levels: a particular pyramidal cell is a component of a particular hippocampal mechanism. This statement is true if the cell is a component in a mechanism for a given activity in which the hippocampus is engaged. It might be, for example, that a given pyramidal cell is a component in some hippocampal mechanisms but not others; if so, it is at a lower level to some hippocampal activities and not others.

Wimsatt describes the compositional relationship between levels as a relationship between types. He writes: “Intuitively, one thing is at a higher level than something else if things of the first type are composed of things of the second type” (Wimsatt 1976, p. 215). This is a departure from the idea of levels of mechanisms and one that threatens to reinstate something like the Oppenheim and Putnam hierarchy. Pyramidal cells are found outside the hippocampus, and those pyramidal cells are not parts in hippocampal mechanisms; they are not at a lower level of mechanistic organization. Likewise, both the hippocampus and the kidney are composed of cells; organs tend to be composed of cells. But the cells in the hippocampus are not at a lower mechanistic level than kidneys because they do not contribute to kidney function. The slide from sentences such as (a) to sentences such as (b) and (c) is a slide back toward the layer-cake model. Of course, scientists typically deal with types. But as I suggest above, this is a generalization over a relationship between tokens. The correct generalization is that the cells that compose hippocampi are at a lower level than the hippocampi they compose.

This is significant for two reasons. First, it helps to show that many objections to thinking about neuroscience and other special sciences in terms of levels simply do not apply to this restricted application of the metaphor. If one thinks, with Wimsatt, me, and probably Oppenheim and Putnam, that the Oppenheim and Putnam layer cake is an overly simplistic representation of the diverse ontological structures one finds in the special sciences—that things like ocular dominance columns and synapses don't readily fit that picture—one can nonetheless retain the idea that mechanisms are susceptible to multiple nested decompositions. These are different applications of the levels metaphor. Secondly, and perhaps more importantly, the idea that levels are local significantly shifts the reductionist world-view for which Oppenheim and Putnam developed their ontology of levels. If one thinks of levels as levels of organization (as levels of mechanism and levels of aggregation), then it is inaccurate to think of reduction as involving relationships among theories developed to describe the items at a particular monolithic level. If reduction is simply a matter of explaining a higher-level phenomenon in terms of the organized activities of components, then reduction is still possible within a mechanistic world-picture, but it will be achieved not through grand reductions of overarching theories, but rather through piecemeal explanatory achievements for specific phenomena. Visions of the unity of science through interlevel reduction have to be revised not as grand unifications across the whole of science but rather as local explanatory successes. Such local explanations will, in fact, integrate findings from different sciences and bring different theoretical vocabularies into conversation with one another (see Craver 2005; Craver & Darden 2001), but it only deceptively resembles the layer cake that Oppenheim and Putnam sketched as a working hypothesis.²²

²² Nothing in this picture is meant to deny token identity between the behavior of a mechanism as a whole and the organized behavior of its parts. Because there are some conceptual difficulties that stand in the way of speaking meaningfully about token identities between levels, I have written with fewer commitments about constitution.

6.3.2 Placement is weak and derivative in levels of mechanisms

One consequence of the mechanistic application of the levels metaphor is that there is no unique answer to the question of when two items are at the same mechanistic level. Only a partial answer is available: X's ϕ -ing and S's ψ -ing are at the same level of mechanisms only if X's ϕ -ing and S's ψ -ing are components in the same mechanism, X's ϕ -ing is not a component in S's ψ -ing, and S's ψ -ing is not a component in X's ϕ -ing.²³ Unlike size levels or levels defined in terms of the types of objects found at a given level, levels of mechanisms are defined fundamentally by the relations question: by the componentency relationship between things at higher and lower levels. If two things are not related as part to whole, they are not at different levels, and so, if they are in the same mechanism, they are, in this very weak sense, at the same level. But this is just to say that sameness of level has no significance within this application of the metaphor.²⁴

If one thinks of levels of organization as levels of aggregates and levels of mechanisms, then spatial containment and size relations between levels follow as an accidental consequence of the componentency relation. The pyramidal cells are contained within the hippocampus, which is contained within the spatial memory system. The activities of these entities are also related as temporal part to whole: the binding of glutamate is a

²³ This has struck some readers as circular because it appears to state that X and S are at the same level if they are not at different levels. Appearances to the contrary, this is not circular. I have defined "same level" in terms of the notion of "different level" and the latter is defined in terms of componentency relations. The appearance of circularity, I believe, results from the fact that most people assume that the notion of "same level" must be primitive relative to the notion of "different level," and I have reversed that assumed order.

²⁴ Another way to see that levels of mechanisms do not answer the placement question is to recognize an apparent failure of transitivity. Suppose X1 and X2 are components in the same mechanism, that neither is a component in the other, and that the behavior of X2 can be decomposed into a set of interacting components, including P1. X1 would, according to this account, be "at the same level" as both X2 and P1 even though X2 and P1 are at different levels from one another. This problem, first raised by Lindley Darden (personal communication), is only a problem if one demands that there must be a unique answer to the placement question for an account of mechanistic levels. My argument against the notion of monolithic levels turns on the absence of any good principle for stretching the ideal of levels beyond its local context.

temporal component in the activity of the NMDA receptor. The objects at lower levels are smaller than (or at least no larger than) the whole, giving the hierarchy a derivative size ordering. Relations of size, rather than defining what it is for an item to be at a level (the placement question), are derivative from the more fundamental relationship between levels (the relations question): namely, the relationship between a mechanism and a component.

6.3.3 Emergence and levels of mechanisms

Mechanisms do things that their components taken individually cannot. This marks a sharp distinction between levels of mechanisms and levels of realization. Kim says this point is “obvious but important”:

This table has a mass of ten kilograms, and this property, that of having a mass of ten kilograms, represents a well-defined set of causal powers. But no micro-constituent of this table, none of its proper parts, has this property or the causal powers it represents. H₂O molecules have causal powers that no oxygen and hydrogen atoms have. A neural assembly consisting of many thousands of neurons will have properties whose causal powers go beyond the causal powers of the properties of its constituent neurons, or subassemblies, and human beings have causal powers that none of our individual organs have. Clearly then macroproperties can, and in general do, have their own causal powers, powers that go beyond the causal powers of their micro-constituents. (Kim 1998, p. 85)

Through aggregation or organization, wholes have causal powers that their parts individually do not have. An activity at a higher level of mechanistic organization is quite literally more than the sum of its parts. It is not an aggregate. The addition and removal of parts leads to nonlinear changes in the behavior of the mechanism as a whole. It matters how the parts are organized; it is in virtue of their organization that

they have properties that go beyond the properties of the individual parts (Wimsatt 1996). This feature of levels of mechanisms is so obvious, so prosaic, and so banal as to be hardly worth mentioning. No fancy complexity is required: two toothpicks stacked perpendicular to one another have the mechanistically emergent capacity to act as a lever or catapult; neither toothpick can do so on its own.

Of course, most mechanisms in biology are substantially more complicated than that. They have many more parts. Those parts interact with one another with bewildering complexity. Often they contain feedback relations that introduce nonlinear interactions into the operation of the mechanism itself. The mechanisms of LTP, for example, have yet to yield their secrets completely despite the dedicated attention of thousands of researchers over forty-odd years. A glance at any recent textbook is enough to convince one that LTP involves myriad intracellular reactions, protein synthesis, structural features of dendritic spines, changes to vesicular release, and retrograde transmission with nitric oxide. The mechanism involves so many parts and interactions that it would be useless, if not impossible, to represent them all in a visual diagram. Keeping track of how they all work together would require a very complicated computational model of some sort that has yet to be developed. As mechanisms get this complicated, we reach the limits of our ability to predict how the behavior of the whole will change as the parts change. Any change introduced to a part has so many ramifications that it is difficult or impossible for creatures like us to keep track of them all. This is an interesting fact about us and the limits of our cognitive and modeling prowess. But, ontologically, it is the same old banal fact about the importance of organization in mechanisms. We have added only that we have difficulty keeping track of it all.

Likewise, a common scientific complaint against reductionistic research programs in biology and neuroscience is that one can make only limited progress by studying the parts of mechanisms in isolation from one another.²⁵

²⁵ This idea of reduction is not the standard notion of theory reduction but something closer to what Eric Kandel means

We can study LTP in cells grown in a culture, and we can study hippocampal computations in a razor-thin hippocampal slice, and we can study spatial learning in highly contrived environmental settings such as a large pool filled with milky water (the Morris water maze). Such reductionist practices are absolutely essential to progress in the sciences. Nonetheless, one engaged in such practices must (and typically does) bear in mind that the behavior of the part when it is isolated for experimental purposes might be very different from the behavior the part exhibits when it is working in the context of a mechanism. Causal interactions with other parts of the mechanism and background conditions “in the wild” might lead to behaviors that would never be discovered in such simplified preparations. This is an extremely important point about reductionist research programs (Bechtel & Richardson 1993), and one might choose to describe this well-known difficulty with the language of emergence. But this is just to say that one cannot truly understand how a mechanism works until one understands how all its parts are organized together and working in the relevant conditions, and this we have already said repeatedly.

I emphasize the banality of these observations to stress that many of the things one wants to say about organization in biological systems can be said within the mechanistic application of the levels metaphor without introducing anything that is metaphysically novel or suspect. As the complexity of a mechanism increases, the epistemic challenges we face in discovering and modeling it increase as well, but this is of no significance for the ontic structures—the entities, activities, and organizational features that exist in the world.

Not so for *spooky emergence*. Spooky emergence is spooky precisely because it is committed to the existence of higher-level properties that have no explanation in terms of the parts, activities, and organizational features of the system in the relevant conditions. Levels of mech-

anisms are levels of ontic mechanistic explanation (Craver 2014): they are defined in terms of componency and constitutive explanatory relevance. If that explanatory relationship is severed, then the sense in which emergent properties are at a “higher level” must be altogether different than the compositional notion of levels in levels of mechanisms. If one imagines that atoms compose molecules, which are organized into cells, which are linked into networks from which mental properties spookily emerge, the first three steps are upward steps in a hierarchy of levels of mechanisms, but the last is not. The ability of organization to elicit novel causal powers (that is, nonaggregative behaviors and properties) is unmysterious both in scientific common sense and common sense proper (Van Gulick 1993; Kim 1998). Appeal to strong or spooky emergence, on the other hand, justifiably arouses suspicion. Indeed, it is unclear why properties that emerge in a spooky fashion should be thought of as higher-level at all. Perhaps the very idea of spooky emergence is incoherent.

6.3.4 Mechanistic levels are not causally related to one another

As with levels of realization, many common assumptions about the nature of causation would appear to make causal relations between mechanistic parts and the properties or behaviors of wholes suspect. Items at different levels of aggregation and at different levels of mechanisms are intimate with one another in much the same way that items at different levels of realization are intimate. Lewis is explicit. If C causes E:

C and E must be distinct events [if they are to be causally related]—and distinct not only in the sense of nonidentity but also in the sense of nonoverlap and non-implication. It won't do to say that my speaking this sentence causes my speaking this sentence; or that my speaking the whole of it causes my speaking the first half of it; or that my speaking causes my speaking it loudly, or vice versa. (Lewis 2000, p. 78)

by the term: choosing to study complex phenomena in extremely simple systems. We might call this experimental reductionism.

The relevant kind of intimacy for levels of mechanisms is overlap between token events or processes. The relationship between LTP and the opening of NMDA receptors during LTP induction is directly analogous to the relationship between speaking the whole of a sentence and speaking its first half. The induction of LTP is partly constituted by the opening of the NMDA receptor. The would-be cause in this top-down causal claim already contains the would-be effect within it. There is nothing additional to be produced in the effect; the occurrence of the effect includes the occurrence of the cause.

What about the bottom-up case? We might say that the spark plugs cause the engine to run, all the while acknowledging that the sparking of spark plugs is part of the operation of the engine. The naturalness of this locution is at least partly due to an ambiguity in the way we commonly describe the behavior of a mechanism as a whole. Sometimes we describe it as an activity or process that starts with the mechanism's setup conditions and ends with its termination conditions (Machamer et al. 2000). Thus we might describe Long-Term Potentiation as a *process*²⁶ or activity beginning with a rapid and repeated stimulus (called a tetanus) to the presynaptic neuron and ending with enhanced transmission across the synapse. Other times we describe the behavior of the mechanism as a whole, the phenomenon, as the *product* of that process (or one of its termination conditions). Thus we might say that the mechanism of Long-Term Potentiation produces a *potentiated synapse*. This way of speaking leads us to think in terms of the antecedent causes of potentiation: the tetanus is a distal cause, and the subsequent changes in the NMDA receptor are more proximal. If we think about the behavior of the mechanism in the second way, as a product, it is natural to think of the opening of the NMDA receptor as a cause of the synapses being potentiated (and indeed it is). But if we think about the behavior of the mechanism in the first way, as an input-output relation starting with the tetanus and ending with a potentiated synapse, then it is wrong to think of the tetanus or the opening of the NMDA receptor as a cause of *that*. The

NMDA receptor is a part of that causal process. These are two equally acceptable ways of describing the relationship between a mechanism and a phenomenon; they are easily translated into one another. However, if one is careless, these ways of speaking and writing invite equivocation of precisely the sort that we are struggling here to avoid.

Figure 5: Why bottom-up causation is conceptually problematic.

Suppose we represent the input-output relationship constituting LTP as in the top of Figure 5, where I is a tetanus and O is a stable, potentiated synapse. Beneath this abstract I-O relation is a more detailed description of the intermediate stages in this mechanism: the tetanus excites the postsynaptic cell (A) which depolarizes it (B), causes NMDA receptors to open (C), and so on. (Nothing turns on the fact that I've idealized this mechanism as a single, step-wise causal chain.) Now, suppose we intervene to open the NMDA receptors directly and thereby potentiate the synapse (as shown in the third line). We might say that this intervention induced LTP; but when we say this, we mean that it produces the end product of the mechanism (it potentiates the synapse). We cannot coherently assert that it causes the process as depicted in the first two lines. This is for the simple reason that the process in the first two lines includes stages I, A, and B, and these are absent in the causal sequence represented in the third line. At most we can say the intervention caused the last half of the process. The NMDA receptor is not a cause of the process of LTP; it is a component of that process.²⁷

²⁷ This case is easiest to make for interventions that start the process mid-way. If an intervention, instead, were to augment C and thereby produce a more potentiated synapse than one would otherwise have had, then causal language would appear to be appropriate. The intervention changes, makes a difference to, the input-output relationship. These considerations generalize naturally to claims about types of

²⁶ Not in the Salmon (1984) sense, but in the colloquial sense of an unfolding sequence of states and activities.

6.4 Levels of mechanisms in relation to other kinds of levels

This application of the levels metaphor, according to which levels of organization are understood in terms of levels of aggregation and levels of mechanisms, thus offers a no-nonsense, ontological picture that comports well with the kinds of explanatory structure one finds in neuroscience and throughout the special sciences generally.

This view eschews the idea that levels are monolithic strata in the structure of the universe, with proprietary causal laws and forces (contra the view in Wimsatt, Oppenheim, and Putnam). Likewise, it allows that items at higher levels have causal powers that things at lower levels do not, in contrast to levels of realization. Single sciences and theories might investigate phenomena at many levels of organization, and an item located at one level in such a compositional hierarchy might be studied by many sciences and described in many theories. Things at different levels of organization (aggregation and mechanism) do not causally interact with one another, though we might find more complicated ways of describing how these items depend upon one another (see Craver & Bechtel 2007). As a result, if we think about the world in terms of levels of organization, we should not be tempted into thinking that things at higher levels control or dominate things at lower levels. Levels of organization are, in a sense, levels of explanation, given that explanations for different topping off phenomena will often decompose the system into altogether different parts within parts. It might be difficult to discern such levels in scientific practice, and the organization of components might be very complex, but nothing emerges from levels of mechanisms except in the banal sense that parts organized together do things that the parts alone cannot. Levels of organiz-

ation, in other words, seem to capture many of the intuitions that accompany the idea that the world is organized into levels but without many of the objectionable elements of other applications of the levels metaphor. The fact that the levels metaphor is often used carelessly and deployed in ways that violate common sense and metaphysical ideas about the structure of the world should not lead one to abandon the metaphor entirely. As we've seen, it can be given a relatively precise and metaphysically unobjectionable formulation that, in addition, fits the multilevel structures that the most advanced special sciences seem to be discovering.

7 Conclusion

Despite the ubiquity of levels talk in contemporary science and philosophy, very little has been done to clarify the notion. Here I defend a kind of descriptive pluralism about the levels metaphor: it is applied usefully in many contexts to describe different relata, different relations, and different senses in which items might be located at a given level. Because the levels metaphor is so ubiquitous and so promiscuously applied, some vigilance is required to keep the applications distinct from one another. I have discussed only a few applications: levels of science, theory, realization, size, mereology, aggregation, and mechanism. Even in these few key examples, we have found good reason to remain vigilant. The implications of the levels metaphor in one application only occasionally transfer when the metaphor is applied differently.

I have also suggested that levels of mechanisms (or, more generally, levels of organization) are especially important to the explanatory structure of neuroscience and the special sciences generally. If one thinks of levels in this way, one can easily see why interlevel causation should seem so problematic (indeed, it is problematic), one is free to jettison Oppenheim and Putnam's idea of monolithic levels of nature, and one can see room in the causal structure of the world for the existence and legitimacy of higher-level causes and explanations. Whether

mechanistic parts and wholes. Separately: When we describe this relation as a kind of production, levels show up as intermediate causes. Perhaps the temptation to speak of levels at all is lessened if one maintains that perspective. But this is not a change in what is being said so much as a change in how it is being said.

the idea of levels of mechanisms truly pays off in such useful ways remains to be seen. I merely hope to have preserved the metaphor, and its application to mechanisms, in the face of problems it inherits only through equivocation.

Acknowledgements

This essay is dedicated to William C. Wimsatt, whose sensitive and pioneering explorations of complexity, levels, and organization have shown how to tame the biopsychological thicket without sacrificing its wildness. Thanks to Anthony Dardis, Jens Harbecke, Donald Goodman-Wilson, Eric Hochstein, Eric Marcus, Lauren Olin, Gualtiero Piccinini, Anya Plutynski, Philip Robbins, Mark Povich, Felipe Romero, and Gary Williams for comments on earlier drafts.

Mechanistic Emergence: Different Properties, Different Levels, Same Thing!

A Commentary on Carl F. Craver

Denis C. Martin

In this commentary I will briefly sketch the notion of “levels of mechanisms” as presented by Carl Craver and propose that we extend it to a more general notion of “level” that ensures wider applicability. The account of levels I develop is essentially based on an account of “properties”, claiming dependence of instantiation on a certain epistemic context. The main goal is then to reconcile Craver’s notion of “mechanisms” with “emergence” resulting in a contemporary account of “mechanistic emergence” implementing the developed concept of a level. Such an account could provide explanatory potential for and elucidate on seemingly mysterious higher-level properties and their ontology.

Keywords

Causation | Descriptive pluralism | Dispositional essentialism | Dualism | Emergence | Epistemic context | Level | Mechanisms | Mechanistic emergence | Mechanistic explanation | New essentialism | Novelty | Ontological novelty | Part-whole relationship | Properties | Property instantiation | Realization | Unexplainability | Unpredictability

1 Introduction

Are mind and brain on the same level? Mental properties and biological properties are so different that some kind of dualism is still an attractive position for many people. Intuitively, mental phenomena are often assumed to be on some kind of higher level than physical phenomena. For example, in order to accurately describe what it means to have compassion for another living being, most people would probably

agree with the popular expression that this simply *cannot amount to nothing but* the description of the underlying neurophysiological activity or behaviour *related* to that compassion—that presenting the neurophysiological activity alone does not fully capture all properties of being in a state of compassion. Instead, especially in everyday life, we might rather refer to the phenomenological properties of compassion,

the properties we draw on to identify that we are in a state of compassion at a given time. These properties seem to have a special value for us. In a way, they seem to be much richer than those of “cold” science. But what, exactly, does it mean to say that mental and physical phenomena are not on the same level? If I were to ask what compassion is, most people would probably agree that it is somehow realized by their body, just as an elaboration of this fact does not suffice for a complete description of compassion, implying that there must be something *more* than that, on a *higher* level. This, at least for a philosopher, inevitably leads to the question of what those levels actually *are*. What does “level” refer to? To what extent do levels *exist* in the world at all? These questions become even more pressing when we make ourselves aware of the extent to which the sciences use the concept of “level”. Whole disciplines, such as psychology and neuroscience, are distinguished as operating on different levels with different theories aiming at specific target phenomena. Levels also play a role within disciplines. In neuroscience, for example, it is quite common to distinguish between lower-level brain functions as realized in the brain stem or primary sensory areas as opposed to higher-level functions like decision-making or emotion regulation that are attributed primarily to the frontal lobe. Likewise, the distinction of processes and functions as operating “bottom-up” or “top-down” is quite prevalent.

There is a general strategy in science that has proven to be effective for explaining a certain phenomenon: decomposition. The reason for that is as follows: to fully explain a phenomenon, it does not suffice for us to be able to elaborately describe it or list certain correlations with singular components or other phenomena. Rather, we need to know in detail how the phenomenon comes into existence, based on how exactly it is realized: which components underlying the phenomenon are doing what, where, when, and how in order to make the phenomenon emerge. These requirements are captured excellently by Carl Craver’s (2007; Craver & Darden 2013, p. 15) famous definition of a mechanistic explanation:

mechadef/mechanistic explanation =_{Df} [m]echanisms are entities and activities organized such that they are productive of regular changes from start or set-up to finish or termination conditions. (Craver & Darden 2013, p. 15)

But in what sense are the mechanistic components of a phenomenon on a lower level than the whole phenomenon? This is the question Craver answers in his article “Levels”, in this collection.

In what follows, I shall first point out I find most important about Craver’s account of levels of mechanisms and where I see some difficulties in his account. I shall then propose an alternative way of defining levels by emphasizing the notion of “properties”. The idea here is that levels are a direct result of property instantiations and thereby constitute “property-dependent epistemic dimensions”. By focusing on properties in general, and not only on properties of mechanisms, I hope to show that an account of levels does not have to be as restricted as Craver proposes. I shall also argue that levels of mechanisms and levels of emergence do not have to be conceived as necessarily distinct, but can rather be combined quite well into a productive account of mechanistic emergence. Expanding Craver’s account of levels this way provides not only a notion of levels with wider applicability but also builds on his account of mechanisms as operating on different levels, which instils explanatory potential into a contemporary account of emergence. This still secures the application of “levels” in science, but at the same time makes transparent how the epistemic contexts of science are property- and level-generative. The ultimate goal of this approach is, of course, to elucidate how one and the same material system may show significantly different properties to an extent that elicits serious confusions about matters of identity.

2 Levels of mechanisms

First of all, the approach Craver takes for defining levels is notable in many ways. What I find especially important, however, is that he develops his definition in an interdisciplinary frame-

work, paying close attention to compatibility with or even application in neuroscience. So what are levels as used in such a scientific context? In his article of this volume, Craver extends his original definition of mechanisms a little to accommodate for the existence of lower-level mechanisms that take part in the realization of higher-level mechanisms.

I use the term ‘mechanism’ permissively to describe non-aggregative compositional systems in which the parts interact and collectively realize the behavior or property of the whole. Mechanisms are by definition more than the sums of their parts: they have properties their parts do not have, and they engage in activities that their parts cannot accomplish on their own. (Craver [this collection](#), p. 16)

Mechanisms as construed here are entities and activities organized in non-aggregative compositional systems, such that they are productive of regular changes from start or set-up to finish or termination conditions, and the properties of the whole mechanism are produced collectively through the interaction of its component mechanisms. This establishes the basis for Craver’s introduction of levels of mechanisms.

Craver’s three defining questions—namely about the relata, the relations, and their placement—constitute a valuable contribution to the conceptual clarification of the term “level” helping to capture the criteria for the correct usage of the term. This already hints at the descriptive pluralism Craver promotes, meaning that there is a set of equally correct ways to use the term depending on the respective answers to these three key questions. In the case of mechanisms, levels are best individuated, according to Craver, in terms of a part–whole relationship between the property “ ψ -ing” of S, given that S is a mechanism as a whole, and the property “ ϕ -ing” of X, given that X is a mechanism component that is a constitutively relevant spatiotemporal part of S.

Summing up Craver’s position on levels and levels of mechanisms as I understand it, they:

- are *metaphors* with multiple distinct conditions of correct usage dependent on the relata, relations, and their placement and
- refer to *part–whole relationships*.
- Levels of mechanisms have *properties* of mechanisms and properties of their parts *as their relata* (as opposed to levels of size, which have objects as their relata),
- are always *non-aggregative* (though aggregative levels do also exist),
- are *not monolithic*, but constitute a *local organizational part–whole hierarchy*, while
- the part–whole relationship must satisfy the *constitutive relevance condition*;¹ **while**
- there is *no causal relation* between them,
- they bear *explanatory potential*,
- and, finally, the *placement* of entities on levels of mechanisms *is weak* in the sense that for all entities that are not related as part and whole it can be said that they are on the same level.

What might the difficulties with this account of levels be? As a minor point, first, there might be some implications of using the concept “metaphor” in connection with levels. By definition, a “metaphor” identifies two things—a primary and secondary subject—with one another, such that one of the two can be captured in description more powerfully (Hills 2010). What could the primary and secondary subject in a level-metaphor be? The primary subject would probably be a level in the sense of a level of mechanisms, the secondary subject could maybe be a plane, a stage, or a degree. But how would that help elucidate what the primary subject levels actually are? As far as I can see, using “level” as a metaphor would more effectively *describe* what a level is, but not actually *define* it and, thereby, simply capture what our intuition about levels is in the first place—namely that it is somewhat analogous to a level in the secondary subject sense. Also, it seems that conceiving of “levels” as a metaphor would

¹ “Constitutive relevance”: “[...] all the lower-level properties, activities, and organizational features of the parts are relevant to—contribute to—the property or activity of the whole” (Craver [this collection](#), p. 15).

already somewhat negatively answer the question of what levels actually are, as solely existent as a figure of speech—an analogy that could be eliminated without any ramifications. Craver’s descriptive pluralist approach is formulated specifically to counteract elimination of levels and thereby to sustain their application in science. However, descriptive pluralism obviously does still act on the assumption that levels are metaphors, and only describes conditions that fit their application better than others. Therefore, this approach does not seem to be particularly helpful for our intended and certainly desirable goal.

Another issue I would like to raise is that in Craver’s account of levels as presented here, the key defining feature of levels seems to be a relation condition² between certain entities. This already becomes apparent with the three questions mentioned above, which aim to help us adequately describe specific instances of levels. Levels of mechanisms in particular are specified as a part–whole relationship between properties of mechanisms that are located on different levels. But does this really capture what *levels* actually are? Or does it rather render the relation condition *between* levels more precise, instead? While helpful to set the criteria for conditions under which the term “level” is correctly employed, and highlighting distinguishing features of different levels, saying that levels are essentially relations between sets of entities is at best an indirect or descriptive definition of levels and does not seem sufficient for a complete definition. It leaves open how levels come into existence, what their ontological status is, and why we posit certain entities on the same level in the first place, that is, what the commonalities of entities are that lead them to be on the same level.

From the key aspect of a part–whole relationship in Craver’s account stems the notion that levels are local and non-monolithic. This means that only those entities that are involved in such part–whole relationships can intelligibly be said to be on different levels. What are our theoretical options for conceptually covering all

other entities? Since they don’t fulfil the part–whole criterion they cannot be on distinct levels and, therefore, in a sense they are all on the same level. However, according to the definition of levels at hand, to be on any level means that there are other levels, which are distinguished from the first level by the part–whole relationship of the entities involved. Since the entities under consideration do not exhibit this kind of relationship, they are on no level at all. In general, this seems like a reasonable option. But let’s consider the case that entities that are not in such a part–whole relationship do, nevertheless, share some features—for example a hedge and a fence both one meter high. In accordance with levels not being monolithic and the previous considerations, these would not be on the same level, but on no level at all. What exactly is wrong, however, with saying that two entities sharing the feature of being one meter high but which are not related as part and whole are on the same level? One could, of course, simply invoke the account of levels of mechanisms and argue that it is designed such as not to warrant such a level. But does this limitation really procure us a better understanding of “level”, or could it rather be too restrictive for that purpose? Its consequence, at any rate, is a very strong focus on the vertical dimension, namely the relation between levels, whereas the horizontal dimension, that is, entities related qua being on the same level, is somewhat neglected. So, let us ask, what are the criteria for two entities being on the same level? It is exactly this relation between entities on the *same* level that the concept is primarily supposed to capture, and yet which seems to be underspecified by the definition provided. And how similar do two part–whole relationship units have to be in order for it to be correct to say that their respective wholes and parts are on the same level? Or does it even follow that two things that are not part of one and the same part–whole relationship cannot even be on the same level at all?

As a third point, finally, there remains the issue of the extent to which levels of mechanisms are similar or distinct from levels of realization and emergence, respectively. All three kinds of levels share that an application of the

² “Relation condition”: “the componency relationship between things at higher and lower levels” (Craver [this collection](#), p. 19).

concept of inter-level causation is not feasible in their case, since they do not fit classical assumptions about causation such as non-synchronicity of cause and effect—a very substantial point Craver emphasizes in the target article. But what are the differences between these kinds of levels?

According to Craver, levels of mechanisms and levels of realization seem to differ in that the former exhibit a relationship between wholes and parts, whereas the latter exhibit a relationship between wholes and sets of realizers. But this distinction seems rather frail. How are the parts involved in levels of mechanisms different from the set of realizers involved in levels of realization, such as to warrant this distinction? At least in levels of mechanisms, as Craver envisages them, the parts are several mechanisms that together form the whole, which is comprised of all the particular “part-mechanisms”. If mechanisms in general realize certain phenomena, this suggests that all “part-mechanisms” are also realizers in the same way. Now, if the “part-mechanisms” on the “part-levels” are all realizers, it is reasonable to say that the “whole-mechanism” on the “whole-level” is realized by the organized coaction of its parts and that the “part-levels” are the realizers of the “whole-level”. Thus, the distinction between levels of mechanisms and levels of realizers conflates.

The difference between levels of mechanisms and levels of emergence, on the other hand, is based on the unpredictability, unexplainability, and metaphysical novelty of higher-level properties, as opposed to lower-level ones. Craver’s point here is that levels of mechanisms, while they can be unpredictable, do not have to be so necessarily, that they are always explanatory, and the novelty of higher-level properties is a trivial fact. But why think that the opposite must hold in the case of emergence? Of course, “spooky emergence”, “[...] the existence of higher-level properties that have no explanation in terms of the parts, activities, and organizational features of the system in the relevant conditions” (Craver [this collection](#), p. 21), is spooky by definition—that much is clear. Also, admittedly, the way emergence was construed

historically by the British Emergentists perfectly fits this view and deliberately opposes mechanisms as it can be found, for example, as per Broad (1925). However, why should we prematurely accept this view of emergence as given and eliminate any possibility of further development towards a notion of emergence that is perfectly commensurable with modern science? In fact, I think the formidable way in which Craver develops his account of levels of mechanisms is perfectly suited to facilitate development in this direction. So what could a definition of emergence be, and how can it be united with mechanisms? The following definition of emergence by Evan Thompson (2007) already seems compatible with Craver’s framing of the way properties of higher-level mechanisms are constituted by properties of lower-level ones.

A network, N , of interrelated components exhibits an emergent process, E , with emergent properties, P , if and only if:

- (1) E is a global process that instantiates P , and arises from the coupling of N ’s components and the nonlinear dynamics, D , of their local interactions.
- (2) E and P have a global-to-local (“downward”) determinative influence on the dynamics D of the components of N .

And possibly:

- (3) E and P are not exhaustively determined by the intrinsic properties of the components of N , that is, they exhibit “relational holism.” (p. 418)

This definition is compatible with Craver’s characterization of levels of mechanisms in the following respects: properties of higher-level mechanisms, global emergent properties, are realized by properties of lower level mechanisms; and there is a part-whole relationship between those relata, as well as a non-causal influence between the levels. What Thompson’s definition additionally contributes is a point about predictability. For many phenomena in

nature, the interactions of lower-level components are so complex that they can only be described by non-linear dynamics. A precise predictability of the higher-level phenomena might not always be possible at present due to there being too many factors involved in the underlying processes—it simply exceeds current computational tractability. Craver acknowledges this point—so it can also be said to be consistent with his account—but worries that this might have ontological ramifications: “[i]f that explanatory relationship is severed, then the sense in which emergent properties are at a ‘higher-level’ must be altogether different than the compositional notion of levels in levels of mechanisms” (Craver [this collection](#), p. 21). More precisely, he suspects that in emergence ontological novelty arises through the epistemological limitations just mentioned; otherwise ontological novelty would simply be a banal fact already expressed by his account.

There are, however, several problems with this view: first, one can make a distinction between the epistemological (e.g., “predictability”) and ontological (e.g., “novelty”) dimension of emergence (O’Conner & Wong 2009). There is, in principle, no reason to assume that the ontological dimension is dependent on the epistemological; rather, they seem to be fully dissociable.

Second, his criticism backfires with regard to the banality of the properties that higher-level mechanisms exhibit in his own account of levels. For there to be “higher” levels of mechanisms, these mechanisms must show *new properties*, that is, in order for them to qualifiedly be on that level. Hence, his account cannot go without ontological novelty of some kind. To now say that this ontological novelty would be only a banal fact undermines his very own striving for mechanistic explanation, which certainly is not banal. In fact, it is still interesting how “higher-level” properties come into existence, what it means to say that they are *new*, and how the concept “level” might be connected to this. A successful reconciliation of mechanisms and emergence in the form of mechanistic emergence could provide a solution to this problem.

Third, the dissociability of the epistemological and ontological dimension of emergence does not contradict the possibility of their mere coexistence. Once we dismiss the idea that ontological novelty follows from epistemological intractability, overcoming the restraints of historical accounts of emergence, the fact that the coming into existence of new properties on a higher level is not tractable at the moment does not mean that it is not so *in principle*. The reason why we call this coming-into-existence “emergence”, as might be conceived by a revised account, is not based on the fact that it *is* epistemically intractable *in principle*, but rather that it shows novel properties on a higher level that *appear* to be epistemically intractable *in principle*, while they might at some point be very well explained in a mechanistic framework combined with a proper theory of property instantiation.

Thompson’s definition leaves room for local components to be part of a mechanism. A mechanistic explanation of the emergent phenomenon, it seems, would not be incompatible with an account of emergence, but rather contribute to its explanation by elaborating on how the organization of the parts is essential for emergent properties to arise. As for the ontological novelty of higher-level phenomena, this is certainly a crucial point in emergence: there are new properties coming into existence on the higher levels that are somehow realized by processes of components on the lower level, which in isolation do not show the same properties as the whole. For this to happen, however, contrary to what Thompson’s definition implies, the underlying interactions of the components or the emergent properties themselves must not necessarily be unpredictable in principle. But I anticipate an objection: this form of emergence would again only be very weak or banal, but not ontologically new. As already mentioned above, unpredictability does not have a bearing on ontological novelty and is therefore not crucial for emergence. What levels of mechanisms and emergent levels share is that on higher levels there are *new properties*, which means that there is a notable ontological difference. How extensive such an ontological difference

must be in order not to be banal remains a matter of debate. Still, in the case of mechanisms, as well as in the case of emergence, it is very likely that there is a significant phenomenon making up the higher level—otherwise it probably would not be of such interest for enquiry as it clearly is.

As a result of these thoughts, in what follows I will try to reconcile levels of mechanisms and levels of emergence as two interconnected forms of realization. This alone, of course, does not solve the problem of what the levels involved actually *are*. So in fact there are two problems to be solved for an account of mechanistic emergence: (a.) what it means exactly for a higher-level phenomenon to exhibit *new* properties, and (b.) what exactly constitutes a *level*. As a route to a possible solution, in the next section I will sketch a definition of properties that can be implemented in a definition of mechanistic emergence and that at the same time provides a positive account of levels.

3 Level-carving properties in mechanistic emergence

In this section, I propose an alternative account of levels that is fully compatible with the mechanistic framework and the way in which levels of mechanisms are construed by Craver, but which at the same time has a wider scope of application. Since this account will rely on properties as the crucial defining criterion, I shall first sketch a working definition of the concept of “properties”. In a second step, this definition of “property” will conceptually ground the alternative account of levels. Finally, I will implement both the definition of properties and that of levels into a formulation of mechanistic emergence.

What might be a working definition for the term “properties”? Inspired by [Brian Ellis’ \(2002\)](#) “new essentialism”³ and [Alexander Bird’s \(2007\)](#) “dispositional essentialism”,⁴ I

propose the following view: what exist in the world are entities with individual dispositional profiles. An example that [Ellis \(2002\)](#) gives is the dispositions of particles to attract or repel each other. These essential dispositions, individuating the particles as that which they are, make it possible for us to formulate laws of nature. Many of these dispositions are the result of structural and organizational combinations of matter with different dispositions, e.g., ions have the disposition to form ionic crystals, which by means of the resulting structural characteristics in turn have other specific physico-chemical dispositions. Those essential dispositions alone, however, are not properties yet. That is because dispositions exist outside of an epistemic context. The property of being one meter high, for example, is dependent on the disposition of an object to exactly fit the measurement revealing it to be the height of one meter. Without the measurement, however, the property is not instantiated—only the disposition of its instantiation exists inherently in the structure of the object. Thus, according to my theory, properties are instantiated through the interaction of the essential dispositions of matter and an epistemic system. Of course, now you will ask what this epistemic system could possibly be. Admittedly, this aspect of the definition is in a particularly embryonic stage and requires further research. As a general characterization, epistemic systems are structured such that they feature sensors or gauges that capture specific dispositions of entities and provide characteristic values as an output. Human and non-human animals, as well as physical devices of measurement, are epistemic systems in this sense. Let us note the following as a working definition of “epistemic system”:

Epistemic system =_{DF} (ES) Epistemic systems are organized (a.) such as they feature sensors or gauges that pick up a specific disposition exhibited by an entity and (b.) such as there is a transformation of that signal into a particular value characteristic of the system’s organization.

³ “[...] things must behave in the sorts of ways they do not because the laws of nature require them to, but rather because this is how they are intrinsically disposed to behave” ([Ellis 2002](#), pp. 3–4).

⁴ “[...] the claim that fundamental natural properties are essentially dispositional. [...] *x* is disposed to manifest *M* in response to stimulus *S* iff were *x* to undergo *S* *x* would yield manifestation *M*” ([Bird 2007](#), p. 24).

With this definition at hand we are able to formulate a working definition of properties:

Properties =_{Df} (P) Properties are instantiated through epistemic processes, which are constituted by interactions between epistemic systems and complementary dispositional profiles of entities.

Let us now turn to how levels depend on properties. The idea here is that levels are established by the epistemic systems in use that instantiate the properties which belong to the respective level. Measuring ion conductance at an axon with electrodes, for example, establishes properties on a cytological level; whereas measuring reaction times of participants in a behavioural experiment establishes properties on a psychological level. The way in which different epistemic systems — e.g., a functional magnetic resonance imaging (f) scanner and a blood test — applied on the same entity — a human — establish different properties — a local decrease in de-oxygenated hemoglobin versus, for instance, cortisol levels in the bloodstream — on different levels — the level of brain activation versus the level of endocrine activation — shows that levels and properties are intimately connected. Coming back to our example from the beginning, different properties of the mental state compassion are instantiated in several ways: (a.) through a person as an epistemic system directed towards a myriad of dispositional interactions of her own body, which can then (b.) be picked up as values of standardized questionnaires probing those experiences while, finally, (c.) some properties of the underlying mechanism of compassion are instantiated by means of fMRI (cf. Klimecki et al. 2014). What becomes strikingly apparent in this example is that each of these different ways of property instantiation yields properties we would intuitively base on very different levels. Experience of compassion seems to have a very different quality and complexity to the more abstract numerical values of questionnaires or activation patterns visualized by fMRI. Thus, we can say that the specific way a certain property is instantiated already establishes a corresponding level. This way of defin-

ing levels offers a broader range of application than the levels of mechanisms account, since it is not restricted to properties of mechanisms but rather bears on properties in general. After these considerations, we are now in a position to put down the following as a working definition of levels:

Levels =_{Df} (L) Levels are sets of properties established with respect to their instantiation through the same or a similar kind of epistemic system, which targets the same or a similar dispositional profile as compared to different epistemic systems targeting different dispositional profiles.

Considering the identity criteria of epistemic systems, an epistemic system identical to itself might be involved in the instantiation of two properties, that are on the same level qua being picked up by the said epistemic system—for example, a ruler instantiating the length of 1 meter and 20 centimetres. Two epistemic systems are similar if they pick up exactly the same kind of dispositions and exhibit a similar dimension of output value. For example, two rulers picking up the dispositions of a set of tables to instantiate the height of 1 meter and 59.1 inches (1.5 m) or two humans seeing the color blue. Note that the properties might be different in these cases but they are still on the same level, since they are instantiated by the same or similar epistemic system. A ruler and an infrared detector, for instance, are neither identical nor similar epistemic systems, since they differ in the kind of dispositions they pick up and have different dimensions of output values.

Having provided the two missing definitions for an account of emergence, let us now consider how these can be connected to mechanisms and implemented into a new account of mechanistic emergence. What could properties of mechanisms be? According to the definition of mechanisms given in the introduction, we have to identify entities and activities belonging to the mechanism, as well as starting and termination conditions. These might all be established by property-instantiating epistemic sys-

tems. We decompose, measure, and intervene with the phenomena or their realizing components to establish temporal, functional, or organizational properties. Properties of mechanisms on higher levels are instantiated differently to properties of mechanisms on lower levels. We can use one epistemic system to track particular sequences within a mechanism on a specific level in order to be able to recognize stepwise changes as they unfold in temporal order. For properties on higher levels, however, we have to change the kind of epistemic systems involved. We are dealing with different properties on a different level, and we cannot capture the same causal chain as in the single lower-level mechanism. Instead, we capture a synchronously emergent property on a higher level. A formulation of such an account of mechanistic emergence that incorporates the above definitions of “properties” and “levels” could be constructed as follows:

Mechanistic emergence =_{Df} (ME) Mechanistic emergence is a special form of property instantiation, in which the novelty of the properties is established by a change in epistemic systems involved in their instantiation and through which they span a higher level compared to the level of the components, which realize the higher-level properties by means of their mechanistic organization and process dynamics, thereby changing the overall dispositional profile of the whole while, at the same time, being constrained with respect to their individual dispositions in virtue of the synchronous, non-causal constituency relation.

What is new in this account of emergence is that it acknowledges how even emergent properties ultimately arise out of perfectly explainable mechanistic processes. Unpredictability or unexplainability are no longer the defining characteristics of emergent properties themselves, but only characteristics of the *epistemic context* involved in their instantiation. However, these emergent properties are still *novel* in the sense that they are non-causal, non-aggregative

products of mechanisms that come into existence only on a higher level, established through the kind of property instantiation that none of the components show in isolation.

4 Conclusion

In this commentary my aim has been to point out (i.) that defining levels as crucially dependent on properties has a wider and more flexible range of application than using part-whole relationships as the defining criterion; and to put forward (ii.) that levels of mechanisms and levels of emergence can be reconciled into an account of mechanistic emergence in which the property-dependent definition of levels finds application.

My argument was (a.) that descriptive pluralism, by conceiving of levels essentially as metaphors, cannot yield sufficient conceptual clarification concerning the term “level”—namely, what levels actually are and how they exist and, even undermines the goal of preserving the use of the concept in science. Further, I highlighted (b.) that in “levels of mechanisms”, as presented by Carl Craver, the core criterion for a definition of “level” is a part-whole relationship in conjunction with a constitutive relevance constraint, and that this focuses solely on the vertical dimension existing between levels, and completely omits the more important horizontal dimension of the conditions that must apply for a set of entities to be on the same level. As such, the concept is only very weakly and indirectly characterized, offering little toward its clarification and broader application. Finally, I showed (c.) that ontological novelty is not dependent on epistemic intractability, and that the ontological novelty of properties on higher levels of mechanisms is not a banal fact either in levels of mechanisms or in levels of emergence. What emergence expresses at its core is that new properties are coming into existence and that they are so strikingly novel that they might not be predictable at the moment—or seem to not be so, even in principle. They are novel to such a degree that their instantiation coinstantaneously establishes a wholly new level.

As positive proposals for an alternative view, I defined (d.) “properties” as instantiated by epistemic systems capturing specific dispositional profiles of entities, and (e.) “levels” as sets of such properties instantiated by the same or a similar epistemic system, as compared to those properties instantiated by another epistemic system. Furthermore, I (f.) provided a definition of “mechanistic emergence” implementing the core idea of emergence as aforementioned, together with the proposed definitions of “levels” and “properties”.

Concerning future directions for research, it seems most pressing to further develop the notion of an “epistemic system”. Moreover, the notion of “levels” needs to be further refined with regard to how much epistemic systems can or must differ in order for there to be a new level. Ultimately, of course, it will be intriguing to see whether the developed definitions hold in the light of practical implementations in scientific contexts.

To finish, let us come back to the initial question of whether mind and brain, or more precisely mental processes and neurobiological processes, are on the same level, which we are now in a better position to answer. So far as we acknowledge that mental properties and properties of the brain are different properties, and if we also consider how I defined levels above, we can conclude that mind and brain are in fact on different levels in this sense. But are we thus slipping back into dualism? Absolutely not, since the definition of properties developed above makes clear how it comes about that there can be different properties of one and the same thing: it is dependent on the kind of epistemic system in use to capture specific dispositions or, in short, on the *epistemic context*. Taking up our example of compassion once again, it is now obvious why the phenomenon did not seem to be fully captured only by reference to, for instance, physiological properties. Of course it makes sense to investigate the physiological realization of compassion, to measure autonomic parameters, conduct blood tests, or undertake fMRI scans, but it is equally important to conduct behavioural experiments or even interviews with participants to target the phe-

nomenological experience that encompasses compassion (cf. [Singer & Bolz 2013](#)). This only means that we are doing research on all the different properties of the phenomenon of compassion. We are doing research in different disciplines with different methods, on different levels, and we are capturing different properties of one and the same thing—so let’s work together to incrementally integrate those epistemic contexts and get the complete picture.

Acknowledgements

I wish to express my gratitude to two anonymous reviewers, and in particular the editors, for their extensive comments on an earlier version of this commentary, which contributed immensely to its reaching the present form.

Mechanisms and Emergence

A Reply to Denis C. Martin

Carl F. Craver

I respond to some of the major issues in Martin's commentary, particularly (i) his insistence on a robust notion of being "at" a level, and (ii) his desire for mechanistic emergence to explain the genuine ontological novelty of higher level phenomena.

1 Introduction

The goal of my target essay is to articulate and recommend a view about what one is and is not committed to when one asserts that the domain of neuroscience or some other special science spans multiple levels of organization. How useful one finds my specific recommendation—that they be understood as levels of mechanisms—will depend on the uses for which one deploys the level metaphor. Martin raises a number of questions about my unpacking of the metaphor that help to clarify what is at stake in this discussion.

2 The levels metaphor

First, a word about the idea that the term level is used as a metaphor. According to the Oxford English dictionary, the term "level" derives from terms describing the idea of being parallel to the ground. From there, the term could easily extend to the idea that a building can have multiple levels, or landings, from the ground up. Something like this spatial arrangement of stacked landings seems to be the basis for many applications of the level metaphor (in other words, landings are the "secondary subject" of the metaphor). Usage of the term "level" increased dramatically in the 20th Century, and surely some of this increase is explained by the

fecundity of the metaphor for ordering items in a set from the highest to the lowest (under some understandings of “high” and “low”). These are the specific topics (the primary subjects) to which the secondary subject (landings) is compared. In asserting that the term “level” has this metaphoric aspect, I do not intend to thereby disqualify the metaphor from also expressing a set of true or false commitments about the structure of the world. Indeed, I think that the mechanistic application of the metaphor more or less accurately describes the structure of at least many systems in the domains of the special sciences.

My point in being a pluralist about the levels metaphor is simply to emphasize that the metaphor of a horizontal landing is used to describe a wide variety of altogether distinct primary subjects. As a result, any understanding of how this level metaphor works, what it is committed to, and whether it works for a particular purpose, must begin with a clear understanding of how the metaphor is unpacked in the given application. (One cannot, to pick a perfectly clear example, equate the great chain of being and levels of mechanisms.) A second point was to emphasize that there are many legitimate applications of the metaphor, and that the utility of the metaphor might vary from one application to the next. I am not arguing for a single, correct way of understanding the level metaphor. However, I am arguing that one prominent use of the level metaphor in sciences such as neuroscience can be usefully unpacked as describing mechanistic levels.

3 Being “at” a level

Martin is particularly concerned with a) the idea that there should be a clear sense of what it is to be “at” a level, and b) the idea there is some significant sense in which being at a level represents a genuine ontological novelty.

The first of these concerns arises from the fact that the placement question cannot be (or has not been) given a satisfying answer within the mechanistic application of the metaphor. The mechanistic account of levels focuses, as Martin correctly notes, on what it means to be

at *different* levels of organization within a mechanism. Concerning what it means to be “at a level,” one can say only that two things are “at” the same level just in case they are not at different levels; if neither thing is a component entity/activity in the behavior of the other, then the two things are not at different mechanistic levels and, in this weak sense, they are at the same level. This provides a sort of answer to the placement question, but not one that will satisfy those, such as Martin, who hanker after some additional factor (such as size or similarity) that unites the items at a level and that explains why all such items are at that level. I take the failure to answer the placement question as one of the key revisionary consequences of thinking clearly about levels of mechanisms. It is a crucial guide to understanding what’s misleading about the monolithic conception of levels.

One apparent problem for this consequence (the absence of a satisfying answer to the placement question) was first raised by Lindley Darden (personal communication): X’s -ing might be a component in (and so at a lower level than) S’s ψ -ing, *and* yet both X’s -ing and S’s ψ -ing might be at the same level as (i.e., not at a different level than) some altogether distinct P’s β -ing. There is a failure of transitivity. This, it seems to me, is simply a consequence of the idea that the application of the level metaphor to levels of mechanisms breaks down when one is not talking about relations between parts and wholes. This is unproblematic; it is simply an alternative way of expressing the idea that being “at the same level” is of no additional metaphysical significance within the mechanistic application of the metaphor than simply not being at different levels. This does not prevent one, of course, from using some other ordering criterion for this expressive purpose; one might lump things together on the basis of their sizes or perhaps the instruments used to detect them. But one should be aware that at this point one has left the mechanistic application of the metaphor.

Another consequence of the mechanistic view is that one might equally correctly carve the boundaries of mechanisms in any number of

ways (see e.g., Craver 2004, 2009, 2012). If so, there will not be a uniquely correct answer to the question of how many levels a given mechanism has. Our decisions to privilege some grains in the decomposition of a mechanism as an appropriate place to locate a level depends on our techniques, our theoretical background assumptions, our characterization of the phenomenon, our representational tools, and perhaps certain features of human psychology. As Simon argued, these systems are only *nearly* decomposable; how a system is decomposed depends, for example, on the relative strength of intra- versus extra-system causal interactions that one takes to be appropriate for carving the system at its near-joints. This is another reason I am hesitant to pin too much on the idea of being “at” a level.

4 Ontological novelty and emergence

I am not hostile to the second idea (b) that levels of mechanisms exhibit a kind of ontological novelty, depending on how this novelty is understood and how one thinks that it is achieved. I suggest in the target article that a mechanism as a whole can do things that its parts (taken individually) cannot do. Lawnmowers mow grass; spark plugs do not. But I also claim that a mechanism as a whole cannot do things that its organized and interacting parts cannot do. This is because the behavior of a mechanism as a whole just is (or at least is ontologically intimate with) the organized interaction of its component parts. I don’t know how to make the notion of “ontological intimacy” precise here (though the behavior of a mechanism in context will surely supervene on the organized collection of interacting components in that context). In my hands, “ontological intimacy,” is meant to denote an exhaustive ontological grounding of the behavior of a mechanism as a whole in the organized interactions of its components in a given causal context, however that is properly to be unpacked. Everything has an ontic explanation in terms of the organized activities of the mechanism’s parts.

The term emergence strikes me as suspicious, and I hesitate to use it even in the con-

text of levels of mechanisms, precisely because it suggests a severing of this ontological intimacy, a slide from the banal fact that mechanisms behave as they do because they are organized arrangements of interacting parts to the ontologically esoteric thought that something comes into being with causal powers ontologically inexplicable in terms of the organized interactions of the parts. Such claims about ontological novelty are almost always accompanied by claims that emergent things have a “downward” causal influence. I have labored to drive a wedge between levels of mechanisms and such ideas.

This connects with Martin’s description of Thompson’s view. According to Martin, Thompson requires that the parts in a system must be coupled and dynamically interacting to produce emergent properties and, further, that the properties of the whole should act “downward” on the dynamics of the components (2007). Take these in turn.

The idea of levels of mechanisms, by itself, requires only that the parts be organized and interact with one another; it does not require that the components interact non-linearly. Mechanisms with components that interact non-linearly are a subset of mechanisms more generally. It should not make any difference with respect to the novelty of higher-level properties that the parts interact non-linearly. Such dynamical interactions might make the behavior of the whole harder to predict on the basis of our understanding of the parts; but this is an epistemic, not an ontological, observation irrelevant to the ontological question to which I am responding. To be ontologically novel is not merely to be surprising.

Perhaps systems with dynamically interacting components are harder to idealize into separable interacting components; again, this would appear to be an epistemic issue. Thompson, at least in Martin’s description, is drawing a more fine-grained distinction than I draw. This is perhaps a terminological matter. The pressing question between us is whether non-linearity (or perhaps some other form of complexity) makes any ontological difference to the kind of thing that “emerges” from the “organized interactions” of the parts. I’m inclined

to say no, but a full consideration of the issue would require a more detailed treatment than I can give it here.

Thompson also requires that the higher-level phenomenon should have “determinative” influence on things at lower-levels. “Determinative” surely cannot mean the existence of a universally quantified material conditional with the behavior of the mechanism as a whole as the antecedent and the organized interactions among the components as the consequent. Multiple realization precludes such an analysis. But “determinative” also cannot be understood in the causally productive sense in which something (such as charge or momentum) is passed from whole to part. And for reasons expressed in the target article, there are many widely shared assumptions about the independence of causes and effects that stand in the way of understanding such top-down relations in causal terms. This is why I suggest (as in [Craver & Bechtel 2007](#)) that the language of downward causation is misleading in the context of token mechanisms. We recommend that claims about downward causation are really shorthand ways of expressing an often complex web of constitutive (about relations between things at different levels of mechanisms and levels of realization) and causal claims (about things that are not at different levels from one another) about the system. However this is to be cashed out, the term “determinative” seems misleading.

5 Levels and techniques

Finally, I’ll offer a brief remark concerning Martin’s positive suggestion for reifying levels. Martin’s central idea—that we often pick out things as being on a level because they are detectable with the same or a similar kind of apparatus or with the same or a similar set of procedures—seems to me correct and important. Among the many possible ways of decomposing a spatio-temporal whole into component parts, some of these correspond to items that for one reason or another are readily detectable as such by one or more experimental apparatus. This way of putting things highlights how pragmatic factors, such as available apparatus, determine what we

will take to be an appropriate “landing” in a hierarchy of levels. And it raises useful questions about, for example, when two different apparatus, or two different tasks, or two different procedures in fact target the same items, or items at the same level. On a fine-grained characterization of our experimental instruments, no two experiments are the same. On a coarse grain, even superficially quite distinct experiments can be targeting the same phenomenon (consider, e.g., implicit bias or spatial memory). As noted above, it seems to me that many other epistemic, theoretical, and psychological factors enter into these decisions as well.

This good point, however, is obscured by an ontology in which properties apparently come into existence during acts of detection. Martin’s view is that objects have disposition profiles, and these profiles are turned into properties when they are measured. It is unclear to me, however, why one would not want to say that properties are there to be detected all along, or perhaps that properties just are the dispositional profiles of things. Martin doesn’t do much to motivate this experimental idealism about properties, but the thought seems hard to motivate, at least for macroscopic phenomena. It is an apparent consequence of Martin’s account that levels don’t exist until they are detected. And it is an apparent consequence of his view that new levels come into existence when we develop new instruments to detect them. And, to reiterate the thought in the last paragraph, we will have to wrestle with the question of when two techniques detect the same thing or different things. Martin’s positive proposal makes this question much more pressing, given that, for Martin’s view, the structure of the world—specifically, the distribution of properties in space and time—apparently hangs in the balance. But if we abandon the idea that the placement question must have a uniquely correct answer, these questions are less pressing for thinking about ontology; nonetheless, questions about how we coordinate different experimental tasks, protocols, and procedures are at the heart of the epistemological challenge faced by any experimentalist (see [Sullivan 2009, 2010](#)).

Mental States as Emergent Properties

From Walking to Consciousness

Holk Cruse & Malte Schilling

In this article we propose a bottom-up approach to higher-level mental states, such as emotions, attention, intention, volition, or consciousness. The idea behind this bottom-up approach is that higher-level properties may arise as emergent properties, i.e., occur without requiring explicit implementation of the phenomenon under examination. Using a neural architecture that shows the abilities of autonomous agents, we want to come up with quantitative hypotheses concerning cognitive mechanisms, i.e., to come up with testable predictions concerning the underlying structure and functioning of an autonomous system that can be tested in a robot-control system.

We do not want to build an artificial system that is, for example, conscious in the first place. On the contrary, we want to construct a system able to control behavior. Only then will this system be used as a tool to test to what extent descriptions of mental phenomena used in psychology or philosophy of mind may be applied to such an artificial system. Originally these phenomena are necessarily defined using verbal formulations that allow for interpreting them differently. A functional definition, in contrast, does not suffer from being ambiguous, because it can be expressed explicitly using mathematical formulations that can be tested, for example, in a quantitative simulation. It is important to note that we are not concerned with the “hard” problem of consciousness, i.e., the subjective aspect of mental phenomena. This approach is possible because, adopting a monist view, we assume that we can circumvent the “hard” problem without losing information concerning the possible function of these phenomena. In other words, we assume that phenomenality is an inherent property of both access consciousness and metacognition (or reflexive consciousness). Following these arguments, we claim that our network does not only show emergent properties on the reactive level; it also shows that mental states, such as emotions, attention, intention, volition, or consciousness can be observed, too. Concerning consciousness, we argue that properties assumed to partially constitute access consciousness are present in our network, including the property of global availability, which means that elements of the procedural memory can be addressed even if they do not belong to the current context. Further expansions are discussed that may allow for the recognition of properties attributed to metacognition or reflexive consciousness.

1 Introduction

In this article we propose a bottom-up approach to higher-level mental states, such as, for example, consciousness. In contrast to most related approaches, we do not take consciousness as our point of departure, but rather aim,

firstly, to construct a system that has basic properties of a reactive system. In a second step, this system will be expanded and will gain cognitive properties in the sense of being able to plan ahead. Only after this work is finished, we

ask to what extent this system is equipped with higher-level properties as for example emotions or consciousness. While other approaches would require an exact definition of, for example, consciousness, in our case we do not have to start from a clear-cut definition and try to fit it into a model. We follow this alternative route because there are no generally accepted definitions concerning these higher-level phenomena. In this way we hope to identify the essential elements required to instantiate, for example, consciousness.

Figure 1: Arrangement of the leg-controllers (boxes: FL front left, ML middle left, HL hind left, FR front right, MR middle right, HL hind right) of the hexapod walker. The arrows show coordinating influences (1–4) that act between neighbouring leg-controllers.

The idea behind this approach is that higher-level properties may arise as emergent properties, i.e., may occur without requiring explicit implementation of the phenomenon under examination but instead arise from the cooperation of lower-level elements. Some authors distinguish between “strong” emergence and “weak” emergence (e.g., Laughlin & Pines 2000). Strong emergence means that there is principally no way to explain the emergent property by known properties of the elements of the system and their coupling. Here we are dealing with weak emergence. In this case, a property recognized when looking at the whole system can at first glance not be traced back

(or perhaps only partially) to known properties of the elements and their couplings. Often, auxiliary assumptions are made to explain this property as a global property, i.e., as a property ascribed to the system as a whole. A more detailed inspection may, however, show that such auxiliary assumptions are not required. Instead, the emergent property follows from the properties of the elements and the specific ways in which they causally interact. This insight allows for an understanding of an emergent property in the sense that this property can be predicted, although we may not understand why it arises, and that one is able to construct a new system showing this property.

Following this approach, one crucial decision to be made at the beginning concerns the granularity of the lower-level elements. In our approach, we start from a behavioral perspective and focus on the nervous system as central to the control of action. Therefore, we use neuronal units as the basic elements for our modeling and for the analysis. Specifically, we use artificial neural network units with analogue activation values and dynamic (low-pass filter) properties¹. That is, our neural elements are qualitatively comparable with non-spiking neurons. Although there are arguments that consciousness, in order to arise, might require synchronously oscillating spikes (Singer & Gray 1995), we claim that the level applied here is general enough to allow for an understanding of such mental processes. As a side effect, this level of abstraction covers different evolutionary groups, such as those represented by insects and mammals, for example. Though much of our discussion, below, focuses on the example of insects, we do not want to argue that insects have all the higher-level properties addressed later in this article, but only that they share the same fundamental functions used in motor control and have, on that level, a comparable structure.

Using these simple neural elements, we start by implementing very basic faculties that include the ability to move one’s own (non-

¹ A low-pass filter is qualitatively characterized by an increase of output activation that, when excited by a constant stimulus, asymptotically approaches a given output value.

trivial²⁾ body, and allow for orientation and navigation in an only partially known environment. To this end we use a body with six, insect-like legs. This means that we deal with at least eighteen active degrees of freedom (DoF) and not two—as is the case for many robots that are restricted to moving around on a two-dimensional plane. This means that the controller has to deal with a large number of redundant DoFs. To control the behavior of the robot we use a reactive and embodied neuronal controller, as it is available from earlier work on insect behavior (Schilling et al. 2013a). Later, a minor expansion of the network will allow for cognitive faculties.

on the walking behavior of stick insects (Dürr et al. 2004; Bläsing 2006; Schilling et al. 2013b). As will be explained in section 2, Walknet was set up as a system for controlling the walking behavior of a six-legged system in an unpredictable environment, e.g., on cluttered terrain or climbing over large gaps—which, when performed in a realistic, natural environment is a non-trivial task. Already on this level we can observe emergent properties. The number of legs on the ground differs depending on the velocity of the walker (for slower walking more legs are on the ground). As a consequence the phase relations between different legs differ depending on the velocity of the walker. Importantly, the resulting stepping patterns (“gaits”) are not explicitly encoded in the control network, but are a result of the interaction of the control network with the environment as mediated through the body (1st order embodiment Metzinger 2014). In a further step, the reactive

Cruse, H. & Schilling, M. (2015). Mental States as Emergent Properties - From Walking to Consciousness. In T. Metzinger & J. M. Windt (Eds). *Open MIND*: 9(C). Frankfurt am Main: MIND Group. doi: [10.15502/9783958570436](https://doi.org/10.15502/9783958570436)

controller is expanded to be able to deal with navigation tasks. This additional network, called “Navinet”, is able to simulate a number of experimental results observed in desert ants and honeybees, such as the capability of finding food sources using path integration and orientation with respect to visual landmarks.

Both networks are characterized by their decentralized nature. These networks consist of procedural, (reactive) elements, namely small neural networks that in general connect sensory input with motor output, thereby forming the procedural memory. Inspired by (Maes 1991), these procedural elements are coupled via a “motivation unit network”, a recurrent neural network (RNN) that forms the backbone of the complete system. This type of architecture has been termed MUBCA (for Motivation Unit Based Columnar Architecture (MUBCA), Schilling et al. 2013b). The motivation unit network allows for selection of different behaviors by adopting different attractor states, where each attractor represents a group of motivation units being activated, which in turn control the procedural elements. As the different groups do in part overlap, albeit in different ways, the network allows for the representation of a heterarchical structure (e.g., see left upper part of figure 2).

As a next “evolutionary” step, this reactive network will be expanded to be able to embrace cognitive properties (sects. 3 and 6). The notion of cognition is often used in a broad and sometimes unspecific way. In the following we will rely on the definition given by McFarland & Bösner (1993) who assume that *a cognitive system is characterized by the capability of planning ahead*. We prefer this clear-cut definition of cognition compared to many others found in the literature, as the latter are generally quite weak (in extreme cases cognitive properties are even attributed to bacteria, which, in our view, would make the term cognition meaningless). While such a specific definition might seem too narrow, in our understanding it captures the essence of cognition. Focusing on planning ahead being realized by mental simulation (Hesslow 2002) allows extending this notion of cognition to easily include other high-level phenomena,

while still relying on the same internal mechanism. Therefore, in this article, apart from section 10.3 (Metacognition) we will use the term cognition in the strict sense as proposed by McFarland & Bösner (1993).

Being able to plan ahead implies the capability of being able to internally simulate behavior, which basically means to be able to simulate movements of one’s own body within a given environment. This faculty requires, as a first step, the availability of a flexible, “manipulable” internal body-model. Planning ahead is interesting in a situation where the actually carried out reactive behavior cannot reach the currently pending goal. Therefore, a further expansion is required that allows for the invention of new behaviors. Together with the faculty of planning ahead, the system can then test newly-invented behaviors by applying internal simulation (“internal trial-and-error”) in order to find a solution for novel problems for which no solution is currently known to the system.³

This system, called “reaCog”, represents a basic version of a cognitive system in the strict sense intended by McFarland & Bösner (1993). As such, cognitive expansion does not function by itself, but only, like a parasite, on top of the reactive structures—a view that has been supported for a long time (Norman & Shallice 1986). The cognitive system depends on its reactive basis (therefore it is called reaCog). Therefore, the evolution of cognitive abilities crucially requires a correspondingly rich (procedural) memory.

In order to increase the richness of the memory of the complete system, in section 5 we introduce perceptual memory and complete the system by implementing “Word-nets”, a specific form of procedural and perceptual memory. In this way, the whole system is equipped with aspects of semantic memory, and can be claimed to represent a minimal cognitive system. We do not deal with learning but only discuss the properties of the finished network. The learning

³ Note that the term simulation is used here in two different ways. “Internal simulation” enables the agent to simulate behaviors internally, i.e. without actually performing them in reality. Simulation of an animal addresses the construction of an artificial agent. The agent may take the form of a software simulation or a hardware simulation (i.e., a physical robot).

of some aspects has, however, been treated earlier (Hoinville et al. 2012; Cruse & Schilling 2010a).

After having introduced reaCog in sections 2–6, we will, in sections 7–11, discuss how more abstract functions, such as those described in, e.g., psychology, can be based on such a simply-structured network.

A fundamental problem when aiming for an understanding of phenomena like emotions or consciousness concerns the phenomenal aspect. The phenomenal aspect, often characterized as the hard problem (Chalmers 1997), refers to the strange, unexplainable phenomenon that physical systems, in our case represented by specific dynamics of neuronal structures, can be accompanied by subjective experience. Basic examples are experiencing pain, a color, or the internal state of an emotion (e.g., joy, fear). In section 7 we discuss this aspect in some detail and postulate that phenomenality is an emergent property. As mentioned, we are not aiming to solve the “hard” problem (Chalmers 1997), but we argue that it is sufficient to concentrate on the functional aspect.

In particular, we focus on the phenomena of emotions and consciousness. According to a number of authors (e.g., Valdez & Mehrabian 1994), these are assumed to be an inherent property for some cognitive systems. Therefore, although we do not want to state that emotions (section 8), attention, volition, intention (section 9), and consciousness (section 10) should necessarily be attributed to our system in any sense, we want to discuss to what extent properties characterized by different levels of description can be observed in our model.

Considering emotions, these are defined on different levels in the literature, so that there is no clear, generally accepted distinction between concepts like emotions, moods, motivations, drives, etc., which appear to form a continuum of overlapping, not clearly separable concepts (Pérez et al. 2012). Focusing on selected examples, in section 8 we will show how these phenomena may be attributed to our system, for example by referring to basic emotions as proposed by Ekman (1999).

Concerning consciousness, as discussed by Cleeremans (2005), this phenomenon should be approached by differentiating different aspects and treating those aspects separately. To this end, following Block (1995, 2001), Cleeremans (2005), introduces a distinction between access consciousness, metacognition, and phenomenal consciousness. In sections 10.1 (access consciousness) and 10.3 (metacognition) we will focus on whether and how the presented model can be related to the different aspects that are described by Cleeremans (2005), such as access consciousness and metacognition. From our point of view the simple control structure presented does fulfill some aspects of both access consciousness and metacognition. We shall finish with discussion and conclusion in sects. 11, 12.⁴

2 Walknet

ReaCog is an expansion of a control system that has been realized as a neural network. The underlying system has been termed Walknet. Walknet is biologically inspired and is supposed to describe the results of many behavioral studies on the walking behavior of stick insects (Dürr et al. 2004; Schilling et al. 2013b). We will briefly sketch the properties of the network as far as is required for understanding the basic abilities considered here.

Overall, the controller has to deal with the difficult task of coordinating multiple degrees of freedom; in the case of the hexapod walker the body consists of twenty-two DoF. There are three DoF for each of the six legs and an additional four DoF are present in between the body segments. The system is redundant, as only six DoFs are needed to define a position and orientation in three-dimensional space. The controller therefore has to deal with sixteen extra DoFs. The architecture of the Walknet controller is decentral. Each leg has an individual and more or less independent controller that decides which action to choose (two such leg-controllers are shown in figure 2, the black boxes in the lower part). A single leg

⁴ This article comprises an essential extension of an earlier paper (Cruse & Schilling 2013).

controller consists of several procedures. In the figure, each procedure is represented as a single black box. In the basic system, the two important behaviors a leg can perform are the swing and stance movement. The procedures themselves are realized as artificial RNN. Examples are the two basic procedures: the “Swing-net”, which controls the swing movement, and the “Stance-net”, which controls the stance movement of the leg. Only two of the six leg-controllers are shown. These networks constitute the procedural memory of the system. The procedural modules receive direct sensory input and provide motor control commands as an output. But there are also modules that provide input to another module. The controller on the leg level determines which procedure should be activated at any given time, depending on the current state of the leg (swing or stance), as well as on sensory inputs (ground contact, position). In addition, controllers of neighboring legs can influence each other through a small number of connections between those controllers. These influences are explicitly derived from experiments on the coordination of legs in walking experiments on the stick insect.

As was found in the insects, during the swing movement (protraction) the legs aim towards a position at the front, close to the position of the anterior leg. Therefore, each leg possesses a so-called “target net” in order to produce these targeted movements. During forward walking the so-called “Target_fw-net” is responsible for this targeting. During backward walking “Target_bw-net” is used. Both directly influence the Swing-net. Procedures marked as blue boxes (“body model”, “leg model”) will be explained below (section 3.1).

ReaCog is expanded by an RNN, which consists of motivation units (figure 2, marked in red). This network allows the system to autonomously select one of the different possible behaviors. For example, the system may choose between forward or backward walking, or standing. A motivation unit is an artificial neuron with linear summation input and piecewise linear activation function, showing output values from zero to one. Applied to a

procedure, for example Swing-net, a motivation unit determines the strength of the output of the corresponding procedural network (in a multiplicative way). As mentioned above, motivation units form a recurrent neural network and can influence each other through excitatory or inhibitory connections (as shown in figure 2).

In addition, there are sensory units that are part of this RNN and that can directly influence the motivation units’ activation, e.g., as shown in figure 2 for the “lower-level” units for Swing and Stance. There, an active ground-contact sensor of a leg reinforces the stance motivation unit for this leg. As the motivation unit network can be arbitrarily expanded, it allows to control of complex behaviors. To illustrate a small group of behaviors only, units as “walk”, “fw” (forward), “bw” (backward), “leg1” are depicted (for more examples see Schilling et al. 2013b; Cruse & Wehner 2011).

The network of motivation and sensory units does not have to form a simple, tree-like structure (see figure 2). It can constitute a heterarchy. Motivation units can be bi-directionally connected through positive (arrow-heads) and negative (T-shaped heads) connections. As shown in the figure, this can lead to cycles. There are also different overlapping subnetworks, e.g., the “leg” units as well as the motivation unit for “walk” are active during backward and forward walking. But only one unit indicating the direction of walking can be active at any given time, i.e. either the unit “fw” or “bw” can be active. As a consequence, there are multiple stable attractor states formed through the combinations of excitatory and inhibitory connections. The stable “internal states” stabilize the behavior of the overall control system, as the system cannot be easily disturbed solely through inappropriate sensory inputs. For example, sensory inputs are treated differently depending on the current state (swing or stance) of the control system, and these internal states can be differentiated on a higher-level, e.g., into walking, standing, or feeding (for details see Schilling et al. 2013a; Schilling et al. 2013b).

Figure 3: Step pattern arising from the decentralized leg-controllers connected by local rules and the environment. Abscissa is time; black bars indicate swing movement; the gaps represent stance movement of this leg (from top to bottom: front left leg (FL), middle left leg (ML), hind left leg (HL), correspondingly front right leg (FR), middle right leg (MR) and hind right leg (HR) for the right side). The lower bars indicate 500 iterations corresponding to 5s real time. These “foot-fall patterns” show various locally or globally stable patterns depending on walking velocity (a: slow, b: fast) and of starting position. In (a) the legs start with an “uncomfortable” leg configuration leading to a gallop-like pattern (indicated by the vertical ellipses) that after about six steps changes to the globally stable pattern, typical for slow insect walking (see inclined ellipses, step # 8). (b) shows fast walking leading to a tripod gait characterized by synchronous swing movements of ML, FR, HR and FL, HL, MR (see vertical ellipses).

For an RNN, maintaining a stable state is a non-trivial problem, in particular, when there are various disturbances. To illustrate the adaptability and at the same time the stability of the behavior controlled by such a motivation unit network, in figure 3 we show two cases of hexapod walking. Figure 3a shows an example of a slow walking speed where the legs begin from a difficult starting configuration (both front legs, both middle legs and both hind legs start from the same position, which is opposite to the coordination found in normal walking,

where opposite legs alternate). Nonetheless, the agent is able to walk. After some steps, the agent reaches a temporally stable pattern corresponding to normal walking. Figure 3b shows a step pattern corresponding to high-speed walking, often termed “tripod gait”. Although usually considered to be a regular pattern, detailed inspection shows that there are local temporal variations, but the overall pattern remains stable (for videos of further walking examples see Schilling et al. 2013b). It is important to note that none of these step-patterns are explicitly implemented, but arise as emergent properties (for details see Schilling et al. 2013a). As another impressive emergent property, Bläsing (2006) showed that, with some minor extensions, this walker is able to climb over large obstacles (which can be more than twice the normal step-width).

3 Internal representation

In addition to using the loop through the environment itself, some form of internalization is a prerequisite for any kind of planning. Therefore, specific internal representations⁵ are necessary for a cognitive system. This is well in line with the embodied perspective, because from an evolutionary point of view internal models are not at first disconnectable from a very specific function, and they work in service of a specific behavior (Glenberg 1997). Internal models have, in this sense, co-evolved with behavior (Steels 2003). An early representation is the representation of one’s own body, and such a representation becomes meaningful early on, in simple control tasks like targeted movements or sensor fusion.

3.1 Body model

In reaCog we introduced an internal model of the body. This model is realized as an RNN (Schilling 2011) and has a modular structure (Schilling & Cruse 2007; Schilling et al. 2012). The overall model consists of two different

⁵ The term representation is used here in the broad sense of Steels (1995) “physical structures (for example electro-chemical states) which have correlations with aspects of the environment”.

levels. On the top level the whole body and the structure of the insect are represented in an abstract way. Only on the lower level are the details filled in. The lower level consists of six leg networks. Here, for each leg the functional structure of the joints and the limb is captured. In this way this level of representation can be used for motor control and provides detailed information about joint movements. On the higher level, the structure of the body and the legs is represented in an abstract form, i.e., only the footholds of the legs appear on this level. Figure 2 shows the different parts of the body model (drawn in blue). The body model is modular. It comprises a holistic system that is realized as an RNN (figure 5, see Schilling 2011; Schilling et al. 2012 for details).

The body model is used during normal walking, meaning that the system is still in the reactive mode, in forward as well as backward walking or when negotiating curves. It coordinates the movement of the joints and delivers the appropriate control signals for the Stance-networks. As explained above, overall the system is redundant, with twenty-two DoFs in the whole body structure, and this makes deriving consistent control signals for all the joints a difficult problem that can't be computed directly, but rather requires application of additional criteria (e.g., for optimizing energy consumption). In our approach, which uses the internal body model, we employ the passive motion paradigm (von Kleist 1810; Mussa-Ivaldi et al. 1988; Loeb 2001). Consider the body model as a simulated puppet of the body (figure 5) that is pulled by its head in the direction of the goal (figure 5b, pull_fw). This information on the target direction could be provided by sensory input, e.g., from the antennae or vision, in the form of a target vector (figure 2, sensory input). When pulled in this direction, the whole model should take up this movement and therefore the individual legs currently in stance should follow the movement in an appropriate way. The induced changes in the joints can be read out and applied as motor commands in order to control the real joints. In backward or curved walking, the body model has only to be pulled into a corresponding direction (in backward walking

using the vector attached to the back of the body model, pull_bw (figure 5b). In this way we obtain an easy solution to the inverse kinematic problem as the body-model represents the kinematical constraints of the body of the walker. It restrains the possible movements of the individual joints through these constraints, and only allows possible solutions for the legs standing on the ground, thereby providing coordinated movements in all the involved joints.

The body-model is also connected to the sensors of the walking system and integrates the incoming sensory information into the currently-assumed state of the body as represented in the body-model. In this way the body-model is able to correct noisy or incorrect sensory data (Schilling & Cruse 2012). Overall, the main task of the body model is pattern completion. It uses the current state and incoming sensory data to come up with the most likely state of the body that fulfils the encoded kinematic constraints. In this way, the model can also be used as a forward-model, meaning that, given specific joint configuration, the model can predict the three-dimensional arrangement of the body, for example the position of the leg tips. The predictive nature of the model is crucial as it allows exploiting the model for planning ahead (see below). It is important to note that while we do not want to claim the existence of such a model in insects, the functions of internal models are prediction, inverse function, and sensor fusion, and these can all already be found in insects.

3.2 Representation of the environment

Of course, internal representation should also contain information on the surroundings. We started with a focus on the body and want to extend this network in a way that reflects how the environment affords (Gibson 1979) itself to the body, i.e., a focus on interaction with the environment.

As an example of how the reaCog architecture could be extended to include representation of meaningful parts of the environment, we want to briefly sketch an expansion of Walknet that would allow for insect-like navigation ("Navinet" Cruse & Wehner 2011; Hoinville et

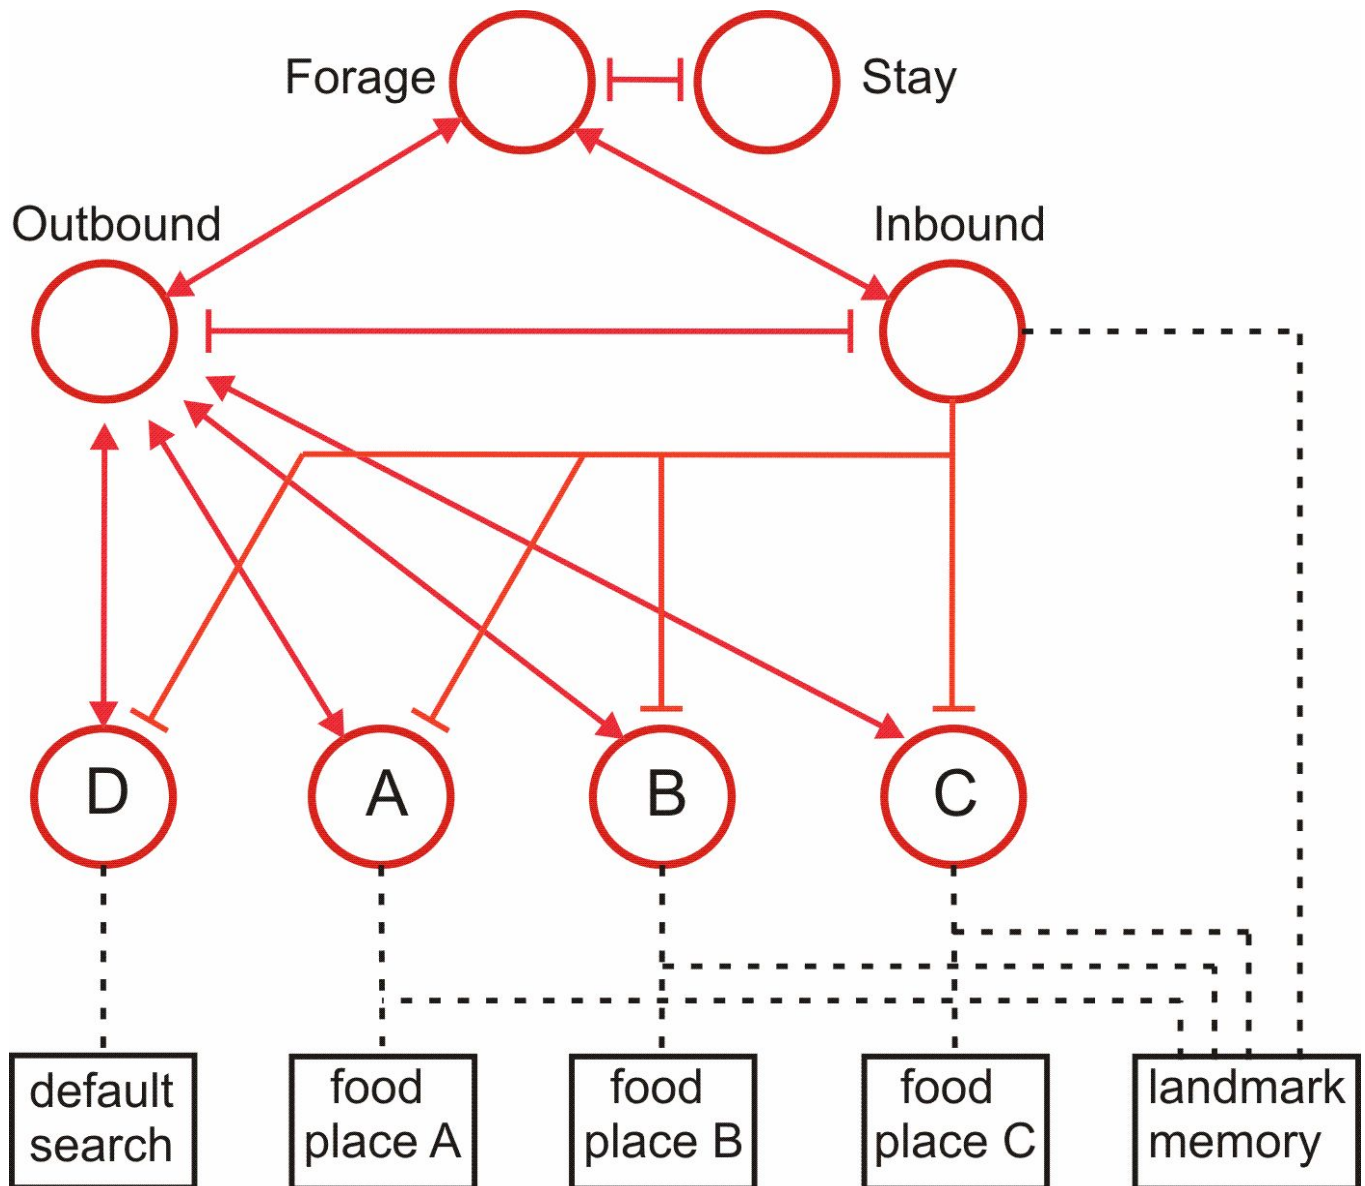

Figure 4: Motivation unit network of Navinet for the control of ant-like navigation. Unit Outbound controls travel from the home to a food source (A, B, C) or a default search for a new source (D). Unit Inbound controls travel back to the home. Memory elements (black boxes) contain position and quality of the food source (A, B, C) or information on visual landmarks (landmark memory).

al. 2012). Navinet provides an output that will be used by the body-model explained above to guide walking direction. Due to the network, the agent can make an informed decision about which learned food source she will visit (e.g., sources A, B or C), or if she is travelling back home or not (Outbound, Inbound, respectively). The output of Navinet is, in this way, on the one hand tightly coupled to the control of walking and the representation of the body. On the other hand, Navinet is constructed using motivation units in the same way as the walking con-

troller, and those motivation units take part in the action-selection process. Importantly, Navinet (like desert ants) shows the capability of selective attention, since it is context dependent and only responds to learned visual landmarks in the appropriate context, i.e., when related to the current active target food source. The structure of the motivation-unit network is sketched in figure 4. Examples of possible stable internal states are (Forage – Outbound – source A – landmarks associated with source A) or (Inbound – landmarks associated with Inbound),

for instance. As an interesting emergent property, Navinet does not presuppose an explicit “cognitive map”. Such a map-like representation has been assumed necessary by several other authors (Cruse & Wehner 2011). How learning of food source positions and food quality is possible has been shown by Hoinville et al. (2012).

4 Planning ahead, cognition

Even though Walknet is set up as a fixed structure consisting of hard-wired connections of the RNN, it can flexibly adapt to disturbances in the environment as needed during, for instance, crossing large gaps (Bläsing 2006). Nonetheless, the system might of course run into novel situations that require an even higher degree of adaption, and as such will require novel behaviors. As an example, think of a situation in which all the legs except the right hind leg are in the anterior part of the working range. When the right hind leg is forced to lift from the ground as it approaches a position very far to the rear, the whole system will become unstable, as the center of gravity is positioned very far towards the rear of the animal. In this case, the center of gravity would not be supported by the other legs, nor by the right hind leg that tries to start a swing movement. As a consequence, the agent would fall over, backwards. This problem could be detected by “problem detectors”, e.g., specific sensory input that reacts to the specific load distribution (a different solution is explained in section 8). In order to overcome this problem, the system would have to break out of its usual pattern of behavioral selection and try to select a different behavioral module that is usually not applicable in the given context. For instance, making a step backward with the right middle leg would be a possible solution, as this would provide support for the body and would afterwards allow going back to the normal walking behavior and the subsequent swing movement of the right hind leg. Usually, backward steps can only be selected in the context of backward walking.

Figure 6 shows an expansion that allows the system to search for solutions that are not connected to the current context. This expansion

is termed the “attention controller”. We introduce a third layer of units (figure 6, in green), that is essentially a recurrent winner-take-all network (WTA-net). For each motivation unit there is a corresponding partner unit in this WTA-network. Currently-active motivation units suppress their winner-take-all (WTA) partner units (T-shaped connections in figure 6). Therefore, a random activation of this WTA-net will lead to the activation of one single unit not belonging to the currently-activated context. The random activation will be induced by another parallel layer, the “Spreading Activation Layer” (not depicted in figure 6, further details are described in (Schilling & Cruse submitted)). The winning unit of the WTA layer then activates its corresponding motivation unit. This triggers the connected behavior that can be tested as a solution to the problem at hand. The network follows a trial-and-error strategy as observed in, e.g., insects.

As has been proposed (Schilling & Cruse 2008), a further expansion of the system that is, most probably, not given in insects is not the testing of a behavior in reality, but instead the application of a newly-selected behavior on the body-model and the use of the model instead of the real body. The motor output is routed to the body-model instead of to the real body, and the real body is decoupled from the control system while testing new behaviors. Due to the predictive nature of the body-model, it can be used to predict possible consequences and to afterwards decide if a behavior solves the current problem and should be tried out on the real body. This procedure is called internal simulation and requires the introduction of switches that reroute motor output signals from the real body to the body model (figure 6, switch SW). Only after a successful internal simulation will the behavior be applied to the real body. McFarland & Bösner (1993) defined a cognitive system as a system that has the ability of planning ahead, i.e., that is able to perform internal simulations in order to predict possible outcomes of behaviors. Therefore, this latter expansion would make the control system cognitive (for details see Cruse & Schilling 2010b).

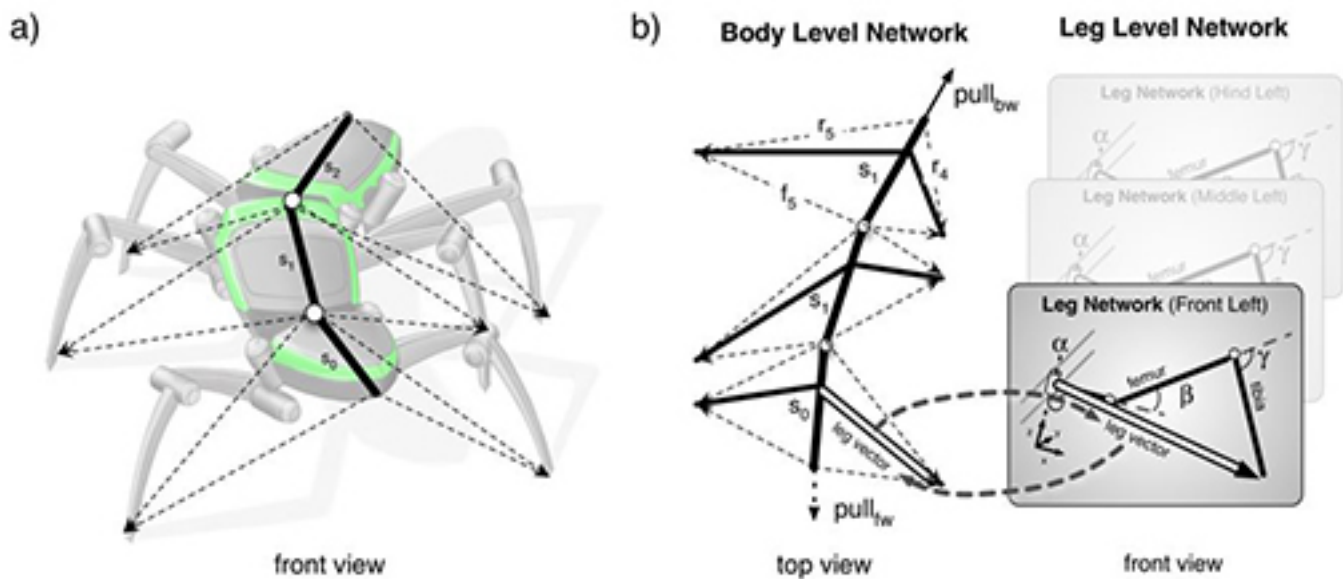

Figure 5: The body-model and its relation to the body of robot Hector (a). (b) shows the vectors forming the central body (left) and the vectors forming one leg model (right). The central model and the leg-models are connected via the shared “leg vector” (white arrows) that point from the hip to the tip of the leg (shown here for the left front leg only). Walking direction and velocity are controlled by the input vectors pull_fw (forward) or pull_bw (backward) provided by sensory input.

5 Word-net and perceptual memory

In our network, we have up to this point only dealt with procedural memories, i.e., memories representing the connections between specific sensorimotor elements that are able to control specific behaviors (e.g., Swingnet, landmark). As a final extension, we will now show how the network might also be equipped with some aspect of semantic memory, such that meaning can be attributed to verbal expressions. To this end, the network can be expanded through the introduction of another layer (not shown in figure 6). In this fourth layer, verbal expressions are stored as procedures or “Word-nets”. These procedures can either be used to pronounce a stored word or to comprehend it, i.e., they can be used for motor control and for auditory perception. As is the case for other procedures, each Word-net is equipped with a motivation unit. As the motivation units of Word-nets have a specific function, for an easier distinction we will call them word units (WU). Following Steels (2007; Steels & Belpaeme 2005) each Word-net is related to a corresponding unit of the motivation network that carries meaning

(e.g., the motivation unit for walking is connected to a Word-net “walk”). The meaning of the Word-nets is in this way grounded in the behaviors of the corresponding motivation units. As an example, figure 7 shows a possible detail of such a network, including some elements of Walknet and Navinet. The motivation units of a procedure (e.g., Swing net) and its corresponding Word-net (e.g., “Swing”) are coupled via bi-directional connections (dashed double-headed arrows). The connections cannot be active at the same time, but depend on an overall state of the network, termed “Report” and “Perceive”. In the Perceive state, only connections from the word unit to the motivation unit of its non-word procedure can be activated (from top to bottom in figure 7), whereas in the Report state only the opposite connections can be activated. As can be seen in figure 7, Word-nets can not only be connected with motivation units of the sensorimotor nets, but also with motivation units that do not directly control a sensorimotor element (e.g., Walk, Outbound).

What might be the function of this extension by Word-nets? In the Perceive state (or react state), a perceived word, uttered by another

agent, will activate, via its word unit, its partner's motivation unit, and thereby possibly influence behavior (depending on the actual internal state of the system and on the strength of the word input). When in the Report state, the actually active motivation units will in turn activate their corresponding word units, which may lead to an uttering of a word. As, of course, only one word can be activated at a given time, some kind of decision network (e.g., a WTA net) is required, though, for reasons of simplicity, not shown in figure 7. In any case, introduction of Word-nets allows for a very basic form of communication between the agent and any other partner, communication being limited to "one-word sentences".

As indicated on the left side of figure 7 (units "front", "left"), further motivation units might be introduced into the network that do not have a direct function within, in this case, the Walknet controller. Of course, these units may be connected to word units. (Note that we do not deal with the question how these units may be connected within the network through training).

This architecture combines sensorimotor procedures with Word-nets (which by themselves represent specific sensorimotor procedures). Together, they form a simple case of semantic memory, because procedural memory representing an action (e.g., Swing-net) is connected with a memory element representing verbal symbols.

To illustrate the versatility of this architecture, we will briefly address how it can also be applied in order to embrace perceptual memory. Following ideas of O'Connor et al. (2009), Cruse & Schilling (2010a) have shown how an RNN, using the same elements as applied here for the motivation unit network, could be used to construct a perceptual memory. This network does not only allow the representation of directly perceived perceptual elements (e.g., the colour or shape of an object), but also of superordinate concepts (e.g., Cow, Animal, four-legged). Note that "four-legged" might also be a feature of non-animals, e.g., a table. Therefore, the ability of our network to deal with heterarchical structures is advantage-

ous for perceptual memory, too. Elements of such a distributed memory can also be connected to specific Word-nets (e.g., "red", "Cow", "animal"), as has been explained above for the sensorimotor motivation units. Correspondingly, activation of one memory element of this perceptual memory may elicit the uttering of the corresponding word, and, in turn, when in Perceive mode, the hearing of a word may activate various elements of the procedural memory that are associated with this word.

6 ReaCog: Emergent properties characterized by applying other levels of description

To summarise, the neural controller Walknet, (for details see Dürr et al. 2004; Schilling et al. 2013a) is an embodied control system (first-order embodiment, cf. Metzinger (2006, 2014)). The reactive system can deal with varying unpredictable environments. It relies only on information that is available to the given mechanosensors, which is possible because both body and environment are integral to the overall computational system. In this way, the system is embodied. Of course, the system has a physical body, but even more, being embodied means that properties of the body (like its geometry) are exploited in computations of the controller. Using its own body as part of a loop through the world allows for dramatically simplifying computations (Schmitz et al. 2008). These properties are of course also present in the expanded version, reaCog. Even though in reaCog an internal body-model is introduced in order to control the high number of DoFs, reaCog still relies heavily on the cooperation of individual parts, i.e., the combination of couplings between body, environment, the internal body model, and the controller itself. In addition, this internal model of its own body is used for planning ahead. Such a network, following Metzinger (2006, 2014) represents a system that is characterized by second-order embodiment.

As shown in figure 2, the procedures forming the decentralized controller are basically arranged in parallel, i.e., each procedure obtains its own sensory input and provides a specific

Figure 6: The controller of the reactive system as depicted in figure 2 expanded by a WTA-net (green units, not all connections are shown). Each WTA unit shows a bi-directional connection to a unit of the motivation unit network. This architecture provides the basis of reaCog, as explained in the main text. (for further explanations see figure 2).

motor output. But procedures can also receive input from other procedures and can provide output directly to other procedures. This relatively flat, heterarchical structure is also applied by the Word-nets and in perceptual memory (Cruse & Schilling 2010a).

ReaCog automatically selects actions on the lower reactive level. Several of these procedures can be performed in parallel. On the cognitive level, decisions about which action to choose are not based solely on sensory input, but are chosen depending on the imagined action, since there is a stochastic effect due to noise in the attention controller. The decision is afterwards tested by internal simulation before it is applied to the real system, and only after successful execution is the proposed behavior stored in long-term memory. Therefore, this decision process can be envisioned as a Darwinian type of selection that begins from stochastic

“mutations” that are then tested for “fitness” and selected based on this fitness. Thus, reaCog is a minimally cognitive system in the sense of the definition given by McFarland & Bösner (1993).

After we have defined the control network quantitatively, we can use reaCog to analyze emergent properties, which haven’t been implemented explicitly. As an example we have already considered a term like “tripod gait” that is sensible on a behavioral level in order to describe the emergent overall behavior of the walker. But on the control level there is no explicit tripod gait controller in reaCog (Schilling et al. 2008; Schilling et al. 2013a). The local influences coupling neighboring legs are responsible for overall coordinated walking behavior (different from many other hexapod controllers), and different gaits can emerge just by choosing different velocities. Therefore, appar-

ent “gaits” or the observation that “cognitive maps” are required can be seen an emergent property of such a network.

In the following, we will turn to concepts that are usually applied in fields different from computer science or behavioral biology, like psychology and philosophy of mind. Choosing another level of description can help us gain a better understanding of the system on a more abstract level. In addition, this approach can lead to more operational definitions for concepts used in other disciplines. This is based on the assumption that many of the above-mentioned phenomena emerge ([Vision 2011](#)) and that they can be used as concepts only on a higher, more abstract level.

For some authors, consciousness is thought to be restricted to human beings. In contrast, other authors share the opinion that there are degrees of consciousness and that consciousness does occur, to a smaller degree, in lower-level animals ([Dennett 1991](#)). Showing that quite small and simplistic networks can allow for interesting cognitive properties ([Chittka & Niven 2009](#); [Menzel et al. 2007](#)) supports such a view, as it provides a plausible evolutionary explanation for consciousness (or better degrees of consciousness). Agreeing with this basic assumption, we want to analyze to what extent our simple control network fulfils certain aspects of consciousness or emotions, even though we did not intend to realize this in our system in the beginning. The graded emergence of such high-level concepts would offer an evolutionary account and might allow us to address questions on the function, e.g., of consciousness, and explain how it relates to the control of behavior.

7 Phenomenality

Before concentrating on specific phenomena, such as emotions or consciousness, we would like to address a more fundamental aspect that appears to be relevant for all higher-level phenomena, namely the occurrence of subjective experience.

An example of subjective experience is pain. Even though it might be possible for us to closely attend to all neuronal activities of a hu-

man test subject while stimulating that person’s skin with a needle, the observed data would be different from the experienced pain, which is only felt by that person. Nobody other than that person can feel the pain. This form of experiencing an internal perspective is therefore only accessible to us through self-observation. Intuitively, other systems—like non-living things or simple machines—lack such an internal perspective. But in many cases, like for animals, it is hard to determine whether they have subjective experience or are merely reflexive machines that do not possess an internal perspective.

This problem is also visible when we consider a human brain, in the contrasting states of being awake or asleep, for example. While in (dreamless) sleep or under anesthesia the same neuronal systems as in a wakeful state may be active, subjective experience is assumed not to be present. And even in a normal wakeful state, we are not aware of all the contents of the different neuronal activities that take place in our brain. Therefore, only a specific type of neuronal activity seems to be accompanied by subjective experience.

There is only indirect evidence on the conditions required for subjective experience. [Libet et al. \(1964\)](#) performed an early experiment, where the cortex of a human subject was directly stimulated, electronically. Only for stimuli longer than 500 ms did the subjects report a subjective experience. Bloch’s law ([Bloch 1885](#)) formulates this connection more generally. The subjectively-experienced strength of a stimulus depends on the mathematical product of stimulus duration and stimulus intensity. In other words, a stimulus is only experienced subjectively when the temporally-integrated stimulus intensity surpasses a given threshold.

More recent experiments have studied the concurrent activation of different procedures that compete for becoming subjectively experienced. A basic experiment has been performed by [Fehrer & Raab \(1962\)](#), and has been followed by detailed later studies ([Neumann & Klotz 1994](#)). First, participants learned to press a button whenever a square was shown on a screen, but not when two squares were shown in a position on the screen flanking the first

square. After the learning period was over, in the experiment the single square was presented for only a short period (about 30 ms), which was then followed by a longer presentation of the two squares. The participants did not report having seen the single square, but reported only having seen the two squares. Nonetheless, they pressed the button. This result shows, first, that the first procedure A (“stimulus single square—motor response”), can be executed without being accompanied by subjective experience of stimulus stimA, the single square. Second, procedure B (“stimulus double squares—no motor response”) appears to influence how the first procedure is experienced, i.e., this procedure inhibits the subjective experience of stimulus stimA. Therefore, stimulus stimA is not subjectively experienced (the “masking” effect), but nonetheless triggers the motor reaction.

This situation can be interpreted in the following way (Figure 8, left). On the input side, each procedure shows temporal dynamics that are similar to that of a low-pass filter (LPF) (see footnote on page 2) followed by an integrator (IntA, IntB).⁶ Stimulation of one procedure inhibits the representation of the other procedure for some limited time (figure 8, Δt). In addition, both integrators are coupled via mutual inhibition (in figure 8 depicted by separate units). In the masking experiment, the first stimulus (stimA) does not inhibit the second procedure (B), because the latter is not yet stimulated, as long as stimulus stimA is active. In contrast, when the second stimulus, stimB, is given, the representation of procedure A may be suppressed. The representation of the input given by units IntA and IntB activate the corresponding motivation units (MU) of the procedures, MUA and MUB, respectively. This could be explained if we assume two different thresholds. First, the motor command of a procedure can be elicited when a small threshold (thr1, figure 8) is reached. But, a second, larger threshold (thr2, figure 8) must be reached in order to have subjective experience. Then, in our paradigm, procedure A, which was activ-

ated first, may reach the level of thr1, which is sufficient to activate the motor output, but not thr2. Only the second procedure, B, has enough time to reach the state of subjective experience (thr2, figure 8, right), which allows the double square (stimB) to become subjectively experienced (however this comes about). The model therefore suffices to explain the basic properties characterizing the backward-masking experiment. As has been shown by Cruse & Schilling (2014), the structure depicted in figure 8 can also deal with a forward-masking paradigm, the so-called attentional blink effect (Schneider 2013). To further describe another experiment, showing the so called psychological refractory period (PRP) paradigm (e.g., Zylberberg et al. 2011), the motivation units (MUA, MUB) of procedure A and procedure B are connected in such a way as to inhibit each other. In other words, the motivation units of these procedures form a WTA network. In addition, each procedure inhibits its own motivation unit after its action has been completed.

From these observations we conclude that there are specific neuronal states that require time to be developed. While eliciting an output signal (like a motor command) is the basic function of the system, this can happen without accompanying subjective experiences. Only some procedures may give rise to such phenomenal experience and might, in addition, trigger subsequent functions in the neural system. For example, this procedure may be able to access more neuronal sources and perhaps allow faster storing of new information (e.g., for one-shot learning). In addition to such functional properties the network can endorse the (mental) property of showing subjective experience, i.e., entering the phenomenal state.

The experimental findings mentioned above support a non-dualist, or monist, view, which means that there are no separate domains (or “substances”), such as the mental and the physical domain, in the sense that there are causal influences from one domain to the other one as postulated by substance dualism. Rather, the impression of there being two “domains”—often characterized as being separated by an ex-

⁶ An integrator performs a mathematical integration, i.e., it sums the input over time.

planatory gap (Levine 1983)—, results from using different levels of descriptions.⁷

An explanation of the necessary and sufficient conditions of neural networks that allow for subjective experience would be extremely interesting. Even though there currently exist only early insights or mere speculations, there has been a lot of progress during the past few years (review Schier 2009; Dehaene & Changeux 2011). The continuation of these research projects will hopefully yield a more detailed understanding. Using combinations of neurophysiological and behavioral studies may lead a better understanding of the physiological properties and functions of this state. It is, however, generally assumed that even if we knew the physical details at some future time, we would not understand why this state, which is characterized by physical properties, is accompanied by phenomenal experience. Here we propose another view. We assume that this problem will be “solved” such that the question concerning the explanatory gap will simply disappear, as has happened in the case of explaining the occurrence of life. Concerning the latter, there was an intensive debate between Vitalists and Mechanists at the beginning of the last century on how non-living matter could be transformed into living matter. The Vitalists argued that a special, unknown force, termed *vis vitalis*, was required. After many decades of intensive research, we are in a position where an internal model is available, which represents the observation that a specific collection and arrangement of molecules is endowed with the property of living. This and similar cases may be generalized as the following rule: If we have enough information, such that we can develop an internal model of the phenomena under examination, and if it is sufficiently detailed to allow the prediction of the properties of the system, we have the impression of having understood the system. In the case of life, indeed we do not need a *vis vitalis* any longer, but consider liveliness an emergent property. Correspondingly, we propose that if

we knew the functional details and conditions that lead to matter having subjective experience well enough, so that the appearance of subjective experience can be predicted, we would have the impression of having understood the problem. Therefore, we assume that the question of the explanatory gap will disappear at some point, as was the case in the example of life.

Adopting a monist view allows us to concentrate on the functional aspects when trying to compare systems endowed with the phenomenality, i.e., human beings, with animals or artificial systems. According to this view, phenomenality is considered a property that is directly connected with specific functions of the network. This means that mental phenomena that are characterized by phenomenal properties—as are, for example, attention, intention, volition, emotion, and consciousness—can be examined by concentrating on the aspect of information processing (Neisser 1967).

To avoid possible misunderstandings, we want to stress that we do not mean that the phenomenal aspect does not have any function in the sense that the system would work in the same way if there was no such phenomenal properties. Since, according to our view, the phenomenality necessarily arises with such a system, a version of such a system showing exactly the same functions but not having the phenomenal aspect would not be possible. A change in the phenomenal properties of a system has to be accompanied by a change in its functional properties. Functional and phenomenal aspects are two sides of one coin. However, remaining on the functional side makes the discussion much easier.

To summarize, the content of any memory element may be subjectively experienced (or available to conscious awareness) if (1) the (unknown) neuronal structures that allow for the neural dynamics required for the phenomenal aspect to occur are given, and (2) the strength and duration of the activation of the memory element is large enough, provided the element is not inhibited by competing elements.

The question of how any system can possibly have subjective experience was famously called the “hard problem” by Chalmers (1997).

⁷ There are various views adopting a monist approach, that differ in detail (epiphenomenalism, emergentism, property dualism and their many derivatives, see Vision 2011). We will not enter into this discussion here.

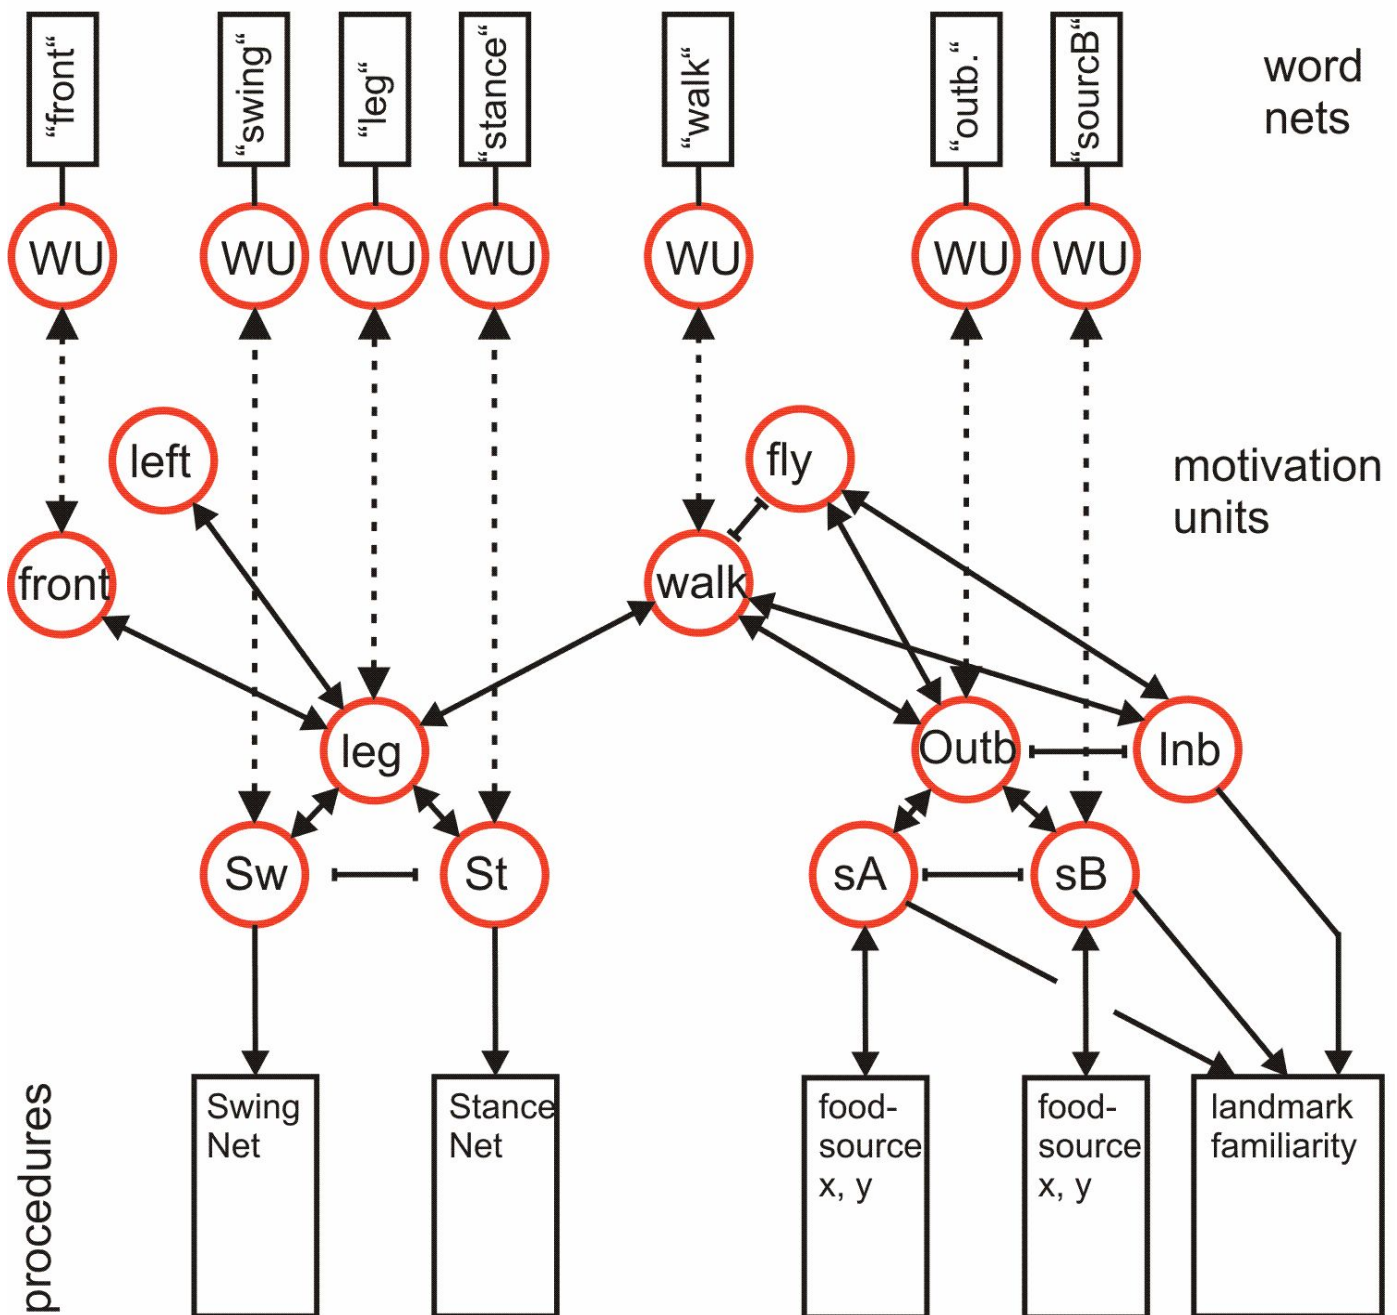

Figure 7: The reactive network expanded by a layer containing procedures that represent words (Word-net, upper row). The motivation unit of a Word-net (WU) is bi-directionally connected (dashed double-headed arrows) with the corresponding motivation unit of the reactive system containing procedural elements of Walknet (left, see figure 2) and of Navinet (right, see figure 4). The word stored in a Word-net is indicated as (“ ... ”). Not all of these motivation units have to be connected with a Word-net.

Adopting a monist view, we can avoid this question and leave it open, as we are interested in understanding the functional aspects of consciousness (on the ethical implications of an artificial system having subjective experience implemented in appropriate neural dynamics see Metzinger 2009, 2013). Regarding what kind of

dynamics could be thought of, it has been speculated that subjective experience might occur in a recurrent neural network that is equipped with attractor properties. Following this hypothesis, subjective experience would occur if such a network approached its attractor state (Cruse 2003). This assumption would mean that any

system showing an attractor might be endowed with the phenomenon of subjective experience. It may, however, not have all the other properties characterizing consciousness. On the other hand, there might be systems in which the functional aspects currently attributed to consciousness are fulfilled, but where there is no subjective experience present. This case would imply that our list representing the functions of consciousness as given in section 10 below is not yet complete.

In the following two sections we shall briefly treat two phenomena—emotions and consciousness—and discuss how they might be related to the minimally-cognitive system as represented by reaCog.

8 Emotions

Most authors generally agree that emotions are accompanied by subjective experience and that they have the function of helping the subject respond adaptively to environmental pressures. So there is the phenomenal aspect of emotions as well as a functional aspect. As we have already treated the phenomenal aspect above, here we will put aside this aspect, i.e., how it feels to be happy, sad, etc., and concentrate on the functional aspect of emotions.

Even though several authors assume or even demand that emotions are already present in simple reactive systems, and that they are necessary for a cognitive system (Valdez & Mehrabian 1994), in our above description of the properties of the network reaCog, any emotional aspects have not been taken into account. We did not require the term “emotions” to explain our approach, nor have we built in any kind of explicit emotional system. However, we will argue that there are emerging properties that are comparable to what is usually ascribed to properties of emotional systems. In the following, we want to focus on which parts in our system take this role and how the functions of these parts can be described and related to attributes of emotional systems.

The attempt to relate the properties of our network with the concept of emotions appears not very promising at first sight, because

a series of interrelated conceptual terms such as emotions, attitudes, motivations, sentiments, moods, drives, and feelings can be found in the literature, and are defined in different but partly overlapping ways by different authors (Pérez et al. 2012). The reason for this disagreement might be that there are indeed no clearly separable mechanisms underlying these phenomena but rather we are dealing with a holistic system, which makes separation into clear-cut concepts difficult, if not impossible. As mentioned, the problem of being confronted with heterarchical structures appeared when looking at the reactive level (and reappeared later when dealing with perceptual memory), which led us to the neutral term “motivation unit” for all “levels” of the heterarchy formed by the motivation unit network. To simplify matters, we will only deal with the term emotions in the following.

What might be possible functions of emotions? As follows from the examples of overlapping conceptual approaches found in the literature and mentioned below, emotions are attributed to various functions characterized by different levels of complexity. These range from enabling the agent to select sensory input (e.g., tunnel vision, Pérez et al. 2012) and activate different procedures, or, at a higher level, to select between different behavioral demands (e.g., hunger – thirst, flight – fight, Parisi & Petrosino 2010) up to more abstract states such as suffering from sadness or being in a state of happiness and controlling the corresponding behaviors (e.g., Ekman 1999). The lower-level decisions are well covered by our motivation unit network, and form a heterarchical system showing attractor states (e.g., swing – stance, Inbound – Outbound). These states allow for selection of sensory input and/or motor procedures that are stimulated by sensory input to specific motivation units. In the following, we therefore focus on higher-level states, such as, for example, emotions, as listed by Ekman (1999).

In general, and as discussed below, one can distinguish between prototypical approaches and reductionist approaches—the latter simplifying emotions down to just a few basic dimen-

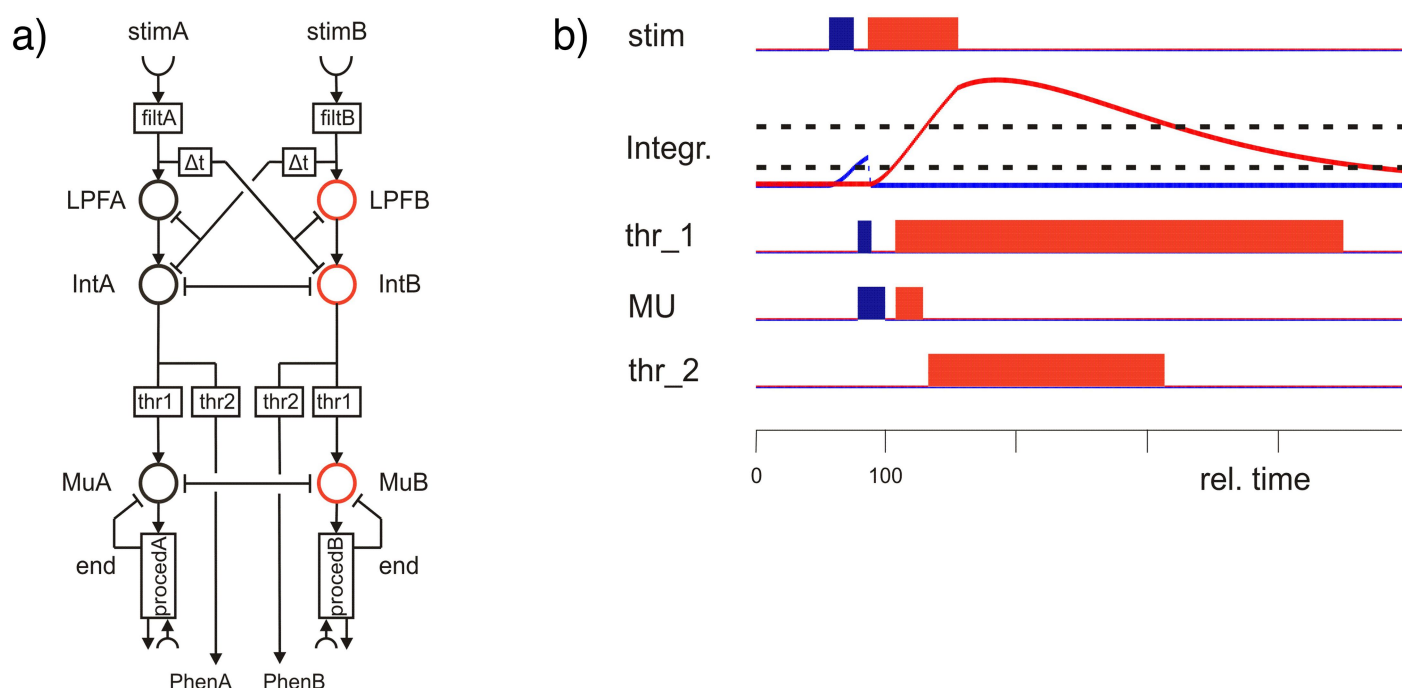

Figure 8: (a) A hypothetical network that is capable of dealing with some dual task experiments, for example the backward masking experiment. Stimulation of one of the procedures, A or B, activates a low-pass filter (LPFA, LPFB) followed by an integrator (IntA, IntB) and inhibits the corresponding units of the other procedure for a limited time (Δt). The integrators are coupled via mutual inhibition. After activation of one of the integrator units has reached threshold thr1 (lower dashed line), the corresponding motor motivation unit (MuA or MuB), coupled via mutual inhibition, is activated, which drives the behavior. If threshold thr2 (upper dashed line) is reached, the stimulus can be phenomenally experienced. A feedback from the procedure can provide an “end” signal to inhibit its own motivation unit. (b) Temporal development of the activation of some units (procedure A, blue, procedure B, red). Abscissa is relative time. If stimB follows briefly after stimA, the unit IntA may reach its motor threshold thr1, but not the threshold thr2 for eliciting the phenomenal experience. In contrast, stimB elicits both the motor output and the phenomenal experience that corresponds to the backward masking effect (for details see [Cruse & Schilling 2014](#)).

sions. In current research, both views appear to be justified as they both try to describe the phenomena observed, though at different levels of description.

Following the first approach, research tries to trace emotions back to a set of basic emotions, the combination of which can explain further derived emotions. This approach has been advocated by [Plutchik \(1980\)](#). A problem with such an approach is how to draw borders between emotions and what counts as a basic emotion. [Ekman \(1999\)](#) proposed a list of characteristics of similarity between emotions and came up with a set of fifteen basic emotions. Later on, based on their relation to facial expressions, he reduced this number to six. This set, which is now widely used as the basic set of emotions in many different contexts, consists of

happiness, anger, disgust, sadness, fear, and surprise. As an example, let us consider happiness. Happiness is elicited when we are in a state of having had or expecting positive situations. The behavioral effect of happiness might be characterized as being open to new ideas, perhaps not being too critical and open to performing new, unconventional behaviors. How might such a phenomenon be represented in reaCog? First of all, a neuronal state of the motivation network would correspond to a specific emotion. Such a network state is usually triggered by some sensory stimulus eliciting an emotion. This stimulus activates specific, basically innate, networks which, when active, influence the system and put it into the respective emotional state. Such a network—which could, in the most reduced case, consist of just one neuronal unit—has not

been introduced in reaCog, but if assumed as given, it may modulate meta-control parameters such as, for example, noise levels, thresholds, or learning rates (Doya 2000, 2002). To stick to our example of “happiness”, activation of such a network, which represents stimulus situations considered to elicit this state may, within the Spreading Activation Layer, lead to a faster diffusion process, perhaps supported by stronger noise amplitude. Such a broadening of the attention range as a consequence of positive affects has been reported by Dreisbach & Goschke (2004). In addition, or as an alternative, the threshold for the problem detectors that we mentioned in section 4 might be increased. As a consequence, the system would take more risks. All these changes would lead to an increase in “creativity”, i.e., the ability to find new ideas for possible solutions. Corresponding structures might be found in the other basic emotions listed by Ekman.

In the second group of approaches to characterizing the emotions, emotions are described through a set of dimensions that represent the emotional state. We will briefly sketch this seemingly alternative reductionist approach and will again draw parallels with reaCog. The connection to reaCog is made on a different level and is therefore not logically exclusive with respect to the former. Wundt (1863) was quite opposed to the idea of breaking down emotions into a set of basic emotions that serve as prototypes, mainly because he assumed that a set of emotions is better described by a continuum than by separable categories. This follows his idea of describing emotions through principal components leading to dimensional systems, like the pleasure-arousal-dominance (PAD) framework (Mehrabian 1996). In the PAD framework, three dimensions span the space of the emotions. The first describes the state pleasure–displeasure and corresponds to the affective state (excited – relaxed). Arousal, as the second dimension, represents the level of mental alertness and physical activity (tense – sleepy). The third axis describes the level of dominance–submissiveness, i.e., the feeling of being in control. The three factors of the PAD framework have successfully been employed as semantic differen-

tial factors to describe emotional states in different contexts, e.g., for describing postures, facial expressions, gestures, and vocal expression. The three dimensions appear to be sufficient as they capture large parts of the variance (Mehrabian 1996). Mehrabian has related the three traits—pleasure, arousal and dominance—to specific cognitive characteristics. First, pleasure–displeasure, according to Mehrabian, deals with the fulfillment of expectations. Fulfillment of an expectation (or not) occurs when, during a problematic situation, planning ahead is activated and after some time and searching a solution is found (or not)—a state that can be found in reaCog, too. But fulfillment of expectation might also occur at lower levels, when, for example, a simple procedure such as Swingnet is equipped with a target value and this goal is either reached or not. The error signal might then be used as a measure for fulfillment of expectation. For example, it might be used as problem detector in the case mentioned earlier, when a subject tries to lift a leg off the ground, but due to an inconvenient load distribution, the body falls down and the leg remains in contact with the substrate. The arousability trait, as introduced by Mehrabian (1996), was meant to incorporate the process of “stimulus screening”. In short, “stimulus screening” is a process of attentional focusing. Such a process of focusing attention occurs in our system, too, as, on the one end of the spectrum, the system broadly attends to all environmental influences as perceived through its sensors, and this is characterized as its being in the “reactive state”. At the other extreme, when a specific problematic situation occurs, it is necessary to focus attention and to guide the search for a solution towards specific modalities, parts of the body, etc. But even on the reactive level, attention selection can be observed, as we mentioned earlier. Finally, the dominance trait (“generalized expectations of control” Mehrabian 1996) concerns the extent to which the agent takes over in the actual situation and is not only responding and reacting, which agrees with the main thesis of our approach, namely that it is possible to switch between the reactive mode and the cognitive mode. Similarly, Russell &

Norvig (2003) have required an autonomous agent to be able to both react to known situations and to be in control of the situation itself (or as Russell and Norvig call it: being proactive).

Our approach, as we have mentioned, does not aim to build specific emotional properties, but tries to build a functional autonomous system and then to look at the aspects of emotional properties that might be found in the network or gained after some further functional expansion of the network. We have listed examples from different levels of description in psychology and point to related properties in our network. We are not arguing that reaCog has emotions (we are in any case agnostic with respect to the subjective aspect). Rather, we claim that by taking a network like reaCog as a scaffold, different conceptualizations of the functional aspects of emotions can be mapped onto such a quantitatively defined system and thus be considered emergent properties.

It might be added here that recent studies support the idea that emotion-like states do indeed occur in brains which are by far less complex than mammalian brains. Yang et al. (2014) could show that the concept of “learned uncontrollability”, generally considered as an animal model for depression as observed in humans, can be found in *Drosophila*, too. For vertebrates, it is known that stress induces the state of fear or of anxiety, the latter being considered as a second order emotion. Fossat et al. (2014) could show that a crayfish treated by stressors (i) avoids illuminated parts of the environment and (b) shows an increased level of serotonin in the brain, as can be observed in vertebrates. As in vertebrates, the state of anxiety could be relieved by application of anxiolytic drugs. Both results have been interpreted such that the ability to adopt emotional states must have been evolved before the separation of the arthropods and vertebrates.

9 Attention, volition and intention

In the following section we want to turn to attention, intention, and volition. To what degree can those properties be attributed to our sys-

tem? We start from the definitions of attention provided by Desimone & Duncan (1995), of intention from Pacherie (2006) and Goschke (2013), and of volition from Goschke (2013).

Attention is the ongoing selection process in perception. It can be driven bottom-up, i.e., by sensory influences, or it can be controlled by top-down influences (Desimone & Duncan 1995). Top-down driving of attention depends on the internal or emotional state and might depend on familiarity with the stimulus.

We can indeed find properties corresponding to attention in reaCog. The motivation network is constituted of local clusters of units that always compete on this local level and form in this way coalitions of units and small subclusters. As an example, we introduced the selection of procedures at the leg level. Either a swing or a stance motivation unit can be active and inhibits the other one. These two units compete for control of behavior. Sensory units can influence this competition. For example, an incoming ground-contact signal ends a swing movement and initiates stance activation. After activating the “Stance” unit only sensory input relevant to stance can be perceived by the system, but not inputs relevant to swing. Therefore, this case corresponds to bottom-up attention control.

Such competition can also be found on a global level, on which different behaviors can be chosen. The activation of these higher-level elements influences the lower level. This activation provides a context for the lower level, which guides the selection process on that level and decides which sensory inputs might be relevant. Thereby, more global clusters control the attention on the lower levels in a top-down fashion. Corresponding examples can be found in Navinet, which we mentioned earlier. Only visual signals concerning landmarks that belong to the current active context are considered and switching between contexts only becomes possible after the food source has been depleted and found empty.

The cognitive expansion of reaCog represents another case of top-down influence. This system comes up with new behaviors and probes them via internal simulation. As men-

tioned, there is a specific WTA layer that mirrors the arrangement of the lower motor control layer (figure 6, green units). This part of the controller can be called an “attention controller”, as the explicit function of this layer is to narrow down the search for suitable behavior and to actively select a single one. We call this selection a cognitive decision, as the system is supposed to select a behavior that would not normally be triggered through the given context. In this way the system represents a special type of top-down attention. The focusing mechanism may correspond to what sometimes has been termed “spot light” (Baars & Franklin 2007 p. 955). Overall, we can therefore observe three different types of attentional influences in reaCog.

Volition is an umbrella term denoting mechanisms allowing for voluntary actions. The latter are “actions that are not fully determined by the immediate stimulus situation but depend on mental representations of intended goals and anticipated effects” (Goschke 2013). For an outside observer, voluntary actions cannot be predicted. As mentioned above, it is crucial for the cognitive expansion that it can select behaviors that are not triggered by the current situation. The system has to invent new behaviors. Even though the consequences of these behaviors are predicted, from the outside the finally chosen behavior is not predictable, as this invention and selection of new behaviors is stochastic to some extent. The application of internal simulation only guarantees that the proposed behavior will lead to a solution, but it does not give away which behavior will be chosen. To the contrary, the search space of possible solutions can easily become very large and has to be restricted. Such restrictions help to span a tractable space of possible solutions. In our example, reaCog looks first for solutions in the morphological neighborhood, i.e., it tries to use the neighboring legs to help find a solution for a locally-given problem. There are still many possible behaviors that must be tested in a somewhat random order. The system will end up with one that has been anticipated as a solution in internal simulation, but this solution is not selected through sensory inputs or the current con-

text as such. Therefore, volition may be attributed to a system like reaCog.

Does an agent controlled by reaCog show intentions? Intentions are present when the controlled action is goal-directed. We are following Pacherie (2006), who proposes a differentiation of three types of intentions (based on Bratman’s (1987) original differentiation into two such types). Pacherie distinguishes future-directed as well as present-directed intentions and introduces motor-intentions as a third type. Present-directed intentions are considered to be under “conscious” (or “rational”) control. In contrast, motor intentions are related to lower-level function (Pacherie 2006). Defining for these types of intention is that they provide guidance for the function on the respective level. In reaCog, motor-intentions are realized by the fact that, on the reactive-control level, behaviors can be selected based on the context. Present-directed intentions can be found on the level of cognitive decision. Future-directed intentions are not treated by reaCog, because its architecture in the current version only allows for dealing with problems that occur in the context of current walking behavior. However, an expansion of reaCog that would include planning ahead using Navinet as a substrate would include future-directed intentions, too.

Goschke (2013) defines intentions as “causal preconditions explaining why a particular stimulus triggers a particular action (rather than a different action)” (Goschke 2013, p. 415). In other words, “intentions can be said to shape the “attractor landscape” of an agent’s behavioral state space” (Kugler et al. 1990, ref. from Goschke 2013, p. 415). In reaCog, such an attractor landscape is described by the motivation unit network. As explained in the preceding paragraph on attention, the activation of a context guides, in a top-down fashion, both the selection of a suitable behavior as well as which sensory inputs the system should attend to. The lower-level activation and incoming sensory inputs influence, on the one hand, the adaptive execution of the behavior as such. On the other hand, the sensory input can inform the higher level in bottom-up fashion and might indirectly trigger changes on this higher-level, too. The ac-

tivation on the higher level will, however, be in general more stable on a temporal scale and will reflect a specific context as well as relate to specific goals. For example, in the case of Navinet, there are different possible goals, such as food sources or the nest, which are represented in the higher-level network. Selecting one of these as a goal will guide the overall function of the system, as its behavior is directed towards approaching that location, while the sensory system will attend only to the specific (expected) sensory stimuli. Therefore, reaCog can be assumed to show goal-directed behavior and intentions.

10 Consciousness

In this section we would like to discuss to what extent properties of consciousness might be found in our system. Even though we start from a common notion of how consciousness can be viewed as consisting of separable domains, we are well aware that this approach is not the only or ultimate solution for approaching this question. But such a differentiation appears well-suited for our bottom-up approach.

Overall, many authors contribute to the view in which consciousness is broken down into a set of properties. We start from a review by Cleeremans (2005), who gives a good overview on the diverse philosophical views on consciousness and tries to integrate them into one framework. While there is disagreement in general and also on the details (see also Vision 2011), Cleeremans interestingly finds a common denominator between the different opinions that characterize possible computational correlates of consciousness. He introduced a differentiation of consciousness into three domains: phenomenal consciousness, access consciousness, and metacognition (or in other contexts referred to as reflexive consciousness). There is disagreement on the phenomenal aspect, as it is seen by one group of philosophers to be an independent domain. In contrast, there is also a view in which phenomenality cannot be separated from metacognition and access consciousness, but must be seen in relation to those (see review Cleeremans 2005).

We have argued in section 7, that the phenomenal aspect as such, i.e., the property of some neuronal structures that are equipped with subjective experience, has *per se* no function, but is, nonetheless, not separable from the functional properties. Therefore, we see the phenomenal aspect not as a separate type of consciousness, but as a property of both access consciousness and metacognition. This view has convincingly been supported by Kouider et al. (2010) as well as, in a recent review, by Cohen & Dennett (2011). Therefore, we will compare properties of reaCog with current definitions found in the literature concerning the phenomena of access consciousness and metacognition, abstracting from the phenomenal aspect.

While other philosophers require metacognition or reflexive consciousness in a system in order to attribute consciousness (see for example Rosenthal 2002 or Lau & Rosenthal 2011 for a recent review defending this view), we do not want and cannot get into this discussion as it is not our goal to review the different types of taxonomies. We basically follow one valid and common perspective, as presented by Cleeremans, and apply it to our system in order to analyze functions of our system that can match the different phenomena described. We do not aim with this approach to give a rigorous definition of consciousness (which does not seem suitable at this point, see also Holland & Goodman 2003). Instead, applying our approach, we aim to provide insight into specific functions of our system that are connected to the phenomena discussed.

10.1 Access consciousness

In this section we want to focus on the aspects of access consciousness that can be found in reaCog. Following Cleeremans, access consciousness of a system is defined by the ability to plan ahead, to guide actions, and to reason, as well as to report verbally on the content of internal representations. In contrast, non-conscious representations cannot be used this way. Selecting behaviors, planning ahead, and guiding actions are the central tasks of reaCog (see section 4, Planning ahead).

Figure 9: A possible expansion of reaCog. Without the connections 1A and 1B the network enables the agent to represent its own actions, as is already possible for the network shown in figure 2, and figure 6. After introduction of connections 1A and 1B the network is also able to represent the actions of a partner using the now shared procedure “grasp”. (a) and (b) show two attractor states where active motivation units are depicted in red, whereas inactive motivation units are shown in black. Half circles indicate sensory input.

Being able to use internal representations for verbal report is currently not a part of reaCog. However, the internal representation of reaCog is already suited to allow for accessing internal representations (section 5 and figure 7). The simple solution proposed allows for communication using one-word sentences only, but provides a way, within the framework of reaCog, for the symbol-grounding problem to be addressed. Steels (2007; Steels & Belpaeme 2005) and Narayanan (1997) have already studied in detail how more complex sentences may be grounded in simple reactive systems. Thus,

there already exists work on similar systems that shows how the ability to report by using more complex language structures could be implemented in a reactive system. Therefore, at least in principle, this property could be realized in reaCog, too.

The last property describing access consciousness, symbolic reasoning, is not addressed by reaCog. In the symbolic domain, there are, however, many interesting approaches in the literature that might be connected to a system like reaCog after the symbolic level has been implemented.

Concerning related work, [Dehaene & Changeux \(2011\)](#) review relevant network models that are supposed to simulate consciousness, including their own approach, which is termed global neural workspace theory (GNW) (see also [Seth 2007](#) for a systematic summary). A comparison of reaCog with these approaches can be found in [Cruse & Schilling \(2013\)](#)). Here we will only refer to one important notion, “global availability” as used by several authors to represent a crucial property of access consciousness (e.g., [Dehaene & Changeux 2011](#); [Dehaene & Naccache 2001](#); [Baars & Franklin 2007](#); [Cleeremans 2005](#)). Global availability describes the notion that many representations of the system can potentially become conscious. These representations can be selected to solve a current problem (as described for reaCog) or could be selected in a task (see GNW).

Are the representations used in reaCog globally accessible? During execution of a form of behavior the reactive system simply reacts to sensory inputs. Single local modules of the procedural memory are activated by the context, for example, the walking behavior that can execute walking even in a cluttered environment. While the behavior is driven by sensory stimuli, it is not “cognitively attended” and runs automatically in response to direct interaction with the environment. In this case, the representations are not attended by cognitive expansion and are clearly not a part of access consciousness. But, importantly, this can change whenever a problem is detected and the reactive (automatic) system is not sufficient anymore. In such a case, the WTA-net of the attention controller is activated and has to select one of the elements of the procedural memory. During planning, these elements become accessible to the attention system ([Norman & Shallice 1986](#)). The WTA-net, which constitutes the essential part of the attention controller, projects directly back to the motivation units of the procedural memories (figure 6, dashed arrows) and thereby selects just one of the possible behaviors (due to the characteristics of a Winner-Take-All network). Therefore, all the procedural modules that could be activated by the attention con-

troller are “globally available” and form possible elements of access consciousness.

10.2 Further relations between reaCog and access consciousness

Another interesting property of reaCog and findings in psychology concern the relation between conscious and automatic procedures. It is well known that humans are able to learn a new behavior by consciously attending to that behavior. Over time, this can change and the execution of the behavior becomes more and more automatic, i.e., it is no longer necessary to be consciously aware of the exact execution of the behavior. A similar shift of attention can be found when reaCog is planning new behaviors. Triggered by the activation of a problem detector, reaCog has to shift its attention towards the new behavior during planning and the following execution of a behavior. As long as the problem-detector is still active, the reactive system is basically suspended (by switching off the loop through the body), and instead the planning system tries out new procedures that have to be attended to. After the successful execution the new solution can also be stored as a procedural memory and become part of the reactive system; it does not require cognitive attention anymore (the procedure how to store this information has not yet been implemented in reaCog). An advantage of this integration into the reactive system is that access to reactive procedures is faster than using the cognitive process, which agrees with the findings mentioned above.

There are other experimental findings highlighting the relation between conscious and non-conscious access to procedural elements. [Beilock et al. \(2002\)](#) found that athletes who have learned a behavior so that it can be performed automatically perform worse when they concentrate on the behavior compared to when performing the behavior while being distracted. In the attention controller of reaCog we can observe a similar phenomenon. If the attention controller is externally activated by a higher-level unit while the connected behavior is performed, this could possibly activate learning.

Such an influence would change the underlying neuronal module and could worsen the result. In contrast, without attention the behavior would be performed as it had been learned earlier.

ReaCog differs in an important aspect from the simulation studies conducted by Dehaene and colleagues, as well as from those conducted by Baars and colleagues. While the latter approaches aim to relate conscious functioning to individual brain areas or brain circuits, reaCog is not intended at all as a model of the human brain or any of its areas. Instead, it is envisioned as a reductionist approach that focuses only on function. From the bottom-up development of more and more higher-level function we offer a post-hoc discussion of the question of to what extent reaCog shows aspects of access consciousness. This approach seems particularly suitable for addressing access consciousness, as it turns out that there is no single identifiable part of reaCog that might be attributed the property of access consciousness. Instead, access consciousness appears to be an emergent property constituted by the complete system. Attention controller, procedural memory, and the connections between those two parts, as well as the internal model and the ability to use it in internal simulation, seem to be the required structures that allow access consciousness, or, in other words, together constitute the “neural workspace.” The dynamics of the neural workspace as defined by Dehaene & Naccache (2001) are given through the WTA-net. But, and this is an important difference, there no re-representation in this neural workspace is necessary. The already-present representations can be reused in novel contexts. The existing modules of procedural memory are recruited in the internal simulation when planning ahead. The only difference is that the body is decoupled from the control loop and instead the loop through the world is replaced by a loop using internal models and their predictions as feedback. Together, these representations form the global workspace (this notion of internal models has been termed “second-order embodiment,” c.f. Metzinger 2014).

Koch & Tsuchiya (2007) differentiate attention and consciousness, as both can be present individually and independently of each other. They conclude that different mechanisms are responsible for attention and consciousness. While such a differentiation is of course based on basic definitions, we can indeed identify different mechanisms related to these two phenomena, even though they seem to be related. In reaCog, attending to a specific stimulus is modelled as a specific activation of motivation units. Only if this activation is strong enough and/or active for enough time, can the procedure enter the phenomenal state (section 7, figure 8). Therefore, both attention and the phenomenal aspect of consciousness refer to different, but tightly coupled properties of our system.

10.3 Metacognition

Although in this article we use the term cognition in the strict sense as proposed by McFarland & Bösner (1993), when dealing with metacognition, this definition is no longer generally applicable. Therefore, in this section the term cognition is used in the usual, more qualitatively-defined way. We will describe how the motivation unit network could be expanded to allow our agent to be endowed with different aspects of metacognition. These expansions, however, have not yet been simulated by being implemented into the complete network.

Metacognition, or reflexive consciousness (sometimes called metarepresentation), the second essential domain of consciousness, according to Block (1995, 2001) and Cleeremans (2005), is characterized by Lau & Rosenthal (2011) as “cognition that is about another cognitive process as opposed to about objects in the world” (p. 365).

While the selection of procedures for control of behavior may occur on the reactive level or by application of access consciousness, metacognition in addition is able to exploit information concerning a subject’s own internal states. As a further property, a metacognitive system, when selecting behavior, can represent itself *as* selecting this behavior (“I make the decision”). Metzinger (2014) classifies this ability as third-

order embodiment, where the subject's own body is "explicitly represented as existing" (p. 274) and the "body as a whole" can turn "into an object of self-directed attention" (p. 275). Thus, metacognition is about monitoring internal states in order to exploit this knowledge for the control of behavior. According to [Cleeremans \(2005\)](#), metacognition may also be used for inferring knowledge about the internal states of other agents from observing their behavior and for communicating a subject's own states to others.

Let us first focus on the individual agent. What kind of information might be used by a metacognitive system? A typical case discussed in the literature concerns some quality measure of the procedure to be selected. During decision-making, a person, when relying on own knowledge, needs to be able to access his or her own internal state in order to estimate how sure he or she is about the specific piece of knowledge. [Cleeremans et al. \(2007\)](#) use as an illustrative example a system consisting of two artificial neural networks. While the first network learns an input-output mapping of the task, the other network, as a second-order network, learns to estimate a quality measure describing the performance of the first-order network. As the combination of the two networks does not only store information in the complete system, but also contains information about and for the system, the authors conclude that such a system already shows a limited form of metacognition. Such a network, using an additional second-order subnet, might be implemented in our system, too. For example, motivation units could be activated by confidence, or quality values estimated by such a second-order network. Such a situation can indeed be found in the network Navinet. Navinet is used for navigation control tasks and is inspired by work on navigation in ants. In this system, the salience of a stored stimulus guides memory retrieval ([Cruse & Wehner 2011](#); [Hoinville et al. 2012](#)). For instance, the decision to choose one of many different food sources is influenced by the internal representation of the learned food quality ([Hoinville et al. 2012](#)). As another example, the confidence value of a visual landmark that is to

be followed or not might depend on the salience of the visual stimulus, similar to the implementation of a Bayesian-like system. A different example is given by reaCog, which, by exploiting its internal body model, is capable of representing its own body for internal simulation as well as for control of behavior. Thus, at least some basic requirements for metacognition, such as being able to use own internal representations for the control of behavior, are fulfilled, if we, again, leave the phenomenal aspect aside. Below we will, in addition, briefly address the ability of the agent to represent itself.

How may metacognition be suited to support information transfer between different agents? We will not refer to communication using verbal or gestural symbols here. Instead, we want to start with the ability to identify oneself with another agent, or, in other words, to be able to "step into the shoes of the other." This faculty has been referred to as Theory of Mind (ToM). Central is the notion of being able to attribute mental states to other agents ([Premack & Woodruff 1978](#)). A classical example is the "Sally–Anne task". In this experiment, two subjects observe how a cover hides a piece of candy lying on a table. While one subject, Sally, is outside of the room, the other subject, Anne, is able to observe how the hidden candy is moved to a new location. After the change the candy lies underneath a white cover and not under the black cover, which it did to start with. The crucial test question is put to Anne: where does she think Sally will search for the candy? If Anne points to the white cover she only uses her own current beliefs about the situation, but does not apply a ToM, i.e., she does not take into account what Sally believes—since Sally has not observed the switch. But if Anne points to the original location, the black cover, she is assumed to have a Theory of Mind as she operates on a set of mental states that she ascribes to Sally.

ToM is crucial when an agent needs to capture not only physical objects, but in addition represent other agents. It becomes necessary to explicitly keep track of others' observations, plans, and intentions. Only such agents that can attribute mental states to other agents

can successfully predict their behavior. There are two common explanations to account for how ToM is realized. First, the so-called theory-theory (Carruthers 1996) assumes that there are dedicated, innate, or learned procedures that allow for prediction of internal states and therefore the behavior of others. We want to concentrate on the second main approach, namely simulation theory (Goldman 2005).

Central to simulation theory is the already introduced notion of an internal simulation. As a prerequisite an agent needs an internal model of him or herself. This model can be used (as explained) for planning ahead using internal simulation. But in the same way this model can also be recruited in order to represent another agent. Thereby, other agents may be mapped onto the own internal model that allows simulating the behavior of the other agent. This faculty would enable the agent to derive all sorts of conclusions based on its own representations, such as, for example, current goals or intentions.

In the case of reaCog, we envision an extension that allows mapping another agent onto the already existing internal model. Internal simulation could be used in this context, too. Therefore, the application of such an internal simulation of another agent could lead to an interpretation of the behavior of the other. However, the two theories mentioned do not necessarily exclude each other, as can be shown when regarding the properties of the cognitive expansion further. If the interpretation found via an internal simulation of another agent is new and succeeds in simulating its behavior, the result could be stored in the procedural memory in a similar way as described for reaCog, when coming up with a new solution to a given problem. In this way, a new procedure has been learned that allows for prediction of the behavior of the other agent. As such, application of simulation theory might in the end lead to results that are described as characterizing theory-theory. The faculty of applying a ToM is currently beyond the ability of reaCog as described above, which allows for an egocentric view only. In the following, we will, however, sketch a way in which such a network may be implemented

into the architecture of reaCog (for more details see Cruse & Schilling 2011).

Figure 9 shows a possible expansion of reaCog. Two motivation units represent the state “awake” and the state “sleep”, respectively. In the awake state, several sensory and/or motor elements can be activated. These elements may form different contextual groups. To simplify matters, here we focus on two such groups only. One group contains the procedure “grasp” and a memory element representing the visually-given input “position of an object” (relative to the agent), in this case the position of a piece of candy (pos.candy), which is hidden under a cover. We further assume that the agent can also recognize, as a specific kind of object, a conspecific (“partner”), (see Steels & Spranger 2008 and Spranger et al. 2009 for solutions), to whom the agent can attribute properties. These are, in our example, the memory elements “face” and “position”, which stand for the visual appearance and spatial location of the partner to be recognized. Together with the unit “partner” these motivation units form an excitatory network (the dashed connections marked 1A and 1B will be treated later). The procedure “grasp” contains a body-model consisting of an RNN (Schilling 2011) that contains information on the arm used for grasping. This network can be applied to both motor control and recognition of the arm. The former function is symbolized by the output arrow. Concerning the latter function, the body-model is used to minimize errors between the position of the internal model of an arm and the (underspecified) visual input of the arm (e.g., Schilling 2011). If the error could be made small enough, the visual input can be interpreted so as to match the morphology and the specific spatial configuration of the model arm. To symbolize this capability, in figure 9 the procedure “grasp” is also equipped with sensory (visual) input.

The network depicted in figure 9 (disregarding connections 1A and 1B) enables the agent to recognize the position of the candy and to grasp it (“Ego grasp candy”), as indicated by the motivation units marked red in figure 9a. It further allows recognition of the face and the position of the partner. But it does not enable

the agent to “put itself into the partner’s shoes”. In other words, the agent is not able to realize that the partner may have his/her own representation of the world. Thus, the capability of a ToM is lacking.

The motivation unit connecting the agent-related elements “pos.candy” and “grasp” has been called “Ego” in the figures. Although not required for the functioning of this network as shown in figure 9a (disregarding connections 1A and 1B), the application of the unit Ego would allow the introduction of a Word-net representing the word “I”. Thus, with this expansion the concept of “I”, as opposed to other agents (e.g., a partner), can be used by our agent, allowing for internal states like “I grasp candy”, and therefore for self-representation.

Unit Ego is, however, necessary in our framework when two units (here “Ego” and “Partner”) share elements, as will be the case in the following example, where we will enable the agent to represent the partner performing a grasping movement. To this end, we introduce mutual excitatory connections between the unit representing the partner and the procedural element “grasp” (dashed excitatory connection 1A, figure 9). In addition, Unit “Ego” and unit “Partner” have to be connected via mutual inhibition (dashed inhibitory connection 1B, figure 9). This inhibitory connection has the effect that only one of the units—either unit “Ego” or unit “Partner”—can be activated at a given moment in time. With these additional connections 1A and 1B, the network can adopt the internal state “Partner grasp candy”. This situation can be represented in the agent’s memory by activation of the motivation units illustrated in figure 9b, highlighted in red. Note that the introduction of connections 1A and 1B does not alter the ability of the agent to represent the situation “Ego grasp candy” addressed above.

The architecture depicted in figure 9, including connections 1A and 1B, has eventually been termed the application of “shared circuits”, since the procedure “grasp” can be addressed by both unit “Ego” and unit “Partner”, which strongly reminds us of properties characterizing mirror neurons. Therefore, application of such shared circuits has been described as

“mirroring” (Keysers & Gazzola 2007). Units of the grasp-net (including the target pos.candy) represent the movement and its goal, and thus correspond to representations of a motor act, such as has been attributed to mirror neurons (Rizzolatti & Luppino 2001). The grasping movement in both cases (figure 9a, b) is represented as being viewed by the agent (“Ego grasp candy”, figure 9a) or by the partner (“Partner grasp candy”, figure 9b). This means that there is still no ToM possible for the agent. To enable the agent to develop a ToM, we need another expansion.

To explain this, we will present a simple simulation of the Sally–Anne task mentioned above. Both protagonists, Sally and Anne, may have different memory contents concerning the position of the candy. This means that the agent, in this case Anne, needs to be able to represent some aspects of the memory of her partner, too. Therefore, the memory section representing her partner will be equipped with a memory element representing the position of the candy as viewed by her partner Sally, who left the room (figure 10, connection 2). Both memory elements that have possible access to the procedure “grasp” have to be connected by mutual inhibition, so that only one of these elements can address the procedure at a given time in order to allow for sensible representation of the situation. Now imagine that the subject Anne is either equipped with a network as depicted in figure 9, or that depicted in figure 10. Application of a system as shown in figure 9 means that the agent (Anne) has only one representation of the candy’s position, namely the one seen last. Therefore only this, correct, position can be activated and it is imagined that the partner grasps the correct position—this kind of prediction is observed in children younger than about four years. Anne cannot take into account the likely assumption her partner will make about the location of the candy. In contrast, in a system as presented in figure 10, there is a difference in thinking of oneself grasping the candy or the partner grasping it. When the agent, Anne, imagines herself grasping the candy, she would grasp its position as under the correct cover (figure 10a). If asked

to simulate the internal state of her partner, as is required in the case of the Sally–Anne test (figure 10b), the position connected to her partner Sally is used and the agent will rightfully deduct that her partner’s grasp would be directed towards this position—which is wrong, but this fact is not known by her partner. Therefore, the network shown in figure 10 allows for ToM, in contrast to the network shown in figure 9. The critical difference between both networks is that the network shown in figure 10 contains a separate representation of (a part of) the partner’s memory. This means that a comparat-

11 Discussion

Consciousness and the relation of the outside world to mental representation are central to philosophy of mind, and have led to many diverse views (Vision 2011). While many of those views appear plausible in themselves, especially from a non-philosopher’s perspective, there appears to be much disagreement among philo-

sophers. Many of the positions are based on high-level views approaching consciousness in a top-down fashion. In contrast, our approach starts from a low-level control system for a behaving agent. The goal is the bottom-up development of higher-level faculties. In this way, the neural architecture implements a minimal cognitive system that can be used as a hypothesis for cognitive mechanisms and higher-level functioning, which are testable in a real-world system, for example, on a robot. This allows deriving testable and quantitative hypotheses for higher-level phenomena. In this way, a bottom-up approach can nicely complement philosophical discussions focusing mainly on higher-level aspects. In addition, such a minimal cognitive system can provide functional descriptions of higher-level properties. We briefly introduced the reaCog system in this article, following this bottom-up approach. The central concern is the emergent properties that can be identified when analyzing this system. In particular, high-level properties, such as emotions, attention, intention, volition, or consciousness have been considered here and related to the system.

From our point of view, such a bottom-up approach leads to a system that can be used to test quantitative hypotheses. Even though the system was not intended to model, for example, consciousness, the system can be thoroughly analyzed and emergent properties can be related to mental phenomena. This is particularly interesting, as high-level descriptions can leave a lot of room for interpretation. In contrast, connecting mental phenomena to mechanisms of a well-defined system allows for detailed studies and clear-cut definitions on a functional level. In this way, a system can be examined with respect to many even diverging views and may allow resolving ambiguities. Knowledge gained from analyzing the system can in this way inform philosophical theories and refine existing definitions by defining sufficient aspects as well as missing criteria.

One might ask if higher-level phenomena as considered here are not simply too far removed for such a simple system. One basic problem is represented by the frequently-formulated assumption that all these phenomena have

to be tied to the notion of an internal perspective and that phenomenality has a function in and of itself. In contrast, we claim that focusing on the functional aspect is a sensible approach. It is possible because we believe that the phenomenal aspect is always coupled to specific, yet unknown, properties of the neuronal system that, at the same time, have functional effects and show subjective experience. In other words, adopting a monist view, we assume that we can circumvent the “hard” problem, i.e., the question concerning the subjective aspect of mental phenomena, without losing information concerning the function of the underlying procedures. Of course, we are not in a position to claim which of these structures, if any, are accompanied by phenomenality. If, however, the function of, for example, the artificial system indeed corresponds well enough to those of the neuronal structures that are accompanied by phenomenality, the artificial system may have this property, too.

The control network reaCog consists of local procedural modules. We have presented two subnetworks: Walknet, which aims at the control of walking, and Navinet, which deals with navigation. Both consist of a heterarchical structure of motivation units that form a recurrent neural network. This, via competition and cooperation between those units, allows for various attractor states that enforce action selection. Selection of one or a group of procedures protects a current behavioral context against non-relevant sensory input. An internal model of the body is part of the control network coordinating joint movements in walking. As this model is quite flexible and predictive, it can be used for planning ahead through internal simulation. Following the definition of [McFarland & Bösner \(1993\)](#), the network, since it is based on reactive procedures and is capable of planning ahead, can be termed a cognitive system, giving rise to its name: reaCog. In combination with the attention controller, the whole framework can come up with new behavioral solutions when encountering problems, i.e., behaviors that are not automatically activated by the current context. Internal simulation allows us to test these behaviors and to come up with pre-

dicted consequences, which can be used to guide the selection process for the real system. The attention controller cannot function independently. It is tightly connected to the reactive structures. The procedural memory of the reactive system is further accompanied with perceptual memory and Word-nets, a specific form of mixed procedural and perceptual memory. The latter memory elements allow the introduction of symbolic information. Symbol-grounding is realized by specific connections between the motivation unit of a Word-net and its partner motivation unit, representing the corresponding concept in the procedural (or the perceptual) memory.

Key characteristics of reaCog are modularity, heterarchy, redundancy, cross-modal influences (e.g., path integration and landmark navigation in Navinet), bottom-up and top-down attention control, i.e., the selection of relevant sensory inputs, as well as recruitment of internal models for planning. The complete control system constitutes a holistic system as the central selection control process—including the internal body-model—is implemented as an RNN. Overall, reaCog follows Anderson’s massive redeployment hypothesis (Anderson 2010), since large parts of the reactive control network structure are reused in higher-level tasks (as discussed in detail in section 4 for planning ahead and in section 10.3 for Theory of Mind).

ReaCog nicely demonstrates how complex behavior can emerge from the interaction of simple control networks and coordination on a local level, as well as through the loop through the environment. Its feasibility is shown through the implementation of the system at first in dynamic simulation (for Navinet on a two DoF, wheeled robot platform; for Walknet using a hexapod, twenty-two DoF hexapod robot). Second, those control networks are currently applied to a real robot, called Hector (Schneider et al. 2011).

Emergent properties are properties that are to be addressed using levels of description other than those used to describe the properties of the elements. In the reactive part of the system (Walknet, Navinet) we have already found

some emergent properties (development of different “gaits”, climbing over large gaps, finding shortcuts in navigation characterized as cognitive-map-like behavior) as well as forms of bottom-up and top-down attention. With respect to the notion of access consciousness, several contributing properties are present in reaCog. Most notably, planning ahead through internal simulation is central to reaCog. New behavioral plans are tested in the internal simulation, thus exploiting the existing internal model and its predictive capabilities. Only afterwards are successful behaviors applied on the real agent. In this way, the agent can deal with novel contexts and is not restricted to the hard-wired structure of the reactive system.

Furthermore, the system shows global availability, which means that elements of the procedural memory can be addressed even if they do not belong to the current context. A third property contributing to elements forming access consciousness concerns the ability of the system to communicate with an external supervisor by following (i.e., understanding) verbal commands and by reporting on its internal states. Therefore, except for the ability of linguistic reasoning, which is clearly missing, the issues characterizing access consciousness as listed by Cleeremans (2005) are fulfilled. But there are also disadvantages: (i) First, reactive automatic control is faster. As cognitive control involves internal simulation (and probably multiple simulations) the whole process takes more time. In addition, there is an overhead of higher-level control going on in contrast to reactive control. (ii) While access consciousness enables the system to deal with novel situations and to come up with new behaviors, the same processes might interfere when they are active during processing of the reactive control level. This might lead to worse performance when both levels are active at the same time. Both mentioned drawbacks have been confirmed in psychological experiments. We have not dealt with the subjective aspect of consciousness. But leaving this aside, we have shown how reaCog shows important constituent properties of access consciousness and how it may provide, in this way, a scaffold for a more complex system that

can manifest additional basic aspects of consciousness.

The property of having an internal body-model and the property of being able to internally simulate behavior have been explicitly implemented and can therefore not be considered emergent properties in our approach. However, when referring to a hypothetical evolutionary process that may have led to the development of these properties, the appearance of the body-model and of cognitive expansion might well be characterized as representing an emergent property.

We based our analysis and discussion on the perspective of Cleeremans, and used his concepts. One counter argument addressing the notion of access consciousness is that this notion is too unspecific as it does not help to distinguish between systems, and may cover “too many” systems. For instance, one may ask, following a minimalist approach, whether this notion of access consciousness might even include programs like chess-playing software. One might also ask whether there is a fundamental difference between such a system and a system like *reaCog*.

While both systems are able to search for the solution to a problem using internal simulation, there are indeed crucial differences. A typical chess program would be not embodied, but, obviously, today this difference can be easily overcome and the system could be realized in a robot equipped with a vision system and a hand that could move the chess figures.

However, more importantly, the basic difference between such a chess player and *reaCog* would be their flexibility in using internal models. A chess-playing robot always operates within the same context, which is stored in a separate memory-domain, for example in a list of symbolic rules. In contrast, *reaCog* basically operates with a reactive system, but can also switch to the state of internal simulation when a problem occurs. It then searches for a solution by testing memory elements not belonging to the actual context. In other words, *reaCog* is able to exchange information between different contextual domains. Such a switch is not available to a chess-playing program at all. Such a

program cannot distinguish between different contexts. In other words, there is no global accessibility in the sense described for systems showing access consciousness. As a consequence, the discussion of drawbacks connected with access consciousness as mentioned in the above paragraph on emergent properties, that is, issues (i), and (ii), is not applicable to such a chess-playing system, and nor are the dynamical effects observed in the experiments of [Beilock et al. \(2002\)](#) 1 (section 10.2).

The same holds for the phenomena of a psychological refractory period, attentional blink, and the masking experiments discussed earlier in section 7. None of these phenomena can be addressed by a classical chess-player system, first, because due to the different architectures, no search of a domain belonging to a different context is possible. A chess player does not meet the requirements of access consciousness as listed by [Cleeremans 2005](#) and represented by *reaCog*. Second, no specific dynamics can be found in such a chess-player system that could be made responsible for the dynamical effects mentioned above and which may provide the substrate for the occurrence of phenomenal experience. Therefore, both systems are qualitatively different. If at all, the chess player may correspond to a subsection of the symbolic domain of access consciousness, which has not yet been explicitly addressed in this article.

In an earlier paper ([Cruse & Schilling 2013](#)), taking a conservative position, we argued that properties of metacognition could not be found in the earlier version of *reaCog*. We have now provided some new arguments that permit a different position concerning this matter. Using this architecture, the agent is able to monitor internal states and use this information to control its behavior. Internal states may also be able to represent the agent itself. A first expansion allows representation of the activations of a partner by using the same procedure as is used for controlling the agent’s own behavior (application of “shared” circuits, “mirroring”). Furthermore, using an expansion proposed by [Cruse & Schilling \(2011\)](#), the agent is also able to exploit and represent knowledge about the internal states of others, specifically by applying ToM.

Cruse & Schilling (2011) have further shown how this network can be expanded to represent the discrimination between subject and object (e.g., Ego push Partner) and to attribute subjective experience (e.g., pain) to the partner using a shared body-model. A further expansion that allows for mutualism—two agents cooperate to reach a common goal (“shared intention”, Tomasello 2009)—requires two body-models, corresponding to what Tomasello calls a we-model.

In the remainder of this section we briefly mention some aspects not addressed by reaCog. First, not all combinations of the elements explained for our network have been tested within the complete system. For example, Walknet and Navinet have been tested in separate software and hardware simulations. Second, we concentrated on solving motor problems alone, and did not deal with how this system could solve problems in the symbolic domain at all. From an embodied point of view, this restriction is not as problematic as it might initially seem, as the solution process for many problems can be traced back to abilities that are based on solving motor tasks (Glenberg & Gallese 2011); for example this holds true even for abstract domains such as mathematical problem-solving (Lakoff & Nunez 2000).

Finally, an important aspect not addressed here in any detail concerns how learning of the memory elements, including the weight of the motivation unit network, is possible. Examples of learning position and quality of new food sources in Navinet are given by Hoinville et al. (2012), examples of learning perceptual networks, including the heterarchical arrangement of concepts, are given by Cruse & Schilling (2010a), but introduction of the ability to learn such properties within the complete system has not yet been introduced.

12 Conclusion

We describe a way to construct an artificial agent whose architecture is characterized by a number of local, reactive procedures controlled by an RNN, termed motivation unit network. This network is able to adopt various attractor

states, or internal states, which are able to protect the complete system from sensory input not belonging to the current internal state. No strict hierarchy can be observed in this network. Instead, internal states may be represented by partly overlapping state vectors.

Where required, further procedures have been introduced that can be interpreted as forming explicit representations of parts of the environment. Specifically, an internal model of the agent’s own body is introduced that can, as a “manipulable” body-model, be used for planning new behaviors via internal simulation. Internal manipulation is possible because the body-model, like a marionette puppet, able to adopt all configurations the real body can assume. This expansion allows the agent to switch between reactive control and cognitive control (in the sense of McFarland & Bösner 1993).

When aiming to study higher mental properties, at least in human beings, we have to deal with the phenomenal aspect of these properties. A number of experimental results suggest that, i) some, but not all neuronal activities are, under specific—and unknown in any detail—conditions equipped with a phenomenal aspect, i.e., show subjective experience, but that ii) there is no specific function of this phenomenal aspect apart from the functions that can be ascribed to the physical properties of the system. Note that this does not mean that the phenomenal aspect has no function. Rather, a network adopts the function only when, at the same time, the phenomenal aspect is given. This view allows us to focus the analysis on the functional aspect of the procedure (see section 7). However, due to our lack of knowledge, as an external observer we cannot decide whether a given internal state is a mental state or not (if mental states are understood as internal states that are equipped with a phenomenal aspect).

The complete network represents a collection of hypotheses that can be tested by comparing their properties with experimental data and by trying to match them with theoretical concepts. Examples studied in this article concern behaviors that, for an external observer, may be conceptualized as various gait patterns, or navigation using an internal map, on the

“lower” level. On a higher level, we deal with inventing new behaviors and planning ahead, as well as phenomena attributed to mental states like emotions, attention, intention, and volition. Last but not least we compare the properties of our approach with different aspects of consciousness, such as access consciousness (including global accessibility) and metacognition. We claim that, at least in their basic form, these phenomena can be attributed to internal states emerging from the cooperation of decentralized elements of our network.

The “Bottom-Up” Approach to Mental Life

A Commentary on Holk Cruse & Malte Schilling

Aaron Gutknecht

With their “bottom-up” approach, Holk Cruse and Malte Schilling present a highly intriguing perspective on those mental phenomena that have fascinated humankind since ancient times. Among them are those aspects of our inner lives that are at the same time most salient and yet most elusive: we are conscious beings with complex emotions, thinking and acting in pursuit of various goals. Starting with, from a biological point of view, very basic abilities, such as the ability to move and navigate in an unpredictable environment, Cruse & Schilling have developed, step-by-step, a robotic system with the ability to plan future actions and, to a limited extent, to verbally report on its own internal states. The authors then offer a compelling argument that their system exhibits aspects of various higher-level mental phenomena such as emotion, attention, intention, volition, and even consciousness.

The scientific investigation of the mind is faced with intricate problems at a very fundamental, methodological level. Not only is there a good deal of conceptual vagueness and uncertainty as to what the explananda precisely are, but it is also unclear what the best strategy might be for addressing the phenomena of interest. Cruse & Schilling’s bio-robotic “bottom-up” approach is designed to provide answers to such questions. In this commentary, I begin, in the first section, by presenting the main ideas behind this approach as I understand them. In the second section, I turn to an examination of its scope and limits. Specifically, I will suggest a set of constraints on good explanations based on the bottom-up approach. What criteria do such explanations have to meet in order to be of real scientific value? I maintain that there are essentially three such criteria: biological plausibility, adequate matching criteria, and transparency. Finally, in the third section, I offer directions for future research, as Cruse & Schilling’s bottom-up approach is well suited to provide new insights in the domain of social cognition and to explain its relation to phenomena such as language, emotion, and self.

1 Biorobotics and the bottom-up approach to mental life

From my perspective, there are two basic ideas underlying the overall research strategy entertained by Cruse and Schilling. The first is that in order to understand a system and its properties, it has to be *reinvented* or *reconstructed* by the researcher. The second is that mental phe-

nomena may arise as *emergent* properties via the interaction of low-level components of a system. I’d like to first provide an outline of these basic ideas and the underlying strategy as I understand them. In the next section, I will critically evaluate what types of questions the ap-

proach is best suited to answer, and what kind of problems it will likely face.

The first of the two main ideas is central to the research area of bio-robotics. If we are able to create an artificial system that exhibits the phenomena of interest, we should be a great deal closer to understanding how these phenomena come about in nature. In order for this approach to lead to valid conclusions, however, the process of reconstruction has to do justice to the systems we are seeking to understand. In the present context we are concerned, above all, with humans and other animals. This means that the way the artificial system achieves the desired results has to be biologically plausible, i.e., it has to be reasonable to assume that the capacities of the organism that we are trying to understand are really based on similar mechanisms. In this vein, [Cruse & Schilling \(this collection\)](#) are realising the basic reactive modules of their system in form of artificial neural networks that were inspired by biological research on, for instance, stick insects (Walknet) and desert ants (Navinet).

The second of the basic ideas derives its plausibility from an evolutionary perspective on psychological faculties. Emotion, attention, the ability to plan future actions, and any other “higher-level” capacities, including consciousness, did not arise suddenly from one generation to the next and independently of pre-existing, more fundamental abilities, such as the ability to control one’s own body and respond adaptively to environmental stimuli. Rather these latter abilities and the interactions between the mechanisms responsible for them might well have been crucial for mental properties to evolve. From this perspective, the idea of reconstructing the evolutionary process by starting with basic reactive structures and examining how through the interaction of these structures unexpected properties might *emerge* seems very promising. Since humans also gradually evolved from simpler organisms, it is natural to assume that the same dependence between reactive structures and “higher-level” phenomena is present in our case as well. The investigation of this dependence might thus provide new insights into the mechanisms underlying human psychology.

But what does it mean exactly to say that a property *emerges* from basic structures? What is an emergent property? The philosophical controversies surrounding the concept of emergence date back over a hundred years and although usage of the term has become increasingly popular in recent years, among both philosophers and scientist, it can hardly be said to have one universal definition. Rather, there are numerous and varied interpretations, a fact which inevitably leads to confusion and misunderstanding (for a good overview see [O’Connor & Wong 2012](#)). It is thus vital to identify precisely what is meant by emergence in any particular case. Notwithstanding this inherent ambiguity, there seems, however, to be a shared idea behind much talk of emergent properties: this is the idea that as systems become increasingly complex they tend to exhibit certain higher-level properties, which are novel or unexpected given their simpler, lower-level, components.

Depending on how this claim is interpreted it can have more or less serious implications regarding the fundamental structure of nature, as well as the structure of science. In order to obtain a particularly strong and at the same time highly influential reading, it must be understood in a two-fold sense. First, as meaning that these properties cannot *even in principle* be predicted or explained on the basis of the lower-level properties of the system and, second, as indicating that such properties are associated with genuinely *new causal powers*, i.e., they make a real difference to the run of events and are not mere epiphenomena (for discussion see [Kim 1999, 2006](#)).¹ This kind of emergence could be called *strong emergence*.² Central to this conception is that emergent properties causally influence the simpler entities from whose organisation they emerge. This sort of causal influence is called “downward causation”, as emergent properties are conceived as

¹ Such conceptions go back to thinkers such as Samuel Alexander, C. L. Morgan, and C. D. Broad, prominent figures in a philosophical movement, which came to be known as “British emergentism”. The following discussion is, however, intended to illustrate the problematic nature of the concept of emergence and not to offer an analysis of the ideas of a particular philosophical school.

² It should be noted that there is no universal definition of the term “strong emergence” in the current literature (for some alternative characterisations see [Chalmers 2006](#); [Bedau 1997](#); [Yates 2013](#)).

higher-level properties arising from certain lower-level properties and relations. Typically, it is assumed that what we find at the lowest level of this hierarchy are the properties and relations of fundamental physical particles. Given this assumption, the existence of emergent properties would entail that a complete description of the fundamental physical organisation of a system might still leave something out. The system might still have some properties that could not be predicted on the basis of such a description and could not be explained in terms of the organisation of its basic physical constituents. Moreover, because emergent properties are causally efficacious, knowledge of the basic physical components of a system and their behaviour may not be sufficient to predict the future evolution of the system. These considerations seem to lead to the conclusion that the meta-scientific thesis, according to which all phenomena can ultimately be explained by the fundamental laws of physics, would turn out to be false. If certain properties belonging to the domains of psychology, biology, or chemistry were emergent properties, these could not even in principle be captured by basic physics alone. All sciences dealing with genuinely emergent properties would remain completely autonomous, positing their own independent laws and explanations. Furthermore, since emergent properties have the ability to causally influence lower-level entities, the fundamental laws of physics would not even suffice to explain processes taking place at the *physical* level (see also [Chalmers 2006](#)).

These are substantial conclusions that could be met with some scepticism. They are also one of the reasons for the fierce controversy surrounding the concept of emergence. Furthermore, the condition that emergent properties are themselves causally efficacious and the general idea of “downward causation” leads to problems in and of itself. This is because there has to be a systematic relationship between emergent and lower-level properties, even though they are conceived as being distinct from another. Often this is expressed by saying that emergent properties are completely determined by lower-level properties and require

them for their existence. In other words, if all lower-level properties of a system are fixed, its emergent properties are also fixed; and without any appropriate lower-level properties, a system cannot have emergent properties. If this weren't the case, it would be unclear in what sense emergent properties *emerge from* lower-level ones ([Kim 2006](#)). If their relationship were completely coincidental, this would surely be an inappropriate description.

Based on this requirement, [Kim \(1999, 2006\)](#) has put forth an influential argument that the idea of “downward causation” is untenable. In summary, Kim's basic argument is this: suppose an emergent property (let's say a feeling of thirst) causes a lower-level property (e.g., a certain activation pattern N in the brain). If feeling thirsty is an emergent property, there have to be appropriate lower-level properties from which it emerges. Let's call these the “emergence base” of feeling thirsty. Now, that feeling thirsty causes N means that there is a natural law that occurrences of feeling thirsty are always followed by occurrences of N (feeling thirsty is nomologically sufficient for N). But since occurrences of feeling thirsty are always accompanied by occurrences of its emergence base, it must also be true that occurrences of its emergence base are followed by occurrences of N. Therefore, if feeling thirsty causes N, its emergence base also causes N. But this makes feeling thirsty completely redundant as a cause of N. Its emergence base is completely sufficient to explain N's occurrence, leaving the feeling of thirst as a mere epiphenomenon. Since this example can easily be generalised, one can conclude that there are no genuine cases of downward causation and hence no genuine emergent properties of the type presently under consideration.

In summary, it can be stated that emergence is a highly controversial concept—not only because of its inherent ambiguity, but also on account of certain varieties of emergentism that have substantial metaphysical and meta-scientific implications as well as a commitment to the problematic idea of downward causation. The crucial questions remaining now are whether [Cruse & Schilling \(this collection\)](#)

provide a clear interpretation of the concept of emergence and whether it provokes the kind of controversy and criticism outlined above. What kind of emergence is involved in their claim that mental states might be construed as emergent properties? In fact, they provide two slightly different characterisations. According to the first, an emergent property is to be understood as a property of a whole system that cannot, *at first sight*, be traced back to the interactions of the systems components. Alternatively, one might say that we cannot, at first sight, predict the emergent properties of a complex system based on our knowledge of its parts and their interaction. Thus, we might be genuinely surprised that the system in question exhibits such properties. Emergence in this sense is sometimes called *weak emergence* (Chalmers 2006). If this is all that it means for a system to have emergent properties, few would raise serious objections. This sort of emergence is just a consequence of our limited knowledge and cognitive capacities and is relative to the judging subject: what might not be immediately predictable for one person might be just so for another. Emergentism, in this sense, has no far-reaching metaphysical or meta-scientific implications and is not committed to any sort of “downward causation”.

Cruse & Schilling (this collection) provide a second, and equally unproblematic, definition of emergence that is specifically tailored for application in the context of robotics. According to that definition, a property of an artificially constructed system is emergent if it was not explicitly implemented by its designers. We might call this *implementational emergence*. This appears to be relatively independent of the sort of “weak” emergence I’ve just described. Even a property not explicitly implemented might be predictable without too much effort, whereas a property deliberately implemented might not be predictable, at least by persons lacking experience or competence. I think that most of the emergent properties Cruse & Schilling (this collection) attribute to their artificial system, reaCog, match both characterisations: they were neither explicitly implemented nor would we immediately expect or predict that reaCog would

exhibit them. At the same time, the properties in question are highly interesting and are not simply insignificant side effects. This is important since, according to the definitions provided by Cruse & Schilling, the claim that an artificial system exhibits emergent properties is, *in and of itself*, not particularly notable. But this depends entirely on what the emergent properties in question precisely are. The finding that reaCog exhibits, in this way, aspects of psychological characteristics, such as emotion or attention and the ability to perform non-trivial body movements, are most certainly of considerable scientific significance. In conclusion, we may say that although the kind of emergentism advocated by Cruse & Schilling does not have the same far-reaching implications as the particularly demanding conception outlined above, it is nonetheless useful and philosophically interesting. This is because it functions as the basis of an intriguing approach to the study of psychological properties, which I shall now endeavour to describe.

Combining the idea of emergence with the idea, outlined above, that in order to understand a system and its properties, it has to be reinvented or reconstructed, we arrive at a fascinating research strategy. The first step consists in observing the behaviour of animals that, although lacking many of the sophisticated abilities with which humans are endowed, are nonetheless capable of flexibly controlling their bodies in order to cope with an unpredictable environment (such as stick insects, desert ants, and honey bees). Based on these observations one then develops a neural network model (e.g., Walknet or Navinet) designed to produce the behaviour observed in the first step. Next, this model is realised in an artificial system (either virtual or robotic) in order to examine to what extent the behaviour produced by the model matches the behaviour of the biological organism on which it is based. If it resembles it to a great extent, this can be taken as *prima facie* evidence that the mechanisms underlying the behaviour are the same for the animal and the robot. Different modules that are constructed in this way are then integrated into a holistic system. Further modules might be added step-by-

step (e.g., Body Model, Attention-Controller, Word-Nets). The result is a complex system (in the present case “reaCog”) the behaviour and properties of which cannot be easily predicted even by its very own designers. The last, and most important step consists of examining whether the system shows characteristics that were not explicitly implemented but instead arise from the dynamic interactions of the system’s components. The most intriguing question in this context is, of course, whether the final system shows aspects of those phenomena that are constitutive of *having a mind*.

Although this is only a rough sketch of the methodology entertained by Cruse & Schilling (this collection), I hope I have captured the essential points sufficiently to proceed with an evaluation of its scope and the possible problems it might face. What kind of questions is the bottom-up approach best suited to answer? Which phenomena or processes can be addressed by research based on this approach? What considerations have to be taken into account in order for the presented research strategy to be successful? Are there any general constraints bio-robotic bottom-up explanations have to meet? As we shall see, the answers to these last two questions are directly connected to two characteristics of the research strategy outlined in the previous paragraph: first, that it involves, at two points, a comparison of the behaviour of significantly different systems and, second, that it is specifically designed to discover emergent properties.

2 The bottom-up approach: Objectives, benefits and constraints

2.1 Mechanisms and the evolution of the mind

The most important aspect of the proposed approach is that it helps to elucidate the *mechanisms* underlying various mental properties. This is possible because many of the basic features of the control system reaCog are known. Using the words of Cruse & Schilling (this collection), it constitutes a “quantitatively defined system”. As all components are realised as artificial

neural networks, all information about the number of neurons, the connection weights between them, and the way individual neurons process information is available. More importantly, however, the basic functional architecture of the system is well understood. Which modules are connected in which ways to other modules, how they receive their input, and what other parts of the system might be affected by their outputs does not have to be figured out by painstaking investigation—as is the case in biological research. Because these facts about reaCog are known, it is possible to provide detailed mechanism descriptions. In this way, reaCog’s ability to plan its future actions by internal simulation can be explained by reference to the interaction of its various sub-modules: a problem detector is activated when sensory input indicates that current behaviour will lead, if continued, to adverse effects for the system (e.g., falling over). This leads to the abortion of current behaviour and activation in the Spreading Activation Layer, which randomly excites the Winner-Takes-All network (WTA-net). After some time, the WTA-net adopts a relaxed state in which only one of its units is active. This active unit in turn stimulates its counterpart in the Motivation Unit Network, leading to activity of the corresponding reactive procedures. These provide motor output that can be redirected to the body model, which then simulates the execution of the proposed behaviour and predicts its likely consequences. If the system predicts that the problem will persist, the process of internal simulation goes on until a solution is found, which can then be used to control the actual movements of the system.

Explanations like these contain a lot of information about which functional subparts of a system are engaged during the exercise of the ability in question. In this particular case it makes clear how the ability to plan ahead, a cognitive ability, depends heavily on basic reactive structures that are designed to control specific leg movements as well as an internal model of the body. The same is true for various other capacities like attention and Theory of Mind. Thus, new insights into the mechanisms responsible for those phenomena in humans could

be gained by considering how body models and motor control mechanisms are realised in our case and how these systems interact. In other words, the bottom-up approach may lead to new directions for future research concerning human psychology by suggesting how specific functional modules interact in order to bring about a particular target phenomenon. Whether this approach is tenable depends on the degree to which findings pertaining to the artificial system might legitimately be used to draw conclusions about human beings. I will propose a number of constraints to ensure that this condition is fulfilled below.

Another class of questions that a bottom-up strategy is well designed to answer has to do with the evolution of cognitive capacities: how did cognitive systems evolve from purely reactive systems? How did emotions, attention, or even consciousness arise? What are the natural precursors of these phenomena? Cruse & Schilling (this collection) show convincingly that no completely new neural modules are needed in order for such properties to occur. Rather, minor changes in the basic architecture might suffice to generate radical extensions of the abilities of a system. In this way, a reactive system with a body model can acquire the ability to plan ahead if it is able to disconnect its motor system from the physical body and instead send the motor signals to its internal body model. No novel “planning module” is needed. Already existing modules just have to become dissociable and can thus acquire new functions (Cruse 2003). In addition, the target paper suggests an answer to the question of the evolutionary function of cognition understood as the ability to plan ahead: it was the necessity of being able to control a complex body in a complex environment that made this ability highly valuable. Detecting problems by perception, finding innovative solutions by internal simulation and acting on them are capacities that are extremely advantageous for any organism possessing a body with a high number of redundant degrees of freedom (see Cruse 2003). This is in line with, and actually extends, the widespread assumption that the evolutionary function of cognition is to deal with environmental complexity (Godfrey-Smith 2002).

2.2 Constraints on bio-robotic bottom-up explanations

In the previous paragraph we saw that the framework Cruse & Schilling (this collection) present is well-equipped to give new insights into the underlying mechanisms of psychological phenomena and the evolution of cognition, as well as a promising approach to creating highly flexible and intelligent robots. There are, however, some problems the proposed strategy has to face, especially if the control structures become increasingly complex. I therefore want to suggest a set of three constraints on good bottom-up explanations of biological/psychological phenomena.

1. *Adequate matching criteria*.³ At two points the research strategy described in section 1 involves a comparison between the behaviour of an artificial system on the one hand and a biological system on the other. First, this is the case in the development of neural network models of animal behaviour. In this context, the comparison is used to ascertain whether the proposed model of the mechanisms underlying certain capacities (e.g., walking) really reproduces the original behaviour of the animal (e.g., a stick insect). Second, there is a similar process of comparison involved in the application of psychological concepts to the complete system. At different points in their discussion, Cruse & Schilling (this collection) argue that their system has certain mental capacities because it exhibits behaviour (or would exhibit it if certain extensions were implemented) connected to those mental capacities in humans. So, for example, just as the performance of athletes might worsen if they consciously attend to what they are doing, the activation of the attention controller in *reaCog* can lead to poorer results compared to unimpeded execution of the reactive procedures.

Both processes of comparison require criteria to identify when the behaviour of the artificial system and that of the biological system

3 I credit this term to Datteri & Tamburrini 2007.

are relevantly similar, i.e., similar enough in order to provide evidence for the claim that similar mechanisms are at work in both cases or that the artificial system and the biological system share certain psychological characteristics (Datteri & Tamburrini 2007). The difficulty of finding such criteria increases the more the bodies of the compared systems differ. In some cases they might nonetheless be easy to find and relatively uncontroversial. This, however, is not always the case. For instance, in their discussion of emotions—and more specifically the emotion of happiness—Cruse & Schilling (this collection) suggest that by increasing the threshold of the problem detector reaCog would take more risks, thus behaving similarly to humans when they are happy. Now, the question is whether the kind of risky behaviour exhibited by reaCog when the threshold of its problem detector is increased is the same kind of risky behaviour humans exhibit when they are happy. Only if this condition is fulfilled can the similarity be taken as evidence that reaCog shows aspects of the emotion of happiness.

2. *Biological plausibility*: Any proposed mechanism should be biologically plausible, i.e., it has to be reasonable to assume that the capacities of the organism that we are trying to understand are really based on such a mechanism. This can, at least to some degree, be ensured by trying to create similarities between the artificial and the biological organism on a basic structural level, for example by using artificial neural networks. Furthermore, it is necessary to decide how fine-grained the model should be. Should the model take brain structures, neurons, or sub-cellular elements as its basic building blocks? Should intracellular processes be neglected or are they important? The answer will of course always be relative to our particular epistemic goals. Finally, there are different options regarding the way artificial neurons process information, i.e., how they calculate their output value depending on the weighted sum of their inputs. All these factors might turn out to be important if the results are to

be used to infer biological mechanisms. The requirement of biological plausibility shouldn't, however, be overemphasised. Cruse & Schilling (this collection) stress that they are not trying to present a realistic model of neuronal activity in living organisms. Hence, they are using biologically implausible, non-spiking artificial neurons as the basic elements of their architecture, while noting that some authors (referring to Singer 1995) have located the neural basis of consciousness in synchronously oscillating spikes. This, however, is not a weighty objection to the proposed approach since it is designed as a *functional approach*. The question is: how do different functional subsystems like a system for controlling the swing-movement of a leg, a system modelling the robot's body, and a system allowing for the selection of different internal states interact in order to produce certain emergent phenomena? Therefore, the concrete physical realisation of these subsystems is of only secondary importance.

3. *Transparency*:⁴ Doubts about the strategy of using artificial systems in order to understand biological systems arise because even if we were to create an extremely intelligent robot, it would not necessarily help us to understand the mechanisms underlying its intelligence. Rather, we might be faced with yet another complex system whose workings we do not understand (Holland & Goodman 2003). Now, the approach Cruse & Schilling (this collection) present is specifically designed to discover emergent properties, i.e., properties that were not explicitly implemented. This means that there will be a high risk of finding properties in the complete system that cannot be readily provided with a clear-cut mechanistic explanation involving the co-operation of the system's components. Although the explanations of the occurrence of various psychological properties presented in the present paper are quite convincing, the

4 The concept of transparency has a number of other well-established interpretations in the literature that should not be confused with the one at issue in the present context. These include, for example, "semantic" (Clark 1989) and "phenomenal" (Metzinger 2004) transparency.

bottom-up strategy might eventually exhaust its potential if the complexity of the system is further increased.

3 Future perspectives: The social insect

I would like to conclude by briefly proposing a perspective for future research based on the system *reaCog*. As presented, its ability to interact and cooperate with other agents is fairly restricted. At the same time, the pre-requisites of a broader social extension of the system seem to be in place. The present paper already shows how *reaCog* could be equipped with the capacities to recognize the behaviour of others and apply a Theory of Mind. In their 2011 paper, Cruse & Schilling further propose that by implementing a two-body model (a “We-model”) *reaCog* might be capable of cooperative behaviour using shared goals. Integration and further expansion of such social capacities, and their application in an actual robot, seems promising considering the importance of social interaction in processes such as language acquisition and emotional regulation. Some have even suggested that the presence of other agents in the environment, or, in other words, dealing with social complexity, was a dominant factor in the evolution of sophisticated cognitive abilities (Humphrey 1976). Thus bio-robotic research in this direction might provide new insights into the mechanisms underlying such developmental and evolutionary processes. Moreover, a social extension of *reaCog* might eventually shed light on potential emergent phenomena *on a group level*, such as labour division, collective planning, social hierarchies and, most fundamentally, joint action coordination. What high-level social phenomena emerge when multiple bio-robotic systems like *reaCog* interact with each other?

Cruse and Schilling’s system seems particularly well-suited to further illuminate motor theories of social cognition. According to such theories, the important social cognitive capacity of understanding another’s actions is directly linked to mechanisms that are active when the observer performs similar actions (Gallese et al. 2004; for criticism see Jacob & Jeannerod

2005). The underlying neural mechanism has come to be known as the mirror-neuron system. Furthermore, there is evidence that the mirror-neuron system plays a role in certain aspects of self-consciousness. For instance, Uddin (2007; see also Molnar-Szakacs & Uddin 2013) suggests that this is the case for representations of the physical self, and ascribes frontoparietal mirror-neuron areas an important function for self-recognition (especially the recognition of one’s own face). As mirroring mechanisms can be integrated in *reaCog* as well, this opens the possibility of further investigating motor theories of social cognition and the relation between internal motor simulation and the self in a quantitatively defined system.

An ability that is highly important for human social interaction is the ability to communicate using language. At this point, the linguistic capacities of *reaCog* still seem quite inflexible and limited in scope. A highly interesting extension of this system would be to provide it with the means to learn words and their meanings by interaction with other agents. Some of the pre-requisites, like the ability to internally simulate the behaviour of others, could, as Cruse and Schilling argue, be implemented in *reaCog* by using its internal body-model to represent another agent. Robotic research in this direction was performed by Steels & Spranger (2009). Their artificial systems are capable of autonomously acquiring a simple language consisting of words for specific body postures. After learning is complete, the artificial agents are able to reliably assume body postures on verbal command by other agents. Since social learning has also been implicated in the process of concept formation (Steels 2002), the proposed extension might also foster our understanding of this intriguing phenomenon.

4 Conclusion

In conclusion it can be stated that Cruse & Schilling (this collection) present a highly fascinating research strategy that is well worth pursuing. The bottom-up approach can provide us with new insights regarding the functional mechanisms underlying psychological phenom-

ena and their evolution. Although the notion of emergence is central to it, Cruse & Schilling ([this collection](#)) avoid the philosophical controversies surrounding this concept by interpreting it in a less demanding, yet interesting and useful way. There are, however, a number of constraints that explanations based on the bottom-up approach have to meet. First, since Cruse & Schilling's ([this collection](#)) strategy involves, at two points, a comparison between markedly different systems, criteria are needed according to which we can determine whether the two systems exhibit relevantly similar behaviour. Second, the structural architecture of the artificial system must have an adequate degree of biological plausibility. And finally, it has to be ensured that increasing the complexity of the system does not lead to the practical impossibility of elucidating the mechanisms underlying its emergent properties.

A promising next step for bottom-up research as presented by Cruse & Schilling ([this collection](#)) would be to take it to the level of social interaction. An extensive social extension of their system could shed light on a wide range of intriguing phenomena. Is it possible to discover emergent properties on a group level? In what precise way are mirroring mechanisms involved in social cognition? What role do such mechanisms play for the phenomenon of self-consciousness? What role do reactive structures and internal body-models play in the processes of language acquisition and comprehension? Of course this is only a small selection of the questions further bio-robotic research might contribute to answering. Cruse & Schilling ([this collection](#)) made clear that starting from the bottom is a strategy with enormous scientific significance. There is no doubt that this work will make an important contribution to a plethora of research projects in the future.

The Bottom-Up Approach: Benefits and Limits

A Reply to Aaron Gutknecht

Holk Cruse & Malte Schilling

Aaron Gutknecht supports our bottom-up approach, specifies possible limits and highlights interesting future aspects. His added perspective is valuable and interesting to us. As we fully agree with his view, we only add some complementary remarks.

1 Introduction

We appreciate the comments given by Aaron Gutknecht very much, in particular his discussion and clarification of the term “emergence” and its philosophical background. This discussion comprises a sensible completion of our article going beyond the scope of our expertise. In this context, Aaron Gutknecht correctly states that our way of

using the term “emergence” may cover two aspects, one called “weak emergence”, the other he addressed as “implementational emergence”. We have – possibly forming some kind of common denominator – a third characterization in mind, one that covers different description levels: a phenomenon is considered emergent if it turns out

that known properties of the network could also be characterized on a different level of description than the one currently used. On this different level the phenomenon conceptually constitutes a term or definition. If we, for example, describe the structure and function of reaCog on the neuronal level, we may realize at some point that there are behavioral aspects which could, by an outside observer, be characterized by a term that is not defined at a neuronal level of description, such as, for example, “intention”.

2 The bottom-up approach

This way of using the term emergence is directly related to the bottom-up approach applied here. This approach is inspired by Feynman, who stated that we understand a system only when we are able to construct it (in [Hawking 2001](#)) and may be even dated back to [Giambattista Vico \(1710\)](#). The bottom-up approach allows us to study the extent to which linguistic concepts proposed in the literature may correspond to properties realized by our artificial system. If one was not prepared to accept that a specific concept would correspond to selected properties of the artificial system, either the linguistic concepts might be adapted accordingly, or the artificial system might be judged as to show deficits. The latter case could then give rise to adapt the current simulation model to better match the verbal proposal given. This capability of the bottom-up approach led [Manuela Lenzen \(2014\)](#) to characterize reaCog as a “concept clarifying machine” (“Begriffspräzisierungsmaschine”).

3 Possible limits of the bottom-up approach

Aaron Gutknecht further proposes a well-chosen list of issues that should be taken into account when following a bottom-up approach as proposed here, namely “adequate matching criteria”, “biological plausibility” and “transparency”.

Concerning the first issue, “adequate matching criteria”, Aaron Gutknecht addresses a possibly critical point. In section 8 (*Emotions*), we characterize happiness by the property that risky decisions are made more probable. We admit that

our example is formulated in a sketchy way, only addressing one basic aspect for illustration. There are, however, more deeply founded examples that have been briefly referred to in the main text and will be explained in more detail here. Two recent studies, one in crayfish, the other in the fruitfly, provide strong hints that emotion-like states can be found in simple organisms as arthropods or, more specifically in the latter-case, insects. In crayfish, [Fossat et al. \(2014\)](#) have convincingly shown that context-independent, anxiety-like behavior can be induced by experimentally applied stress or by application of serotonin. Both methods lead the animals to avoid illuminated sections of their environment which they are normally interested to explore. Anxiety is related to fear but considered a secondary emotion that occurs after the stressing signal has disappeared. Thus, the probability of selecting specific behaviors, in this case exploration of illuminated places, is decreased. This avoidance behavior could be abolished after application of drugs that are known to have anxiolytic effects in mammals. Applied to reaCog, these results could be interpreted in the following way. Emotion-like states would not only influence the global WTA net, but also thresholds of local, lower level WTA networks that are responsible for switching between different procedures.

Another interesting case has been reported by [Yang et al. \(2014\)](#) in *Drosophila*. These animals learnt that various behaviours selected in trying to avoid a problem, in this case escape from a heated ground, were not successful. As a consequence, they ended up in a state of passivity. This result has been discussed as an example of “learned helplessness”, which is considered an animal model of depression. In our framework, this could simply be realized by freezing activity in the Spreading Activation Layer network that provides input to the WTA net (section 4).

Concerning the second issue, “biological plausibility”, we fully support Gutknecht’s perspective and have only a minor aside. Application of non-spiking neurons is not necessarily biologically implausible. Rather, non-spiking neurons do exist in invertebrate and in vertebrate brains. They play important functional roles, but are generally less well-known, mainly

because investigating them involves methodological problems that are more difficult than those of spiking neurons. The third issue, “transparency”, addresses the view that the bottom-up strategy may eventually exhaust its potential when the complexity of the system is further increased. Although we agree with Gutknecht here, we would like to add that the bottom-up approach still bears the advantage that, as the details of such a system are known, its properties can be thoroughly analyzed by physical and/or mathematical methods. This ability, of course, does not guarantee that one will find answers in such a hypothetical case, but there are various methods available to address such questions. Further, we believe that the problem of lacking transparency may not happen to occur too often. This belief is supported by the observation that already our simple system, *reaCog*, appears to be able to reach integration levels characterized by terms such as intention, volition and consciousness.

4 What should be done next?

Aaron Gutknecht closes his comments by considering future aspects. Again, we agree with his recommendations and have, partly, indeed started with two of the aspects addressed. We applied the internal model in a cooperative scenario in which the visual impression of another agent performing an action was mapped onto the system’s own internal body model. In this way the internal model was driven by the visual input and the internal model reenacted what the other agent was doing. This mapping allows one to connect the experiences of somebody else to one’s own action repertoire as one steps into the shoes of the other (Schilling 2011; see also Gallese & Cuccio this collection). Second, as mentioned in the main text, shared circuits are required for an agent to represent the action of a partner (Cruse & Schilling this collection, figure 9). In order to allow for ToM, an additional separate representation of the partner’s memory is required (figure 10). To be able to apply a supermodel (or we-model, Tomasello 2009), a more complex model is required (see Cruse & Schilling 2011, figure 6).

5 Conclusion

The bottom-up approach advocated here to understand higher-level phenomena may be considered a non-Platonic approach that aims to construct artificial, but strongly biologically inspired systems. These systems should be able to simulate complex behavioral tasks, but do so by application of simple elements, artificial neurons, and a simple decentralized neuronal architecture. If successful one could then study whether more abstract concepts introduced in psychology or philosophy, for example, could sensibly be applied to such a system. We claim to have shown an example supporting this approach.

Why and How Does Consciousness Seem the Way it Seems?

Daniel C. Dennett

Are-expression of some of the troublesome features of my oft-caricatured theory of consciousness, with new emphases, brings out the strengths of the view and shows how it comports with and anticipates the recent introduction of Bayesian approaches to cognitive science.

1 Introduction

People are often baffled by my theory of consciousness, which seems to them to be summed up neatly in the paradoxical claim that consciousness is an illusion. How could that be? Whose illusion? And would it not be a *conscious* illusion? What a hopeless view! In a better world, the principle of charity would set in and they would realise that I probably had something rather less daft in mind, but life is short, and we'll have one less difficult and counterintuitive theory to worry about if we just dismiss Dennett's as the swiftly self-refuting claim that consciousness is an illusion. Other theorists, including, notably, [Nicholas Humphrey \(2006, 2011\)](#), [Thomas Metzinger \(2003, 2009\)](#)

and [Jesse Prinz \(2012\)](#), know better, and offer theories that share important features with mine. I toyed with the idea of trying to re-offer my theory in terms that would signal the areas of agreement and disagreement with these welcome allies, but again, life is short, and I have found that task simply too much hard work. So with apologies, I'm going to restate my position with a few new—or at least newly emphasized—wrinkles, and let them tell us where we agree and disagree.

I take one of the usefully wrong landmarks in current thinking about consciousness to be Ned Block's attempt to distinguish “phenomenal consciousness” from “access consciousness.”

His view has several problems that I have pointed out before (Dennett 1994, 1995, 2005; Cohen & Dennett 2011), but my criticisms have not been sufficiently persuasive, so I am going to attempt, yet again, to show why we should abandon this distinction as scientifically insupportable and deeply misleading. My attempt should at least help put my alternative view in a better light, where it can be assayed against the views of Block and others. Here is the outline, couched in terms that will have to be clarified and adjusted as we go along:

1. There is no double transduction in the brain. (section 1)
Therefore there is no second medium, the medium of consciousness or, as I like to call this imaginary phenomenon, the *MEDium*. Therefore, qualia, conceived of as states of this imaginary medium, do not exist.
2. But it seems to us that they do. (section 2)
It seems that qualia are the source or cause of our judgments about phenomenal properties (“access consciousness”), but this is backwards. If they existed, they would have to be the *effects* of those judgments.
3. The seeming alluded to in proposition 2 is to be explained in terms of Bayesian expectations. (section 3)
4. Why do qualia seem simple and ineffable?
This is an effect, a byproduct, an artifact of “access consciousness.” (section 4)
5. *Whose* access? Not a witness in the Cartesian Theater (because there is no such functional place). (section 5)
The access of other people! Our “first-person” subjectivity is shaped by the pressure of “second-persons”—interlocutors—to have practical access to what is going on in our minds.
6. A thought experiment shows how even color qualia can be understood as Bayesian projections.

2 There is no double transduction in the brain

The arrival of photons on the retina is transduced thanks to rhodopsin in the rods and

cones, to yield spike trains in the optic nerve (I’m simplifying, of course). The arrival of pressure waves at the hair cells in the ear are similarly transduced into spike trains in the auditory nerve, heat and pressure are transduced into yet more spike trains by subcutaneous receptors, and the presence of complex molecules in the air we breathe into our noses is transduced by a host of different transducer molecules in the nasal epithelium. The common medium of spike trains in neuronal axons is well understood, but used to be regarded as a baffling puzzle: how could spike trains that were so alike in their physical properties and patterning underlie such “phenomenally” different phenomena as sight, hearing, touch, and smell? (see Dennett 1978, for an exposure of the puzzle.) It is still extremely tempting to imagine that vision is like television, and that those spike trains get transduced “back into subjective color and sound” and so forth, but we know better, don’t we? We don’t have to strike up the little band in the brain to play the music we hear in our minds, and we don’t have to waft molecules through the cortex to be the grounds for our savoring the aroma of bacon or strawberries. There is no second transduction. And if there were, there would have to be a third transduction, back into spike trains, to account for our ability to judge and act on the basis of our subjective experiences. There might have been such triple transductions, and then there would have been a Cartesian Theater Deluxe, like the wonderful control room in the film *Men in Black*. But biology has been thrifty in us: it’s all done through the medium of spike trains in neurons. (I recognize that dualists of various stripes—a genus thought extinct not so many years ago—will want to dig in their heels right here. I will ignore their howls for the time being, thinking that I can dispatch them later in the argument when I provide an answer to their implied question “What else could it be?”)

So there is no *MEDium* into which spike trains are transduced. Spike trains are discriminated, elaborated, processed, reverberated, re-entered, combined, compared, and contrasted—but not transduced into anything else until some of them activate effectors (neuromuscular

junctions, hormone releasers, and the like) which do the physical work of guiding the body through life. The rich and complex interplay between neurons, hundreds of neuromodulators, and hormones is now recognized, thanks to the persuasive work of Damasio and many others, as a central feature of cognition and not just bodily control, and one can speak of these interactions as transduction back and forth between different media (voltage differences and biochemical accumulations, for instance)—but none of these is the imagined *MEdium* of subjective experience.

So there just is no home in the brain for qualia as traditionally conceived. My point can be clarified by a simple comparison between two well-understood media: cinema film and digital media. First imagine showing some stone-age hunter-gatherers a movie using a portable Super-8 film projector. Amazing, they would think, but when they were then shown the frames of film up close, they would readily understand—I daresay—that this was not magic, because there were little blobs of color on each frame. (The soundtrack might still be baffling, but perhaps they would hold the film up to their ears and decide, eventually, that the sounds were just too faint for them to hear with their naked ears.) Then show them a film on a portable DVD player, and demonstrate the powers of the removable, interchangeable disks, and let them ponder the question of how such a disk managed to store all the sounds and colors they just observed on the screen. It would probably be tempting for them to declare that it *must* be magic—dualism, in other words. But with a little instruction, they could no doubt catch on to the idea that you don't have to represent color with color, sound with sound. You can *transduce* color, sound—anything, really—into a system of patterns of differences (0s and 1s, spike trains, ...) and then *transduce* the elements of that system back into color and sound with playback equipment. This could lay magic to rest.

I had better make my implicit claim explicit, at the risk of insulting some readers: if you think there *has* to be a medium in the brain (or in a dualistic mind) in which subjective colors,

sounds, and aromas are *rendered*, you are making the stone-ager mistake. This, I have come to believe, is the stone wall separating my view from wider acceptance. People pay attention to my arguments, and then, confronted with the prospect that qualia, as traditionally conceived, are not needed to explain their subjectivity, they just dismiss the idea as extravagant. “OF COURSE there are qualia!” This thought experiment is meant to shock them: your confidence here, I am saying, is no better grounded than the imagined confidence of the stone-agers that there just *have to be* colors and sounds on the DVD for it to convey colors and sounds to the playback machine. A failure of imagination mistaken for an insight into necessity. “But when I have a tune running through my head, it has pitch and tempo, and the timbre of the instruments is there just as if I were listening to a live performance!” Yes, and for that to be non-magically the case, there has to be a representation of the tune that progresses more or less in real time, and that specifies pitch and timbre, but that can all be accomplished without transduction, without further *rendering*, in the sequence of states of neural excitation in auditory cortex.

Vision isn't television, and audition isn't radio. We are accustomed, now, to playback devices that do transduce the signals back into the colors and sounds from which they were transduced, but we need to take advantage of our twenty-first century sophistication and recognize that the second transduction is optional! The information is in the signal, and all that information can be processed, discriminated, translated, re-coded, simplified, embellished, categorized, tagged, adjusted, and used to guide behavior without ever being transduced back into colors and sounds (or “subjective” colors and sounds).

3 It still seems that qualia exist

But it sure seems that qualia exist, in spite of the foregoing! How could they not? Aren't they needed, for instance, to be the source or cause of our judgments about them? If I have a conviction that I'm seeing an American flag after-

image (see [figure 1](#)), and note that the lowest short red stripe intersects the central cross, doesn't there have to be the red stripe I deem myself to be experiencing? Isn't the presence of that red stripe *somewhere* a necessary condition for me seeming to see a red stripe? No, and the alternative has been at least dimly understood since Hume's brilliant discussion of our experience of causation.

Figure 1: Inverted American Flag.

Consider what I will call Hume's Strange Inversion (cf. [Dennett 2009](#)). We think we see causation because the causation in the world directly causes us to see it—the same way round things in daylight cause us to see round things, and tigers in moonlight cause us to see tigers. When we see the thrown ball causing the window to break, the causation itself is somehow perceptible “out there.” Not so, says [Hume \(1739, section 7 “Of the idea of necessary connexion”\)](#). What causes us to have the idea of causation is not something external but something internal. We have seen many instances of *As followed by Bs*, Hume asserts, and by a process of roughly Pavlovian conditioning (to put it anachronistically) we have been caused by this series of experiences to have in our minds a disposition, when seeing an A, to expect a B—even before the B shows up. When it does, this *felt* disposition to expect a B is mis-identified as an external, *seen* property of causation. We think we experience causation between A and B, when we are actually experiencing our internal judgment “here comes a B” and “projecting” it into the world. This is a special case of the mind's “great propensity to spread itself on external objects” ([Hume 1739, I, xiv](#)). In fact, Hume insisted, what we do is misinterpret an inner “feeling”—an anticipation—as an external property. The “customary transition” in our

minds is the source of our sense of causation, a quality of “perceptions, not of objects,” but we mis-attribute it to the objects, a sort of benign user-illusion, to speak anachronistically again. As Hume notes, “the contrary notion is so riveted in the mind” that it is hard to dislodge. It survives to this day in the typically unexamined assumption that all perceptual representations must be flowing inbound from outside.

Hume wrote that the ‘mind has a great propensity to spread itself on external objects’ (T 1.3.14.25; SBN 167) and that we ‘gild and stain’ natural objects ‘with the colours borrowed from internal sentiment’ (EPM Appendix 1.19; SBN 294). These metaphors have invited a further one: that of ‘projection’ and its cognates. Though not Hume's own, the projection metaphor is now so closely associated with him, both in exegetical and non-exegetical contexts, that the phrase ‘Humean projection’ is something of a cliché in philosophical discourse. ([Kail 2007, p. 20](#))

Here are a few other folk convictions that need Strange Inversions: sweetness is an “intrinsic” property of sugar and honey, which causes us to like them; observed intrinsic sexiness is what causes our lust; it was the funniness out there in the joke that caused us to laugh ([Hurley et al. 2011](#)). There is no more familiar and appealing verb than “project” to describe this effect, but of course everybody knows it is only metaphorical; colors aren't literally projected (as if from a slide projector) out onto the front surfaces of (colorless) objects, any more than the idea of causation is somehow beamed out onto the point of impact between the billiard balls. If we use the shorthand term “projection” here to try to talk, metaphorically, about the mismatch between manifest and scientific image ([Sellars 1962](#)), what is the true long story? What is literally going on in the scientific image? A large part of the answer emerges, I propose, from the predictive coding perspective. Every organism, whether a bacterium or a member of *Homo sapiens*, has a set of things in the world that matter to it and which it (therefore) needs to

discriminate and anticipate as best it can. Call this the ontology of the organism, or the organism's "Umwelt" (von Uexküll 1957). This does not yet have anything to do with consciousness but is rather an "engineering" concept, like the ontology of a bank of elevators in a skyscraper: all the kinds of things and situations the elevators need to distinguish and deal with. An animal's "Umwelt" consists in the first place of affordances (Gibson 1979), things to eat or mate with, openings to walk through or look out of, holes to hide in, things to stand on, and so forth. We may suppose that the "Umwelt" of a starfish or worm or daisy is more like the ontology of the elevator than like our manifest image. What's the difference? What makes our manifest image manifest (to us)?

4 Bayesian expectations

Here is where Bayesian expectations (see Clark 2013) could play an iterated role: our ontology (in the elevator sense) does a close-to-optimal job of representing the things in the world that matter to the behavior our brains have to control (cf. Metzinger 2003, on our world models). Hierarchical Bayesian predictions accomplish this, generating affordances galore: we expect solid objects to have backs that will come into view as we walk around them, doors to open, stairs to afford climbing, cups to hold liquid, etc. But among the things in our Umwelt that matter to our wellbeing are ourselves! We ought to have good Bayesian expectations about what we will do next, what we will think next, and what we will expect next! And we do. Here's an example:

Think of the cuteness of babies. It is not, of course, an "intrinsic" property of babies, though it seems to be. What you "project" out onto the baby is in fact your manifold of "felt" dispositions to cuddle, protect, nurture, kiss, coo over, ... that little cutie-pie. It's not just that when your cuteness detector (based on facial proportions, etc.) fires, you have urges to nurture and protect; you expect to have those very urges, and that manifold of expectations just is the "projection" onto the baby of the property of cuteness. When we expect to see a

baby in the crib, we also expect to "find it cute"—that is, we expect to expect to feel the urge to cuddle it and so forth. When our expectations are fulfilled, the absence of prediction error signals is interpreted as confirmation that, indeed, the thing in the world with which we are interacting has the properties we expected it to have. Without the iterated expectations, cuteness could do its work "subliminally," outside our notice; it could be part of our "elevator ontology" (the ontology that theorists need to posit to account for our various dispositions and talents) but not part of *our* ontology, the things and properties we can ostend, reflect on, report, discuss, or appeal to when explaining our own behavior (to ourselves or others). Cuteness as a property passes the Bayesian test for being an objective structural part of the world we live in (our *manifest* manifest image), and that is all that needs to happen. *Any further "projection" process would be redundant. What it is to experience a baby as cute is to generate the series of expectations and confirmations just described. What is special about properties like sweetness and cuteness is that their perception depends on particularities of the nervous systems that have evolved to make much of them. The same is of course also true of colors. This is what is left of Locke's (and Boyle's) distinction between primary and secondary qualities.*¹

Similarly, when we feel the urge to judge something about "that red stripe" (in the American flag afterimage (see Figure 1) that hovers in our visual field, we have the temptation to insist that there is a red stripe—there has to be!—causing us to seem to see it. But however natural and human this temptation is, it must be resisted. We can be caused to seem to see something by something that shares no features with the illusory object. (Remember Ebenezer Scrooge saying to Marley's ghost: "You may be an undigested bit of beef, a blot of mustard, a crumb of cheese, a fragment of an underdone potato. There's more of gravy than of grave about you, whatever you are!") Many would insist that there has to be a ghost-shaped intermediary in the causal chain between blot of

¹ The material in the previous five paragraphs is adapted from Dennett (2013).

mustard and belief in Marley, but Scrooge might be right in addressing his remark to the cause of his current condition, and be leaving nothing Marley-shaped out.) And as for the idea that without being *rendered* such contents are causally impotent, it is simply mistaken, as a thought experiment will reveal. Suppose we have a drone aircraft hunting for targets to shoot at, and suppose that the drone is equipped with a safety device that is constantly on the lookout for red crosses on buildings or vehicles—we don’t want it shooting at ambulances or field hospitals! With its video eye it takes in and transduces (into digital bit streams) thirty frames a second (let’s suppose) and scans each frame for a red cross (among other things). Does it have to project the frame onto a screen, transducing bit streams into colored pixels? Of course not. It can make judgments based on un-transduced information—in fact, it can’t make judgments based on anything else. Similarly your brain can make judgments to the effect that there is a red stripe out there on the basis of spike train patterns in your cortex, and then act on that judgment (by causing the subject to declare “I seem to see a red stripe,” or by adjusting an internal inventory of things in the neighborhood, or ...). (I am deliberately using the word “judgment” for the drone’s discriminations and the brain’s discriminations; I have elsewhere called such items micro-takings or content-fixations. The main point of using “judgment” is to drive home the claim that these events are *not* anything like the exemplification of properties, intrinsic or otherwise. They are not qualia, in other words. Qualia—as typically conceived—would only get in the way. Don’t put a weighty LED pixel screen in a drone if you want it to detect red crosses, and don’t bother installing qualia in a brain if you want it to have color vision. Whatever they are, qualia are unnecessary and may be jettisoned without loss.)

So the familiar idea (familiar in the context of Block’s proposed distinction between access consciousness and phenomenal consciousness) that phenomenal consciousness (= qualia) is the basis for access consciousness (= judgments about qualia, qualia-guided decisions,

etc.) is backwards.² Once the discerning has happened in the untransduced world of spike trains, it can yield a sort of Humean projection—of a red stripe or red cross or just red, for instance—into “subjective space.”

But what is this subjective space in which the projection happens? Nothing. It is a theorist’s fiction. The phenomenon of “color phi” nicely illustrates the point. When shown, say, two disks displaced somewhat from each other, one sees the apparent motion of a single disk—the phi phenomenon that is the basis of animation (and motion pictures in general). If the disks are of different colors—the left disk red and the right disk green, for instance—one will see the red disk moving rightward and changing its color to green in mid-trajectory. How did the brain “know” to move the disk rightward and switch colors before having access to the green disk at its location? It couldn’t (supposing precognition to be ruled out). But it could have Bayesian expectations of continuous motion from place to place that provoke a (retrospective) expectation of the intermediate content, and this expectation encounters no disconfirmation (if the timing is right), which suffices to establish in reality the illusory sequence in the subject’s manifest image. So the visual system’s *access* to the information about the green disk is causally prior to the “*phenomenal*” motion and color change. Here is a diagram of color phi

2 I once had an occasion to point out this prospect to Block. He had just participated in a laterality test, to see how strongly lateralized for language his brain was. There are two oft-used ways of testing this: with dichotic headphones, which send different words into each ear, where the subject is asked to identify the word heard (typically you only hear one of them!). A second, visual test involves looking at a center target on a screen and having a word or non-word (e.g., “flum” or “janglet”) flashed briefly in either the left or right visual field. The subject presses the word button or the non-word button and latencies and errors are recorded. If you are strongly lateralized left (your left hemisphere is strongly dominant for language and does most of the work of language processing), you are faster and more accurate on words and nonwords flashed to the right hemifield. Ned had taken the visual test, and I asked him what he had learned. He was, he said, strongly lateralized left for language, like most people, and he added “the words flashed on the left actually seemed blurry!” I asked him whether the words seemed blurry because he noted the difficulty he was having with them, or whether he had the difficulty because the words were blurry. He acknowledged that he had no introspective way of distinguishing these two hypotheses. Supposing that Block doesn’t have some remarkable problem with his eyes, in which the left half of each lens is occluded or misshapen, producing a blur on the left side of his retinas, it is highly likely that the blurriness he seemed to experience was an effect of his felt difficulty in responding, not the cause of this difficulty.

from [Consciousness Explained](#) (and [Dennett & Kinsbourne 1992](#)):

Figure 2: Superimposition of subjective and objective sequences.

In order to explain “temporal anomalies” of conscious experience, we need to appreciate that not only do we not have to represent red with something red, and round with something round; we don’t have to represent time with time. Recall my example “Tom arrived at the party after Bill did.” When you hear the sentence you learn of Tom’s arrival before you learn of Bill’s, but what you learn is that Bill arrived earlier. No revolution in physics or metaphysics is needed to account for this simple distinction between the temporal properties of a representation and the temporal properties represented thereby. It is quite possible (in color phi, for instance) for the brain to discern (in objective time) first one red circle (cat time 3) and then a green circle (fat time 5) displaced to the right, and then to (mis-)represent an intermediate red-turning-green circle (eat time 8) yielding the subjective judgment of apparent motion with temporally intermediate color change. Here our Bayesian probabilistic anticipator is caught in the act, jumping to the most likely conclusion in the absence of any evidence. Experienced or subjective time doesn’t line up with objective time, and it doesn’t have to. The important point to remember from the diagram is that the subjective time sequence is NOT like a bit of kinked film that then has to be run through a projector somewhere so that c is followed by e is followed by f in real time. It is just a theorist’s diagram of how subjective time can relate to objective time. Subjective time is not a further real component of the causal picture. No

rendering is necessary, the judgment is already in, and doesn’t have to be re-presented for another act of judging (in the Cartesian Theater).

The temptation to think otherwise may run deep, but it is fairly readily exposed. Consider fiction. Sherlock Holmes and Watson seem real when one is reading a Conan Doyle mystery—as real as Disraeli or Churchill in a biography. When Sherlock seems real, does this require him and his world to be rendered somewhere, in—let’s call it—*fictoplasm*? No. There is no need for a medium of fictoplasm to render fiction effective, and there is no need for a mysterious medium, material or immaterial, to render subjective experience effective. No doubt the temptation to posit the existence of fictoplasm derives from our human habit, when reading, of adding details in imagination that aren’t strictly in the book. Then, for instance, when we see a film of the novel, we can truly say “That’s not how I imagined Holmes when I read the book.”

Isn’t such rendering in imagination while reading a novel a case of *transduction* of content from one medium (written words as seen on the page) into another (imagined events as seen and heard in the mind’s eye and ear)? No, this is not transduction; it is, more properly, a variety of *translation*, *effortlessly expanding the content thanks to the built-in Bayesian prediction mechanisms*. We could construct, for instance, a digital device that takes problems in plane geometry presented in writing (“From Euclidean axioms prove the Pythagorean Theorem.”) and solves them through a process that involves making Euclidean constructions, with all the sides and angles properly represented and labeled, and utilizing them in the proof. The whole process from receipt of the problem to delivery of the called-for proof (complete with printed-out diagrams if you like), is conducted in a single medium of digital bit strings, with no transduction until the printer or screen is turned on to render the answer. (A more detailed description of this kind of transformative process without transduction is found in my discussion (1991) of how the robot Shakey discriminated boxes from pyramids.)

Consider [Figure 2](#) above. Does the access/phenomenal consciousness distinction get depicted therein? If so, access consciousness should be identified with the objective time line, and phenomenal consciousness (if it were something real in addition to access consciousness) would be depicted in the line that doubles back in time. The content feature that creates the kink is an effect of a judgment or discernment that came later in objective time than the discernment of the green circle at time 5. It is because the brain already had access to red circle, then green circle that it generated a representation (but not a *rendering*) of the in-between red-turning-green circle as an elaborative effect.³

5 Why do qualia seem so simple and ineffable?

Qualia seem atomic to introspection, unanalyzable simples—the smell of violets, the shade of blue, the sound of an oboe—but this is clearly an effect of something like the resolution of our discernment machinery.

If our vision were as poorly spatially resolved as our olfaction, when a bird flew by, the sky would suddenly “go all birdish,”—that peculiar, indescribable birdishness that one would experience in the visual presence of birds. And this resolution is variable: music lovers and wine enthusiasts and others can train up their ear and their palate and come to distinguish, introspectively, the combining elements of what used to seem atomic and unanalyzable. [David Huron \(2006\)](#), has done some ingenious work teasing out and explaining the combinations of neuroarchitectonic properties that explain the otherwise ineffable characteristic qualia of scale tones (the way *do* sounds different from *re* and *mi* and *so*). It turns out that these “qualia” are actually highly structured properties of neural representations. The explanation, needless to say, is ultimately in the medium of spike trains.

But why should the resolution (if that is the right term) be so low? Why should our brains ignore so much detail in the representations to which “we” have “access”? [Minsky](#)

³ Thanks to David Gottlieb for drawing my attention to this way of looking at access consciousness.

(1985), [Dennett \(1991\)](#), [Norretranders \(1999\)](#), [Metzinger \(2003\)](#), and others have said that it is the brain’s own access to its own complex internal activities that accounts for the simplicity. This is the brain’s effective user-illusion for itself, in much the way the desktop with its icons and various metaphors (click and drag, highlighted targets, etc.) is an elegantly designed user-illusion for laypeople who don’t need to know how their computers work.

The brain does not have a single internal witness or homunculus, but it does need something like a lingua franca to get the different and semi-independent subsystems to communicate with each other. (For instance, in the Global Neuronal Workplace model⁴ of [Dehaene et al. \(2006\)](#), and others, one should not take it for granted that the *local* meanings of spike train patterns—in the dorsal vision stream, say, or the olfactory bulb—are readily “understood” by all the elements to which some of these signals are broadcast.) I think there is bound to be some important truth in that theme, but it is only part of the story.

6 Whose access?

I think the more interesting suggestion is that the effective “we” when we talk about what “we” have access to, is, indeed, *we*—not just *I*, but *you and me*. It is, more particularly, *your* access to *my* mind that simplifies the information that *we* have access to!

The linguist [Stephen Levinson \(2006\)](#) has studied the remarkable language, Yéî Dnye, of the three thousand or so inhabitants of Rossel Island in the South Pacific—to the north of Papua New Guinea. It is a completely isolated language, unlike any other in the world in many regards. In particular, it is hideously complex, with:

the largest phoneme inventory (ninety distinct segments) in the Pacific, and many

⁴ Isn’t the Global Neuronal Workplace the derided Cartesian Theater after all? No, because what goes on there is not transduction-and-rendering, but informational integration: the coalition and consilience of competing elements. There is no transduction threshold that determines the time-of-entry “into consciousness”, and none of the multiple drafts competing in it are singled out as being conscious except retrospectively. This is the point of my admonition always to ask the Hard Question: “And then what happens?” ([Dennett 1991](#), p. 225)

sounds (such as doubly articulated labial coronal stops) that are either unique or rare in the languages of the world. Among the fifty-six consonants are many multiply articulated segments: e.g., /tɸɲm/ is a single segment made by simultaneously putting the tongue behind the alveolar ridge, trilling the lips, and snorting air through the nose. [...] Once the learner is past the sound hurdle, he or she faces another formidable obstacle. The language has an extremely complex system of verb inflection (with thousands of distinct inflectional forms). [...] In addition, substitute forms are used where the subject has been mentioned before, is close or visible, is in motion, or where the sentence is counterfactual or negative, thus providing well over a thousand possibilities [...]. (Levinson 2006, p. 20)

Levinson reports, not surprisingly, that “[h]ardly any mature individuals (such as non-native spouses) who have immigrated into the island community ever learn to speak the language, and children of expatriate Rossels do not fully acquire it from their parents alone.” His explanation is speculative, but plausible: a language, left to itself for centuries, will grow ever more complex, like an unpruned bush, simply because it can. The extreme isolation of Rossel Island over the centuries (for various geographic reasons) means that the language has hardly ever been confronted with non-native speakers of another language with whom communication is imperative, for one reason or another. The need for communication soon generates a small cadre of bi-lingual interpreters, and maybe also a pidgin (and maybe later a creole), and all of these alien interfaces work to simplify a language. The least learnable, most baroque (in the sense of exceeding the functional) features of the language are dropped under this pressure. We can see it happening with English today, with simplified dialects such as Emblish (as spoken at the European Molecular Biology Laboratory in Heidelberg) arising naturally and imperceptibly.

I would like to speculate that a similar process of gradual but incessant simplification has shaped the language we have available to explain and describe our minds to each other. Wittgenstein’s famous claim about the impossibility of a private language has not weathered the storms of controversy particularly well, but there are neighboring claims—empirical claims—that deserve consideration. Many years ago, [Nicholas Humphrey \(1987\)](#) made the point that has begun to attract adherents today:

While it is of no interest to a person to have the same kind of kidney as another person, it is of interest to him to have the same kind of mind: otherwise as a natural psychologist he’d be in trouble. Kidney transplants occur very rarely in nature, but something very much like mind-transplants occur all the time [...]. [So] we can assume that throughout a long history of evolution all sorts of different ways of describing the brain’s activity have been experimented with but only those most suited to doing psychology have been preserved. Thus the particular picture of our inner selves that human beings do in fact now have—the picture we know as ‘us’, and cannot imagine being of any different kind—is neither a necessary description nor is it any old description of the brain: it is the one that has proved most suited to our needs as social beings. That is why it works. Not only can we count on other people’s brains being very much like ours, we can count on the picture we each have of what it’s like to have a brain being tailor-made to explain the way that other people actually behave. Consciousness is a socio-biological product—in the best sense of socio and biological. (p. 18)

Chris Frith, for instance, has recently taken up the theme (in conversation) that consciousness has some features, because everything in consciousness has to be couched in terms that can be communicated to other people readily.

The ineffability barrier we all experience when trying to tell others what it is like to be

us on particular occasions is highly variable, not just between individuals, but over time within a single individual, as a result of formal or informal training. It plays a dynamic role in shaping the contents of our consciousness over time.⁵ (This would be true only for human consciousness, obviously.)

7 A thought experiment: Mr. Capgras

Finally, it might seem that whereas some subjective properties—cute, sweet, funny, sexy, the characteristic sounds of scale tones—might be accounted for in terms of Bayesian expectations about how one will be disposed to behave in their presence, the very simplicity of colors must block any attempt to treat them in a similar fashion. There is no way one expects to behave in the presence of navy blue, or pale yellow, or lime green. So it may seem, but this is itself an artifact of our penchant for thinking—as Hume famously did—of colors as simples. Hume was discountenanced by the notorious missing shade of blue, and found it ideologically inconvenient to suppose, as we now know, that color experience is in fact highly complex and compositional, and deeply anchored in dispositions of our perceptual systems.⁶ Moreover, color experiences are no more atomic than scale tone experiences, and give rise to all manner of expectations, which tend to go unnoticed, but can be thrown into sharp focus by a thought experiment: my fantasy about poor Mr. Clapgras, the man who wakes up to find all his emotional dispositions with regard to colors inverted while leaving intact his cognitive habits and powers (see [Dennett 2005](#), pp. 91–102, for a more detailed account, with objections considered and rebutted). Ex hypothesi, Mr. Clapgras identifies colors and sorts colors correctly (he does not suffer from the well-studied conditions color

anomia, or cerebral achromatopsia), but he finds the world disgusting, unbearable. Food looks just terrible to him now, and he has to eat blindfolded, since his emotional responses to all colors have shifted 180 degrees around the color circle ([Grush this collection](#)). He calls shocking pink “shocking pink” but marvels at the inappropriateness of its name. The only way we can explain his distress is by observing that he notices that something is wrong—which has to mean he was expecting something else. He is surprised that breaking a fresh egg into a frying pan on a sunny morning doesn’t bring a smile to his face, that a glimpse of his obnoxious neighbor’s lime green convertible doesn’t irritate him the way it used to do, that he feels no stirring of childhood patriotism when he sees the red white and blue waving in the breeze. Like the sufferers of Capgras delusion, poor Mr Clapgras senses a disturbance: something is very wrong, but it isn’t the evaporation of intrinsic internal properties.

8 Conclusion

The considerations I have raised in this essay are not new, but perhaps bringing them together as I have done will help show that a counter-intuitive theory like mine still has an advantage over some of the fantasies in which philosophers have recently indulged. It may well be, as [Paul Bloom \(2004\)](#) has suggested, that we are all “natural born dualists,” but just as eyeglasses can correct for myopia, natural-born or not, so science can correct for this innate cognitive disability. Intuitions to the contrary are important data, but should not be taken to indicate a limitation of science, as some have thought. In fact, if the best scientific theory of consciousness turns out not to be deeply counterintuitive at first, among the data it will have had to explain is why it took us so long to arrive at it.

Acknowledgements

Thanks to Michael Cohen, and to Andy Clark, and the rest of Dmitry Volkoff’s Greenland Consciousness and Free Will workshop (June 10-17, 2014), for editorial advice on this essay.

⁵ Note that I am not saying that our day-to-day consciousness wouldn’t occur in the absence of human company, but an implication of my speculation is that a Robinson Crusoe human, somehow raised from birth without human contact, would have subjectivity more inaccessible to us—once we discovered him and attempted to communicate with him—than the speech acts of the Rossel Islanders.

⁶ In [Cohen & Dennett](#), we point out that limbic or emotional responses to colors have to count as instances of “access” to color-representing states “however coarse-grained or incomplete, because such a reaction can obviously affect decision making or motivation” (2011, p. 5).

Qualia explained away

A Commentary on Daniel C. Dennett

David H. Baßler

In his paper “Why and how does consciousness seem the way it seems?”, Daniel Dennett argues that philosophers and scientists should abandon Ned Block’s distinction between access consciousness and phenomenal consciousness. First he lays out why the assumption of phenomenal consciousness as a second medium is not a reasonable idea. In a second step he shows why beings like us must be convinced that there are qualia, that is, why we have the strong temptation to believe in their existence. This commentary is exclusively concerned with this second part of the target paper. In particular, I offer a more detailed picture, guided by five questions that are not addressed by Dennett. My proposal, however, still resides within the framework of Dennett’s philosophy in general. In particular I use the notion of intentional systems of different orders to fill in some details. I tell the counterfactual story of some first-order intentional systems evolving to become believers in qualia as building blocks of their world.

1 Introduction

The first of Rapoport’s Rules¹ for composing a critical commentary states that one should present the target view in the most charitable way possible (Dennett 2013a). Although I generally agree with many of Daniel Dennett’s

views, especially his argument against the existence of qualia (constituting the first part of the target paper), the diagnosis that there is the *zombic hunch*,² along with his strategy for explaining why it exists, the connection between qualia and predicted dispositions, was hard to grasp. Dennett presents the idea that when we talk about qualia, what we really refer to are our dispositions in earlier works (e.g., Dennett 1991). But the connection to predictive pro-

¹ Dennett named these rules after social psychologist and game theorist Anatol Rapoport. They are not to be confused with another “Rapoport’s Rule”, named after Eduardo H. Rapoport (cf. Stevens 1989). Here is the full list of Dennett’s Rapoport’s Rules:

1. “You should attempt to re-express your target’s position so clearly, vividly, and fairly that your target says, ‘Thanks, I wish I’d thought of putting it that way.’”
2. “You should list any points of agreement (especially if they are not matters of general or widespread agreement).”
3. “You should mention anything you have learned from your target.”
4. “Only then are you permitted to say so much as a word of rebuttal or criticism.”

(Dennett 2013a, p. 33)

² A philosophical zombie has nothing to do with any other sort of zombie. It behaves in *every* way like a normal person. The only difference is, that it lacks phenomenal experiences (though *ex hypothesi* it believes that it has phenomenal experiences). The zombic hunch is the intuition that a philosophical zombie would be different from us.

cessing is new (see also [Dennett 2013b](#)). There still seem to be some stepping stones missing, which I hope to fill in with my reconstruction. My goal is to provide a complete story that sticks as close to Dennett's argument as possible. This paper is not supposed to be a "rebuttal" or "criticism", but an "attempt to re-express [Dennett]'s position" (see footnote 1).

The structure of this commentary is as follows: in the [first](#) section I shall give a short outline of Dennett's explanation of why we have the zombic hunch. Since this involves the predictive processing framework, I shall give a very short introduction to this first. Following this, I present a short list of five questions that have not, in my opinion, yet been sufficiently addressed. In the [second](#) section I present an interpretation, or perhaps an extension, of Dennett's answers to these questions, by relying on the concept of an intentional system and using a strategy involving telling the counterfactual story of the evolution of some agents who end up believing in qualia (although *ex hypothesi* there are none). In the [third](#) section I shall analyze which features qualia should have, according to the beliefs of these agents, and show that there is at least a significant overlap with features many consider qualia to have.

I want to give a short justification for the unorthodox way of accounting for *beliefs* about *x* instead of for *x*'s existence itself. This is a general strategy found in other areas of Dennett's work. For example, he has asked, "Why should we think there is intentionality although there is none?" ([Dennett 1971](#)), "Why should we believe there is a god although there is none?" ([Dennett 2006](#)), and "Why should we think there is a problem with determinism and free will although there is none?" ([Dennett 1984, 2004](#)). Dennett's philosophy can in parts be seen as a therapeutic approach to "philosopher's syndrome"—"mistaking failures of imagination for insights into necessity" (e.g., [Dennett 1991](#), p. 401; [Dennett 1998a](#), p. 366)—by making it easier to see why we are convinced of the existence of something, even when there are good reasons to believe that it doesn't exist.

I want to draw attention to Hume's *Of Miracles* ([Hume 1995](#), X), where he states that the likelihood of a testimony about miracles being wrong is always greater than the likelihood of the miracle itself. This serves as a nice analogy for the case at hand: we might think of our own mind as a good "witness", but we already know too much about its shortcomings. So we should be suspicious when it cries out for a revolution in science or metaphysics, because this cry rests on the belief that something is missing, when no data but this very belief itself makes the demand necessary. Instead we should examine what else could have led our minds to form this conviction.

2 Dennett's proposal

In "Why and how does consciousness seem the way it seems?" Dennett gives an argument for why philosophers and scientists should abandon Ned Block's distinction between access consciousness and phenomenal consciousness, zombies, and qualia altogether. The argument is twofold: first Dennett lays down his argument for why the assumption of phenomenal consciousness as a second medium whose states are conscious experiences or qualia is "scientifically insupportable and deeply misleading" ([Dennett this collection](#), section 2). It is insupportable because there is simply no need to posit such entities to explain any of our behavior, so for reasons of parsimony they should not be a part of scientific theories (see also [Dennett 1991](#), p. 134). The assumption is deeply misleading because it makes us look for the wrong things, namely, the objects our judgments are about, rather than the causes of these judgments, which are nothing like these objects.

In a second step Dennett shows why creatures like us must be convinced that there are qualia, that is, why we have such a strong temptation to believe in their existence, *even though* there are no good reasons for this ([Dennett this collection](#), section 2 and 3; other places where Dennett acknowledges this conviction, the zombic hunch, are [Dennett 1999](#); [Dennett](#)

2005, Ch. 1; Dennett 2013a, p. 283). The following sections are exclusively concerned with this part of the target paper.

After completing the second step, Dennett explains why we ascribe qualia their characteristic properties—simplicity and ineffability (Dennett this collection, section 4 & 5). Although I also say something about this point (see section 4), Section 6 is an intuition pump (cf. e.g., Dennett 2013a) that will help the reader to apply Dennett’s alternative view to the experience of colors.

Before I present a short outline of Dennett’s second step, I want to briefly describe the predictive processing framework. This is necessary since both Dennett’s argument as well as my reconstruction make use of this framework. I shall not go into details of hierarchical predictive processing (PP) accounts here, since at least three papers in this collection (Clark, Hohwy, and Seth), as well as the associated commentaries (Madary, Harkness, and Wiese), are concerned with this topic and also offer ample references for introductory as well as further reading. I will instead give a very short description of the points that are most relevant to Dennett’s argument and recommend the above-mentioned papers and the references given there to the interested reader.

2.1 Predictive processing

In the PP framework, the brain refines an internal generative stochastic model of the world by continuously comparing sensory input (extero- as well as interoceptive) with predictions continuously created by the model. The overall model is spread across a hierarchy of layers, where the sensory layer is the lowest and each layer tries to predict (that is, to suppress) the activation pattern of the layer beneath it. The whole top-down activation pattern might be interpreted as a global hypothesis about the hidden causes of ongoing sensory stimulation. The difference between predicted and actual activation (*prediction error*) is what gets propagated up the hierarchy and leads to changes in the hypothesis. To be exact, this is only one possibility. Another is

that this leads to an action that changes the input in such a way that the prediction is vindicated (*active inference*, see e.g., Friston et al. 2011). However, although this aspect of PP—that it provides one formally-unified approach to perception and action—is a strength of the framework, it is not important here, given the context of this commentary. These changes are supposed to follow Bayes’ Theorem, which is why one might speak of Bayesian prediction (cf. e.g., Hohwy 2013).

The higher the layer in the hierarchy the more abstract the contents and the longer the time-scales or the predictive horizon. One example of a very abstract content is “only one object can exist in the same place at the same time” (Hohwy et al. 2008, p. 691, quoted after Clark 2013, p. 5).

One point to keep in mind is that, according to Hohwy (2014), this framework implies a clear-cut distinction between the mind and the world. That is, there is an *evidentiary boundary* between “where the prediction error minimization occurs” and “hidden causes [of the sensory stimulation pattern] on the other side” (Hohwy 2014, p. 7). I will come back to this point later in this commentary.

2.2 The outline of Dennett’s argument

1. Our own dispositions, expectations, etc. are part of the generative self-model instantiated by our brains. “We ought to have good Bayesian expectations about what we will do next, what we will think next, and what we will expect next” (Dennett this collection, p. 5)
2. When our brains do their job (described in (1)) correctly, i.e., there are no prediction-error signals, we misidentify dispositions of the organism with properties of another object. For instance, instead of attributing the disposition to cuddle a baby correctly to the organism having the disposition, our brain attributes “cuteness” to the baby.³ Color qualia

³ “Think of the cuteness of babies. It is not, of course, an ‘intrinsic’ property of babies, though it seems to be. [...] We expect to expect to feel the urge to cuddle it and so forth. When our expectations are fulfilled, the absence of prediction error signals is interpreted as confirmation that, indeed, the thing in the world with which we are in-

and other types of qualia also belong to this category.⁴

3. This means, under a personal level description, that we believe that there are properties *independent of the observer*, such as the cuteness of babies, the sweetness of apples, or the blueness of the sky, etc.
4. This is why it is so hard for us to doubt that qualia exist in the real world.

The crucial points seem to be (1) and (2). Before I lay out my interpretation I want to highlight some points that are not addressed in Dennett ([this collection](#)), but which are crucial if we are to have a complete picture. In the section *Our Bayesian brains*, I present a reconstruction that addresses these issues.

2.3 Five questions

1. **Why do we need to monitor our dispositions?** As noted in Dennett (2010), self-monitoring, in the sense of monitoring of our dispositions, values, etc., isn't needed unless one needs to communicate and to hide and share specific information about oneself at will. In his paper, Dennett does not address this issue, yet presupposes that "among the things in our *Umwelt* that matter to our well-being are ourselves". This is obvious if one reads "ourselves" as the motions of our bodies, but not so obvious if one includes things

interacting has the properties we expected it to have" (Dennett [this collection](#), p. 5).

- 4 The intuition pump of Mr. Clapgras in Dennett's section 6 is there to make the point that colors can be seen as dispositional properties of the organism rather than as properties of perceptual objects, in the same way as cuteness. Whether one is convinced by this or not, the intuitive problem seems to be the same: science tells us there are no properties like cuteness or color, while the zombic hunch tells us that this cannot be true. A more detailed discussion can be found in Dennett (1991, p. 375). I will not go into this here, but for the sake of argument I shall assume that this admittedly counter-intuitive categorization is acceptable. The reader's willingness to accept it might be helped by the following point given by Nicholas Humphrey, which reminds us that although at first thought colors do not *seem* to have action-provoking effects (like cuteness or funniness), after second thought one might think differently:
 "As I look around the room I'm working in, man-made colour shouts back at me from every surface: books, cushions, a rug on the floor, a coffee-cup, a box of staples—bright blues, reds, yellows, greens. There is as much colour here as in any tropical forest. Yet while almost every colour in the forest would be meaningful, here in my study almost nothing is. Colour anarchy has taken over."
 (Humphrey 1983, p. 149; quoted in Dennett 1991, p. 384).

like "what we will think next, and what we will expect next", as Dennett does (Dennett [this collection](#), p. 5). The next question is concerned with this latter form of self-monitoring:

2. **How is self-monitoring accomplished?** Hohwy (2014) refers to an evidential boundary in the predictive processing framework (see the section 2.1): there is a clear distinction between the mind/brain and the world (of which the body without the brain is a part), whose causal structure is yet to be revealed. Our expectations are part of our mind, which, if talk of the boundary is correct, does not have direct access to its own states *as* its own states—the mind is a black box to itself. So the prediction of its expectations needs to be indirect (just like the predictions of the causes of the sensory stimulation in general), and therefore the question arises how the self-monitoring of the mind is achieved according to Dennett. There is a further concern with self-monitoring, which one might call the "acquisition constraint" (cf. e.g., Metzinger 2003, p. 344):
3. **How did this self-monitoring evolve in a gradual fashion?** Large parts of [Breaking the Spell](#) are dedicated to making understandable how "belief in belief" could have evolved over the centuries, beginning long before the appearance of any religion. Dennett's goal here is quite similar: the explanation aims to make understandable how we came to believe in qualia, etc. But a step-by-step explanation is missing. I consider this form of the acquisition-constraint one of the most crucial for any satisfying explanation of this sort: each single step has to be understandable as one likely to have happened. One reason for this is that it would support a more fine-grained and mechanistic understanding; another is that it would satisfy the gradualism-constraint of Darwinism, which says that minds (just like anything else) "must have come into existence gradually, by steps that are barely discernible *even in retrospect*" (Dennett 1995, p. 200, emphasis in original).

Once we know why and how our brains accomplish the task of monitoring our dispositions and how they came to do so, one might still wonder why (as claimed in point 2, page 3) exactly these abstract properties of the organism would be misidentified as concrete properties of other things:

4. **Why do we misidentify our dispositions?** One of Dennett's central claims is that we misidentify our own dispositions, which leads to belief in qualia.⁵ Although misidentification seems to be ubiquitous (see superstition, religion, magic tricks, the rubber hand illusion—Botvinick & Cohen 1998; and even full body illusions—Blanke & Metzinger 2009) it nonetheless requires a special explanation in each case: is this a shortcoming of a system that has no disadvantages, or is it even something that benefits the system in some way (cf. McKay & Dennett 2009)? Keeping this last possibility in mind one might ask:

5. **Why are we so attached to the idea of qualia?** There seems to be something more that leads people to believe in qualia. There is the intuition that without qualia we would be very different—we would be “mere machines”, we could not *enjoy* things like a good meal or the smell of the air after it rains (a discussion of this characteristic of beliefs-about-qualia can be found in Dennett 1991, p. 383). Some might go further and say that our whole morality rests on the existence of qualia of pain and suffering (this worry is dealt with in Dennett 1991, p. 449). However, what I am concerned with here is not whether it is true that qualia are the basis of our morality, but why we should think them to be so. From the argument presented by Dennett it is not clear why we are so attached to the idea of qualia. It is not obvious why we do not react as disinterestedly to their denial as we did to the revelation that there is no

ether.⁶ But, as a matter of fact, we react differently: this is not like when any other entity, posited for theoretical reasons, is shown to not exist; it is as if without qualia we couldn't possibly be *us*.

3 An interpretation

3.1 Intentional Systems Theory

An important part of what follows is Intentional Systems Theory (IST). What is crucial here is that according to IST, all there is to being an agent in the sense of having beliefs and desires upon which to act is to be describable via a certain strategy: the *intentional stance*. The intentional stance is a “theory-neutral way of capturing the cognitive competences of different organisms (or other agents) without committing the investigator to overspecific hypotheses about the internal structures that underlie the competences” (Dennett 2009, p. 344). If one predicts the behavior of an object via the intentional stance, one presupposes that it is optimally designed to achieve certain goals. If there are divergences from the optimal path, one can, in a lot of cases, correct for this by introducing abstract entities or false beliefs. Since there are presumably no 100%-optimally-behaving creatures in the world, every intentional profile (a set of beliefs and desires), generated via adoption of the intentional stance, contains a subset of false beliefs.⁷ It seems that humans have a “generative capacity [to find the patterns revealed by taking the intentional stance] that is to some degree innate in normal people” (Dennett 2009, p. 342). I will come back to this point and its connection to PP in the next section.

Let us assume for the sake of argument that IST gives a correct explanation of what it is to be an agent (in the sense of someone who has beliefs and desires and acts according to

⁵ What qualia are [...] are just those complexes of dispositions. When you say ‘This is my quale,’ what you are singling out, or referring to, whether you realize it or not, is your idiosyncratic complex of dispositions. You seem to be referring to a private, ineffable something-or-other in your mind's eye, a private shadshade of homogeneous pink, but this is just how it seems to you, not how it is. (Dennett 1991, p. 389).

⁶ This property of the beliefs is acknowledged in Dennett (2005), p. 22, fn 18: “[The Zombic Hunch] is visceral in the sense of being almost entirely arational, insensitive to argument or the lack thereof”.

⁷ See Dennett (1987) for an elaborate discussion of the intentional stance and its implications, Dennett 1998b for the ontological status of beliefs and desires, Bechtel (1985) for another interesting interpretation, and Yu & Fuller (1986) for a discussion of the benefits of treating beliefs and desires as abstracta.

them), and that PP allows us to see how an agent can be implemented on the “algorithmic level”(see Dennett’s discussion in [Dennett 1987](#), p. 74, where he refers to the IST as a “competence model”). Whenever I say that an agent believes, wants, desires, etc. something I mean it in exactly the sense found in IST.

Intentional systems can be further categorized by looking at the content of their beliefs, e.g., a second-order intentional system is an intentional system that has beliefs and/or desires about beliefs and/or desires, that is, it is itself able to take an intentional stance towards objects ([Dennett 1987](#), p. 243). A first-order intentional system has (or can be described as having) beliefs and desires; a second-order intentional system can ascribe beliefs to others and itself. If something is a second-order intentional system it harbors beliefs such as “Peggy believes that there’s cheese in the fridge”. But taking the intentional stance towards an object is an ability that comes in *degrees*. I now want to describe what one might call an intentional system of 1.5^{th} order, an intermediate between first- and second-order intentional systems. This is a system that is not able to ascribe full-fledged desires and beliefs with arbitrary contents to others or itself. We, as intentional systems of high order, have no difficulty in ascribing beliefs and desires with very arbitrary contents, such as “She wants to ride a unicorn and believes that following Pegasus is a good way to achieve that goal”. But the content of beliefs and desires that such an intentional system of 1.5^{th} order can ascribe should be constrained in the following way:

1. An intentional system of 1.5^{th} order is able to ascribe desires only in a very particular and concrete manner, i.e., actions that the object in question wants to perform with certain particular existing objects, that the system itself knows about (e.g., the desire to eat the carrot over there), but not goals directed at nonexistent objects, described by sentences like “he wants to build a house”, or objects the ascriber itself does not know about.
2. It is only able to ascribe beliefs to others that it holds itself. That means it is able to

take the basic intentional stance with the default assumption that the target object in question believes whatever is true (if we assume the ascriber’s beliefs are in fact all true), but lacks the ability to correct the ascriptions if it leads to wrong predictions for the behavior of the target. A real-world example can be found in [Marticorena et al. \(2011\)](#): rhesus macaques in a false belief task can correctly predict what a person will do, given that the person knows where the object is hidden and they have seen the person getting to know this. They can also tell when a person doesn’t have the right knowledge, but they cannot use this information to make a prediction about where the person will look.

The implementation of such an intermediate between first- and second-order intentional systems can be easily imagined following predictive coding principles, as I will soon show. Following this, I argue that this sets down the basic fundamentals for systems evolving from this position to be believers in qualia, etc.

The reason for introducing this idea is that I want to show how, given predictive processing principles and a certain selection pressure, a 1.5^{th} -order-intentional-system might develop from a first-order-intentional-system. In a next step, I will argue that under an altered selection pressure such a system might become a full-fledged n^{th} -order-intentional-system, where n is greater or equal to two. Systems evolving in such a way, as I will describe, are bound to believe in the existence of something like qualia. In some sense this is only a just-so story, but the assumed selection pressures are very plausible, and the empirically-correct answer might not be too far away from this.

3.2 Our Bayesian brains⁸

To see how the pieces fit together imagine the situation of some first-order intentional systems, agents, which are the first of their kind. They act according to their beliefs and desires. They do so because the generative models im-

⁸ This section takes strong inspiration from Wilfrid Sellars’ section “Our Rylean Ancestors” in [Sellars \(1963, p. 178\)](#).

plemented in their brains generate a sufficient number of correct predictions about their environment for them to survive and procreate. They do a fairly good job of avoiding harms and finding food and mates. Since they are first-order intentional systems, the behavior of their conspecifics amounts to unexplained noise to them, because they are unable to predict the patterns of most of their behavior (which is what makes them *merely* first-order intentional systems), though they might well predict their behavior as physical objects, e.g., where someone will land if she falls off a cliff, for instance.

When resources are scarce, this leads to competition between these agents and it becomes an advantage to be able to predict the behavior of one's conspecifics. This behavior is by definition pretty complex (they are intentional systems), but one can get some mileage out of positing the following regularity: some objects in the world have properties that lead to predictable behavior in agents, e.g., if there is an apple tree this will lead to the agents approaching it, if they are sufficiently near, etc., whereas if there is a predator, they will run from it, etc. Their model of the world is populated by properties of items that allow the (arguably rough) predictions of *agent behavior*. One might indeed say that the desires of the agents are *projected*⁹ onto the world.¹⁰ Those who acquire this ability are now 1.5th order intentional systems (see above; monkeys and chimpanzees might turn out to be such, see

Roskies [this collection](#)).¹¹ However, findings in this area are controversial. See [Lurz 2010](#)), since they can predict the behavior of others, given that their behavior is indeed explainable via reference to actually-existing objects, such as apples or potential sexual partners. In addition to these properties, there is a new category of objects in “their world”: beings that react to these properties in certain ways.¹²

In a next step we might suppose that a system of communication or signaling evolves (the details are not important), turning our intentional systems of 1.5th order into communicative agents. As communicative beings they have an interest in hiding and revealing their beliefs according to the trustworthiness of others and their motives (cf. [Dennett 2010](#)). That is, any of those beings needs to have access to what it itself will do next, so that they can hide or share this information, depending on information about the other. One might think of hiding the information about one's desire to steal some food, and so on.

This is a situation where applying the predictive strategy that was formerly only used to explain the behavior of others to *oneself* becomes an advantage for each of the agents.¹³ Agents like this believe in the existence of a special kind of special kind of properties, i.e., they predict their *own* behavior on the basis of generative models that posit such properties: they believe that they approach apples *because* they are *sweet*, cuddle babies *because* they are *cute*, laugh about jokes *because* they are *funny*. Applying the strategy to their own behavior puts them in the same category (according to the generative model) as the others: they are unified objects that react to cer-

9 What I mean by “project” is that instead of positing an inner representation whose content is “I (the system in question) want to eat that apple” and whose function is a desire, along with correct beliefs about the current situation, what is posited is an eat-provocative property of the apple itself. Both theoretical strategies allow for the prediction of the same behavior. The crucial difference is that attributing new properties to objects that are already part of the model is a simpler way of extending the model than positing a complex system of internal states to each agent. Thus it is also more likely to happen. It's definitely much simpler than extending the model to incorporate all the entities that explain the behavior on a functional level (i.e., all the neurons, hormones etc.). It is successful to the same extent the intentional stance is successful, that is, in an arguably noisy way, but still successful enough to gain an advantage (since *ex hypothesi* all the conspecifics are intentional systems).

10 This is very close to Gibson's affordances (e.g., [Gibson 1986](#)) in that “values and meanings are external to the perceiver” (p. 127) and in a couple of other respects (*ibid.*). It is, however, different in that the postulated properties serve to predict the behavior of *others* and not to guide the behavior of the organism itself. For the relation between Gibsonian affordances and predictive processing see e.g., [Friston et al. \(2012\)](#).

11 “[R]ecent work on non-human primate theory of mind suggests that monkeys and chimpanzees have a theory of mind that represents goal states and distinguishes between knowledge and ignorance of other agents (the presence and absence of contentful mental representations), even if it fails to account for misrepresentation.” ([Roskies this collection](#), p. 12).

12 The selection of goals and other cognitive capabilities, etc., is all placed outside of the target object (see [footnote 9](#)). It will approach the object that has the highest attraction value, given that there is no object with a higher repulsion value, i.e., there is no internal selection process represented *as* internal selection. What makes other agents special objects, in this model, is that they react to properties that no other things react to, not that they have an internal life that is somehow special.

13 Notice that according to PP, there is no shortcut to be taken: the mind is a black box to itself—it has to infer its own properties just as any others.

tain properties, not a bunch of cells trying to live among one another.¹⁴

The agent-models of these beings might improve by integrating the fact that sometimes it is useful to posit non-existing entities or omit existing entities in order to predict the behavior of a given conspecific (think of subjects in the false belief-task looking in the wrong box). By this the concept of (false) beliefs arises. One can imagine how they further evolve into full-fledged second and higher-order intentional systems, in an arms-race for predicting their fellows.¹⁵

A further step: they develop sciences like we did and will come to have a scientific image of the world, which contains no special simple properties of objects that cause “agents” to behave in certain ways. They come to the conclusion that the brain does its job without taking notice of properties like cuteness or redness, “instead relying” on computations, which take place in the medium of spike trains and nothing but spike trains (cf. [target](#), section 1). Their everyday predictions of others and most importantly of themselves still rely on the posited properties. And some might wonder whether there isn’t something missing from the scientific image.

According to the scientific image, they, as biological organisms, react to photons, waves of air, etc., but these are not the contents of their own internal models employed in solving the continuous task of predicting themselves. The simplest things they react to seem to be colors and shapes, (perceived) sounds, etc. The reaction towards babies is explained via facial proportions and the like, but this is far from what their generative models “say”, which is “the reaction to babies is caused by their cuteness”.

They begin to build robots, which react to babies like they do. They say things like, “all this robot reacts to are the patterns in the baby’s face, the proportions one can measure;

but although it reacts like we do, it does not do so because of the baby’s cuteness”. Of course only non-philosophers might say that science misses a property of the baby, but philosophers still see that there is *something* missing, and since cuteness is not a property of the outside world, they conclude that it must be a property of the agents themselves.

This seems to me to be the current situation. We have the zombic hunch because it seems to us that there is something missing and it seems so because our generative models are built upon the assumption that there are properties of things out there in the world to which systems like us react in certain ways. We never consider others like us to be zombies because they are agents like us or better: we are systems like them. We dismiss robots because we know they can only react to measurable properties, which do not *seem* to us to be the direct cause of *our* behavior.

4 An analysis

Is it true that properties such as cuteness do not correspond to anything? In a sense it is false to deny that any such correspondence exists: such properties do correspond to the cuddle-provocativeness of a baby, the eating-provocativeness of an apple, etc., *as a cause of the behavior of agents*. They are “lovely” properties ([Dennett 1991](#), p. 379), and there is a way to measure them: we can use ourselves as detectors. But the reason we, intuitively, do not accept a robot as a subject like ourselves is because we know how the robot does it: we know that it calculates, maybe even in a PP-manner—we know that it does not react directly to the properties that seem to exist and that seem to count. Neither do we, or the beings described above. But their own prediction of themselves treats such complex properties as simple, because there is nothing to be gained by being more precise than is necessary for *sufficiently* accurate prediction.¹⁶

This is my reconstruction of Dennett’s claim that the mind projects its dispositions

¹⁴ This is where one might speak of the origin of a self-model ([Metzinger 2003](#)) in some sense, where there is not only a model of the body (built up by proprioceptive inputs) but also a model of the self as having (primitive) goals, at least in any given moment.

¹⁵ Maybe language plays an important part in this further development as an external scaffold (cf. [Clark 1996](#); [Dennett 1994](#)). One fact supporting this view is that monkeys do not seem to be able to understand the concept of false belief (and therefore the concept of belief) (cf. [Martcorena et al. 2011](#), but also [Lurz 2010](#) for an overview of this debate).

¹⁶ This is also true of affordances (see e.g., [Gibson 1986](#), p. 141).

onto the world via Bayesian prediction. I want to draw attention to some of the features ascribed to those properties that this story predicts:

1. These properties are “given directly” to a person

The overall generative model depicts the whole organism as a unified object that reacts *directly* to the posited properties in the world. Any system that represents itself in such a way is bound to believe that there are properties of the world given directly to the object, which it takes to be itself. In subpersonal terms this object and these properties, as well as their relation to each other, are postulated entities that explain the sensory input. For instance, the fact that others talk about the system as someone with beliefs and desires (which is rooted in the same principle) can be explained by predicting itself in the same way.

2. These properties are irreducible to physical, mechanical phenomena.

Since the generative model does not depict these properties as built up from simpler ones, but simply posits them to predict lower-level patterns, these properties don't seem (to the system) to be reducible to other properties.

3. These properties are atomic, i.e., unstructured.

There are as many posited properties as there are distinct dispositions to be tracked. This also explains why one can learn to find structure in formerly unstructured qualia (cf. [Dennett 1991](#), p. 49) once new discriminative behavior is learned.

4. These properties are important to our lives/beings as humans/persons

This felt importance is obvious, given the putative role they play in the explanation provided by the generative model. These properties seem to be the causes of all our behavior: if one did not feel the painfulness of a pain, one would not scream; if one did not sense the funniness of a joke, one would not laugh, etc. Since the model is still needed for interacting with others, despite theoret-

ical advances in the sciences this felt importance of qualia to our lives is very difficult to overcome.

5. These properties are known to every living human being; it is not possible to sincerely deny their existence

This is due to the fact that our brains predict the behavior of others via a model that posits direct interaction between “agents” and first-order, non-relational object properties—the entities that are then named “qualia”.

This list has considerable overlap with lists of features ascribed to qualia (e.g., [Metzinger 2003](#), p. 68; [Tye 2013](#)), lending support to the thesis that we don't need a revolution in science to accommodate qualia, but rather a change in perspective: we might look at the creatures described above and see that “[t]hey are us” ([Dennett 2000](#), p. 353).

5 Conclusion

I have given an interpretation of Dennett's theory of why there seems to be something more to consciousness than science can explain. My aim was to thereby address crucial questions, while sticking as closely to Dennett's philosophy as possible. The answer is a just-so story that shows how (plausible) selection pressures lead to beings that cannot help but believe that they are *more* than just “moist robots” ([Dennett 2013a](#), p. 49)—because some important entities seem to be missing from the scientific description.

This story answers the questions why and how beings like us monitor their dispositions, and how this ability could have evolved. It also offers an answer as to why we don't recognize them as representations of our dispositions and why qualia are unlike other theoretical entities in that they are important for what we consider ourselves to be. The notion of an intermediate between first- and second-order intentional systems was introduced as a new conceptual instrument for satisfying the acquisition constraint and to lay the fundamentals for the belief in mind-independent simple properties that dir-

ectly cause the behavior of agents. This in turn is the basis for the belief in qualia as intrinsic properties of experience.

This story might not provide an “insight into necessity” (cf. Dennett 1991, p. 401), but I am happy if it contributes to showing and clarifying a possibility: although it may *seem* that our best hypothesis for accounting for our belief in qualia is that they actually exist, this hypothesis might still be explained away.

Acknowledgements

I want to thank Thomas Metzinger and Jennifer Windt for the unique opportunity to participate in this project. I am also very grateful for the helpful remarks they and two anonymous reviewers gave to an earlier version of this paper.

How our Belief in Qualia Evolved, and Why We Care so much

A Reply to David H. Baßler

Daniel C. Dennett

David Baßler's commentary identifies five unasked questions in my work, and provides excellent answers to them. His explanation of the gradual evolution of higher-order intentionality via a Bayesian account leads to an explanation of the persistence of our deluded belief in qualia.

Keywords

Belief in belief | Dispositions | Intentional systems | Qualia

David Baßler's commentary is a model of constructive criticism, not only pointing to weaknesses but offering persuasive repairs. I have just two points of minor correction to offer before turning to my understanding of his interesting proposals for extensions to my view, which I am inclined to adopt.

First, then, the quibbles. I am happy to see him endorsing my frequent tactic of asking not how to explain *x* but rather asking how to explain why we believe in *x* in the first place, but I think that this is a procrustean bed on which to stretch my concept of intentional sys-

tems. In [Dennett \(1971\)](#) I was indeed offering an account of intentionality that was *demoting*, in that intentionality was not seen as a feature that sundered the universe into the mental and physical (as Brentano and others had claimed), but I don't like to think of it as dismissing intentionality as a real phenomenon—though of course many have interpreted me that way. [Dennett \(1991\)](#) tried to correct that misconstrual, showing that the phenomena of intentionality are real in their own way—any beings that don't discover these patterns are missing something important in the world. That aside, I

love the use he makes of Hume on miracles to introduce his treatment of our minds as witnesses, just not very good witnesses; their testimony can be explained in ways that do not grant the truth of some of their most cherished claims. As he puts it, the assumption of phenomenal consciousness “is deeply misleading because it makes us look for the wrong things, namely, the objects our judgments are about, rather than the causes of these judgments, which are nothing like these objects” (Baßler [this collection](#), p. 2).

My other quibble is a similar elision I want to resist. He says: “Large parts of *Breaking the Spell* are dedicated to making understandable how ‘belief in belief’ could have evolved over the centuries, beginning long before the appearance of any religion” (Baßler [this collection](#), p. 4). This misidentifies higher order belief, beliefs about beliefs, with belief in belief. The former did indeed evolve gradually over the eons, and I find Baßler’s “just so story” about this gradual process enticing indeed, and will have more to say about it below, but belief in belief is a much younger (and almost always pernicious) phenomenon, which involves the deeply confused judgment that it is morally obligatory to try to get yourself to believe traditional nonsense when you know better. “If you don’t believe in God, you are immoral. Therefore you must strive to believe in God. Belief in God is a good thing to inculcate in our children and in ourselves.” Belief in belief didn’t arrive on the human scene until the proto-religions (which originally had no need for the concept) hit upon this obligation as a way of protecting their hegemony against the lures of competing dogmas. Some proto-religions were blithely ecumenical, adopting the gods and demons of their neighbors’ creeds as just another bit of lore about the big wide world, but this credulity could not long stand in the face of market competition and growing common knowledge about the objective world. Since many—probably most—people in the world now see through at least most of the nonsense, their persistent belief in belief is now a deplorable anachronism, a systematic source of hypocrisy. (A delightful cartoon in a recent *New Yorker* perfectly cap-

tures this folly. Two armies confront each other, flying identical banners; one mounted warrior says “There can be no peace until they renounce their Rabbit God and accept our Duck God.”)

As I say, these are quibbles I have to get off my chest. Now to Baßler’s substantive proposals. He organizes his commentary around five questions he says I haven’t properly asked, and he has answers to all of them. He’s right that these are gaps in my account. (1) Why do we need to monitor our dispositions? (2) How is self-monitoring accomplished? (3) How did this self-monitoring evolve in a *gradual* fashion? (4) Why do we misidentify our dispositions? (5) Why are we so attached to the idea of qualia?

His answers are constructed by taking on, for the sake of argument, my Intentional Systems Theory, and he gets it right, in all regards. Intentional Systems Theory (IST) presupposes, tactically, that any entity treated as an intentional system “is optimally designed to achieve certain goals. If there are divergences from the optimal path, one can, in a lot of cases, correct for this by introducing abstract entities or false beliefs.” IST is, as I say, a competence model that leaves implementation or performance questions unaddressed.¹

Then comes Baßler’s major novelty: the idea of an intermediate competence between mere first-order intentional systems—which have no beliefs about beliefs (their own or others’)—and full-fledged second-or-higher-order intentional systems—which can iterate the belief context. Such entities he calls (what else?) 1.5th order intentional systems (shades of [David Marr’s 1982](#) two-and-a-half-D sketch!). This is proposed to answer his first and second questions with a plausible and in principle testable evolutionary hypothesis. A system with only 1.5th order intentionality “is able to ascribe desires only in a very particular and concrete

¹ In this regard it is strikingly similar to the free energy principle as presented by [Hohwy \(this collection\)](#); both use the assumption of biofunctional optimizing as an interpretive lever to make sense of the myriad complexities of the brain, assigning to the brain a fundamental task of acquiring accurate anticipations of the relevant causes in the organism’s world. I have not yet been able to assess the costs and benefits of these two different ways of thinking of brains as future-producer: both are abstract, both court triviality if misused. This is a good topic for future work.

manner, i.e., actions that the object in question wants to perform with certain particular existing objects, that the system itself [the ascriber] knows about” (Baßler [this collection](#), p. 6). He is wise to choose basic desires (for food, mating opportunities, safety, . . .) as the intentional states ascribed in this precursor mentality, since they are so readily “observable” in the immediate behavior of the object, giving our pioneer mind-reader a quick confirmation that it’s on the right track, a small, gradual step for a Bayesian brain.

Now what selection pressures would favor such systems evolving gradually from mere first-order systems? To the primitive first-order systems, “the behavior of their conspecifics is unexplained noise to them.” But then they make some simple discoveries. When they see an apple tree, they approach it, *and so do their conspecifics*. If they see a predator, they run, as do their kin. “One might indeed say that the desires of the agents are projected onto the world”, Baßler says. Then, in a very substantive footnote that I wish were in the text—his footnotes contain much of value, and should not be passed over!—he adds: “What I mean by ‘project’ is that instead of positing an inner representation . . . whose function is a desire, along with correct beliefs about the current situation, what is posited is an eat-provocative property of the apple itself. Both theoretical strategies allow for the prediction of the same behavior. The crucial difference is that attributing new properties to objects that are already part of the model is a simpler way of extending the model than positing a complex system of internal states to each agent” (Baßler [this collection](#), p. 7, footnote 9). This answers question (3).

He then imagines, plausibly, that these 1.5th-order systems will evolve a system of communication, but this (as I and others have argued) necessarily involves hiding information from others, which involves having an internal cache of self-monitored knowledge one can choose to divulge or not, depending on circumstances. And this in turn—Baßler’s next major innovation—leads them to become “Agents [who] believe in the existence of a special kind of properties: they believe that they approach

apples because they are sweet, cuddle babies because they are cute, laugh about jokes because they are funny.” This primitive concept of causation serves them well, of course, and is just the sort of simplification to expect in a Bayesian brain, answering question (4).

Now for the icing on the cake, Baßler’s answer to question (5) about why we care about qualia. As he notes, “It is not obvious why we do not react as disinterestedly to their denial as we did to the revelation that there is no ether” (Baßler [this collection](#), p. 5). Here is his explanation: science comes along and starts to dismantle the handy manifest image, with all its Gibsonian affordances, and for those creatures capable of understanding science, a new problem arises: something is being taken away from them! All those delectable properties (and the abhorrent properties as well, of course). Philosophers “still see that there is something missing, and since cuteness is not a property of the outside world, they conclude that it must be a property of the agents themselves” (Baßler [this collection](#), p. 8). “We have the zombic hunch because it seems to us that there is something missing and it seems so because our generative models are built on the assumption that there are properties of things out there in the world to which systems like us react in certain ways. . . . We dismiss robots because we know they can only react to measurable properties, which do not seem to us to be the direct cause of our behavior” (*ibid.*).

This rings true to me, and I hadn’t seen this way of accounting for the persistence of the zombic hunch. Baßler proposes that “the reason we, intuitively, do not accept a robot as a subject like ourselves is because we know how the robot does it; we know that it calculates, maybe even in a PP manner—we know that it does not react directly to the properties that seem to exist and that seem to count” ([this collection](#), p. 9). He goes on to list five further features his account provides for. The properties we delusionally persist in “projecting” as qualia are (1) “‘given directly’ to a person”, (2) “irreducible to physical, mechanical phenomena”, (3) “atomic, unstructured”, (4) “important to our lives/beings as humans/persons”, and (5)

“known to every living human being; it is not possible to sincerely deny their existence” (Baßler [this collection](#), p. 9). I particularly like the way that his account explains why (4) is a feature: “These properties seem to be the causes of all our behavior: if one did not feel the painfulness of a pain, one would not scream; if one did not sense the funniness of a joke, one would not laugh, etc. Since the model is still needed for interacting with others, despite theoretical advances in the sciences this felt importance of qualia to our lives is very difficult to overcome” (Baßler [this collection](#), p. 9).

I see that my response consists in large measure of approving quotations from Baßler’s commentary! But that is as it must be; I want to confirm in detail and acknowledge the nice way his proposals dovetail with my account, expanding it into new territory, and helping me see what I have so far only dimly appreciated: just how valuable the new Bayesian insights are.

But let me end with a friendly amendment of my own. Baßler’s interpretation of my view is at one point a simplification, probably just for gracefulness of exposition, and perhaps meant itself as a friendly amendment, but I want to issue a caveat. Baßler takes me to be saying that, for such properties as cuteness and color, “we misidentify dispositions of the organism with properties of another object” ([this collection](#), p. 3) and goes on to have me holding that “This means, under a personal level description, that we believe that there are properties independent of the observer, such as the cuteness of babies, the sweetness of apples, or the blueness of the sky” (*ibid.*, p. 4). I want to put this slightly differently. It is not that there is nothing objective about babies that makes them cute (or of the sky that makes it blue) but just that these objective, observer-independent properties are themselves curiously dispositional: they are, as he notes at one point, what I have called “lovely” properties. They can only be *defined* relative to a target species of observers, such as normally sighted—not “color-blind”—human beings, as contrasted with tetrachromats such as pigeons, for instance. But their existence as properties is trivially objective and observer-independent. Thus rubies were *red* before color

vision evolved on this planet in the sense that if a time machine could take normal human beings back to the early earth, they would find rubies to be red. And some strata exposed by primordial earthquake faults would have been *visible*, to some kinds of eyes and not to others. Probably dinosaur babies were cute, since, as John Horner (1998) has argued, evidence strongly suggests that they were altricial, requiring considerable parental attention, and having the foreshortened skull and facial structure of prototypically cute juvenile animals, including birds. The science-endorsed properties, both external and internal, are so hugely different from what the manifest image makes them out to be, that it is a pickwickian stretch to say that science has discovered “what cuteness is” or “what color is,” but it is also deeply misleading to say that science has discovered that nothing is cute, or colored, after all. And so in a similar vein, I have to contend with how to occupy the awkward middle ground between denying that there are qualia at all, or saying that qualia are something real, but something utterly unlike what most people *think* (and philosophers *say*) qualia are.

1 Conclusion

Baßler has provided me with a plausible and testable extension of my Intentional System Theory with his innovation of a 1.5th-order intentional system, showing in outline how higher-order intentional systems might evolve from their more primitive ancestors. And he has also shown new ways of explaining a point that many people just cannot get their heads around. As my former student Ivan Fox (1989) once put it, “Thrown into a causal gap, a quale will simply fall through it.” See also Fox’s essay, “[Our Knowledge of the Internal World](#)” (1994) and [my commentary](#) on it (1994), which I discovered, on rereading just now, to be groping towards some of the points in Baßler’s commentary. I challenged Ivan Fox to “push further into the engineering and not just revel in the specs” (Dennett 1994, p. 510), and Baßler has done just that.

The Heterogeneity of Experiential Imagination

Jérôme Dokic & Margherita Arcangeli

Imagination is very often associated with the experienceable. Imagination is said to “re-create” conscious experiences. For instance, philosophers often talk of vision-like or audition-like imagination. How many varieties of experiential imagination are there, and how are they related? In this paper, we offer a detailed taxonomy of imaginative phenomena, based on both conceptual analysis and phenomenology, which contributes to answering these questions. First, we shall spell out the notion of experiential imagination as the imaginative capacity to re-create experiential perspectives. Second, we suggest that the domain of experiential imagination divides into objective and subjective imagination. In our interpretation, objective imagination comprises both sensory and cognitive imagination. In contrast, subjective imagination re-creates non-imaginative internal experiences of one’s own mind, including proprioception, agentive experience, feeling pain, and perhaps internal ways of gaining information about other types of mental states, such as sensory experience and belief. We show how our interpretation of the notion of subjective imagination differs from Zeno Vendler’s, who relies on an orthogonal distinction between two ways in which the self is involved in our imaginings. Finally, we show the relevance of our taxonomy for several important philosophical and scientific applications of the notion of imagination, including modal epistemology, cognitive resonance, mindreading and imaginative identification.

Keywords

Cognitive imagination | Cognitive resonance | Experiential imagination | External experience | Imagination | Imagination from the inside | Imaginative identification | Internal experience | Introspection | Mindreading | Motor imagery | Objective imagination | Recreative imagination | Self-involvement | Sensory imagination | Subjective imagination

1 Introduction

Many theorists have pointed out that imagination, or at least a salient type of imagination, is bound to the “experienceable”.¹ In this sense, we can imagine only what can be experienced. For

¹ This is a widespread claim that dates back to Plato and Aristotle and pervades the history of philosophy. See [White \(1990\)](#) for a good survey and a critical view of the standard picture (suggested by etymology) according to which imagination is akin to perception only. Among contemporary philosophers see also, for instance, [Wollheim \(1984\)](#), [Williams \(1976\)](#), [Casey \(1976\)](#), [O’Shaughnessy \(1980\)](#), [Vendler \(1984\)](#), [Peacocke \(1985\)](#), [Walton \(1990\)](#), [Mulligan \(1999\)](#), [Kind \(2001\)](#), [Currie & Ravenscroft \(2002\)](#), [Martin \(2002\)](#), [Noordhof \(2002\)](#), [Chalmers \(2002\)](#), [Carruthers \(2002\)](#), [McGinn \(2004\)](#), [Goldman \(2006\)](#), [Byrne \(2010\)](#).

instance, we can visually imagine only what can be seen and auditorily imagine only what can be heard. To capture the latter examples, philosophers often talk of vision-like and audition-like imagination. More generally, the relevant type of imagination is *experience-like* or (as we shall also say) *experiential*, whether or not one believes that experiential imagination exhausts the field of possible imaginings.

However, the precise sense in which imagination is experiential remains a deep and complicated issue. In this essay, we would like

to inquire into the scope of experiential imagination. In particular, we want to relate the notion of experiential imagination to two important distinctions present in the contemporary literature on imagination, namely the distinction between sensory and cognitive imagination (Currie & Ravenscroft 2002; McGinn 2004) and the distinction between subjective and objective imagination (Vendler 1984; Dokic 2008). We aim at proposing, eventually, a systematic and hopefully enlightening taxonomy of the varieties of experiential imagination.

The essay is structured as follows: Section 2 tackles the broad phenomenological sense in which our imaginings are experiential. Sensory imagination will emerge as an important sub-type of experiential imagination.

Section 3 individuates two more fundamental sub-species of experiential imagination, namely objective and subjective imagination. We shall point out that this distinction maps onto an independently motivated distinction in the field of non-imaginative mental states, namely that between external and internal experiences. While external experiences (such as vision) are only accidentally *de se*, internal experiences (such as proprioception or agentive experience) are essentially or at least normally *de se*. The upshot will be that sensory imagination is best seen as a paradigmatic case of objective imagination.

Section 4 discusses the distinction between objective and subjective imagination, as Zeno Vendler introduces it on the basis of intuitive contrast examples. We shall show that Vendler's distinction diverges from ours, since it seems to hinge on a distinction between two ways the self can be involved in our imaginings. We shall suggest that the latter distinction is in fact orthogonal to our distinction between objective and subjective imagination (section 4.1). Moreover, upon closer look, the contrast examples offered by Vendler motivate our construction of the objective versus subjective distinction, which will prove to be more fruitful for the theory of imagination (section 4.2).

Section 5 presents the notion of cognitive or belief-like imagination and gives some reason to resist its interpretation as a form of non-ex-

periential imagination. Cognitive imagination can be construed as experiential, provided that at least some of our occurrent beliefs are conscious. Moreover, if belief is an experience, it is clearly an external experience. Therefore, cognitive imagination will emerge as a sub-species of objective imagination, along with sensory imagination.

Section 6 further investigates the domain of subjective imagination and its heterogeneity. We shall suggest that, along with proprioception, agentive experience, introspection, and feeling pain, subjective imagination may re-create other internal ways of gaining information about one's mental states, including beliefs.

Although much of our discussion in this essay belongs to conceptual clarification informed by phenomenological considerations, section 7 briefly describes several upshots of our account with respect to modal epistemology, cognitive resonance phenomena, mindreading, and imaginative identification. It is our contention that the relevance of the conceptual distinctions proposed by our taxonomy of experiential imagination has been crucially neglected in many important philosophical and scientific applications of the notion of imagination.

2 Experiential and sensory imagination

Let us start with Christopher Peacocke's analysis of imagination, which can help us to delineate what we mean by "experiential imagination." Peacocke (1985) puts forward what he calls the "General Hypothesis" about imagination, or GH (General Hypothesis) for short:

GH =_{DF} To imagine something is always at least to imagine, from the inside, being in some conscious state (Peacocke 1985, p. 21).

Peacocke does not offer an explicit definition of the phrase "from the inside", but we shall follow Kendall Walton's interpretation and assume that "the question of whether an imagining is from the inside arises only when what is imagined is an experience (broadly construed)" (Walton 1990, p. 31). For instance, I may ima-

gine being a descendant of Napoleon, but, according to Walton, my imagining does not essentially involve the perspective of any experience properly speaking. There is nothing it is like to be a descendant of Napoleon.² So there is no question of imagining “from the inside” having this relational property. In contrast, when I visually imagine a white sandy beach, my imagining involves an experiential perspective. I imagine “from the inside” a specific visual experience.

Peacocke’s notion of imagining from the inside is broadly related to other notions in the philosophical literature on imagination. For instance, Gregory Currie and Ian Ravenscroft introduce the notion of *recreative imagination* as the capacity to have “states that are not perceptions or beliefs or decisions or experiences of movements of one’s body, but which are in various ways like those states—like them in ways that enable the states possessed through imagination to mimic and, relative to certain purposes, to substitute for perceptions, beliefs, decisions, and experiences of movements” (Currie & Ravenscroft 2002, p. 12). Similarly, Alvin Goldman puts forward the notion of *enactment imagination* (or *E-imagination*) as “a matter of creating or trying to create in one’s own mind a selected mental state, or at least a rough facsimile of such a state, through the faculty of the imagination” (Goldman 2006, p. 42).³

Many other philosophers have held the view that imagination is the capacity to “modify” non-imaginative kinds of mental state (Husserl 1901; Meinong 1902; Mulligan 1999; Weinberg & Meskin 2006a, 2006b), where the relevant modification is to be understood as the “preservation” of some features of the non-imaginative states, such as part of their functional roles, despite phenomenological discrepancies or different overall cognitive underpinnings. This view is independent of a strong kind of simulationism, according to which each of several types of imagination shares with a proper non-imaginative *counterpart* some cognitive mechan-

ism (or set of information-processing systems), which is redeployed off-line.

To recapitulate, according to the terminology used in this essay, imagination is the general capacity to produce *sui generis* occurrent mental states, which we call “imaginings”. Whenever a subject imagines something, she is in a particular mental state of imagining. What type of mental state the subject is in depends on the non-imaginative conscious state that is re-created. Here we want to remain as neutral as possible with respect to the relationship between imaginings and their analogues in the non-imaginative mental realm. It is enough for our purposes to accept the idea that a phenomenologically useful taxonomy of imagination can be guided by a corresponding taxonomy of non-imaginative mental states (and perhaps also the other way around, as we shall suggest toward the end of the essay).

From now on, instead of using Peacocke’s phrase “imagining from the inside”, which is potentially misleading (see footnote 16 below), we are going to use phrases of the form “X-like imagination”, or “re-creating X” in imagination, where X is a type of non-imaginative state (as in “vision-like imagination”, or “re-creating a proprioceptive experience”). However, our use of these phrases should not be interpreted as carrying all the commitments of simulationist or recreative theories of imagination (whence the presence of the hyphen in “re-creating”).

GH turns out to be a general definition of imagination as essentially involving the perspective of a conscious experience—precisely what we call “experiential imagination”. Peacocke then introduces a more specific hypothesis precisely in order to identify sensory imagination as a sub-domain of experiential imagination.⁴ He himself calls this hypothesis the “Experiential Hypothesis”,

4 What is the relationship between sensory imagination and mental imagery? The latter phenomenon is at the heart of the well-known debate about the format of representations involved in cognitive tasks such as mental rotation (see Kosslyn 1980, 1994; Tye 1991; Pylyshyn 2002; Kosslyn et al. 2006). This debate concerns the kind of *content* of the relevant representations, and one of the issues is whether such content is propositional or iconic. In contrast, the notion of sensory imagination is defined here by reference to the psychological *mode* of the re-created mental state, namely a conscious perceptual experience. For our purposes we can leave open the nature of the contents of sensory imaginings.

² Throughout the paper, we assume that experiences are conscious mental states.

³ Goldman himself acknowledges that these two treatments of imagination are similar (Goldman 2006, p. 52, fn. 21).

but in order to avoid confusion and make it clear that only sensory imagination is at stake, we are going to call it the “Sensory Hypothesis” (or Sensory Hypothesis (SensH) for short), and rephrase it as follows:

SensH =_{Df} To imagine something sensorily is always at least to re-create some sensory experience.

For instance, imagining being in front of the Panthéon or at the helm of a yacht (Peacocke’s examples) may involve re-creating some visual experience as of being in front of the Panthéon or at the helm of the yacht.

Sensory imagination is not confined to vision. In Peacocke’s words, SensH deals with “imaginings describable pre-theoretically as visualizations, hearings in one’s head, or their analogues in other modalities” (Peacocke 1985, p. 22).⁵ A similar definition of sensory imagination can be found in the work of other philosophers (Kind 2001; Noordhof 2002; McGinn 2004). The same type of imagination has also been labeled “perception-like” (Currie & Ravenscroft 2002), “perceptual imagination” (Chalmers 2002), and even “experiential imagination” (Carruthers 2002).

To the extent that SensH is concerned only with cases in which the subject re-creates a specific type of experience, namely sensory experience, it deals with a sub-type of experiential imagination as covered by GH, namely sensory imagination. At this point, the question arises as to what other types of experiential imagination there are beyond the sensory type. Walton suggests that the notion of experience at stake in GH should be interpreted in a broad way, and we may wonder about its precise breadth.

3 Objective and subjective imagination

Peacocke himself intends GH to cover genuine instances of experiential imagination that are not covered by SensH—what we shall call non-sensory

imagination. For instance, one can imagine “the conscious, subjective components of intentional action” (Peacocke 1985, p. 22). On Peacocke’s view, imagining playing the Waldstein sonata may involve re-creating a non-sensory experience, namely the intimate experience one has of one’s own action while or in acting.

Of course, the precise nature of what we may call “motor imagery” is controversial.⁶ Currie and Ravenscroft suggest that “motor images have as their counterparts perceptions of bodily movements. They have as their contents active movements of one’s body” (Currie & Ravenscroft 2002, p. 88). So on Currie and Ravenscroft’s suggestion, imagining playing the Waldstein sonata involves re-creating the perception of bodily movements.

Certainly, in order to imagine performing an action, it is not enough to re-create a *visual* experience of the appropriate bodily movements—otherwise, the relevant type of imagining would belong to sensory imagination after all. Alternatively, one might suggest that motor imagery involves re-creating a *proprioceptive* experience of the appropriate bodily movements. However, such imagining does not entail re-creating an agential experience, even if it may accompany the latter. In a similar vein, Goldman claims that motor imagery “is the representation or imagination of executing bodily movement” and has as its counterpart “events of motor production, events occurring in the motor cortex that direct behavior” (Goldman 2006, pp. 157–158). Following Goldman, we can say that imagining playing the Waldstein sonata may involve re-creating an execution of the appropriate bodily movements.

In fact, an ordinary case of imagining playing the Waldstein will probably involve (at least) three types of imagining:

- Imagining *seeing* movements of one’s fingers on the keyboard.
- Imagining *having a proprioceptive experience* of these movements.
- Imagining *playing* the sonata.

⁵ At this point we can count at least the five senses (vision, audition, touch, taste, and olfaction) as sensory modalities. Later on, we shall suggest that a sensory modality involves an *external* perceptual perspective on the world. This excludes proprioception and the sense of agency as sensory modalities, insofar as they involve *internal* perspectives on oneself.

⁶ See section 7.2. As Thomas Metzinger reminded us, the existence of motor imagery has been acknowledged by twentieth century phenomenology. For instance, Karl Jaspers has coined the German term “Vollzugsbewusstsein”, which can be translated as “executive consciousness”.

The three types of imagining are typically entangled within a single imaginative endeavor. That is, someone who imagines playing the sonata will typically imagine having a proprioceptive experience of her fingers running on the keyboard but also various sensory experiences: visual experiences of her moving fingers and auditory experiences of the music. Still, each type is essentially distinct from the others, and might even be dissociable in special circumstances (although we do not want to insist too much on the possibility of such dissociation). Suppose for instance that one imagines one's limbs being remotely controlled. One can imagine from a proprioceptive perspective one's arms and legs going through the motions characteristic of playing the piano without imagining oneself playing the piano. In this case, (ii) is instantiated but (iii) is not. More controversially, suppose that one imagines oneself being selectively anesthetized, or in the situation of a deafferented subject.⁷ Perhaps one can then imagine playing the piano without imagining having a proprioceptive experience; (iii) but not (ii) would be instantiated. Given the role of proprioceptive feedback in the ordinary execution of action, it is probably hard if not impossible to imagine playing a whole sonata in the absence of any proprioceptive-like imagining, but the relevant dissociation is in principle possible for simpler actions, such as stretching one's finger. Finally, it seems possible to imagine playing the piano without re-creating any visual or auditory experience. For instance, one can imagine playing the sonata with one's eyes closed or one's ears blocked. Here, (iii) is instantiated but (i) is not. Again, given the role of sensory feedback in the ordinary execution of action, it might be hard to form such a selective imagining, especially if the action gets complicated.

The upshot of the foregoing discussion is that only (iii) is a genuine case of motor imagery. It involves the re-creation of what philosophers of action call the "sense of agency" or the "sense of control" (see e.g., Haggard 2005 and Pacherie 2007). Since the sense of agency or control is a conscious experience, motor imagery clearly falls under the umbrella of experiential imagination.

⁷ Deafferented patients have lost the sense of proprioception; see e.g., Cole (1995) and Gallagher (2005).

Moreover, to the extent that motor imagery is (at least in principle) dissociable from sensory imagination, even if it typically depends on the latter, it is a case of non-sensory imagination.⁸

What about (ii)? Proprioception is arguably a mode of perception; it is a way of perceiving the spatial disposition of one's body.⁹ In this respect, (ii) is like (i), which is a case of sensory imagination. However, proprioception is also essentially or at least normally a way of gaining information about oneself; what proprioception is about is a bodily state of oneself. In this respect, (ii) is more like (iii), which also involves a way of gaining information about oneself, and more precisely one's actions.¹⁰

What unifies (ii) and (iii) as cases of non-sensory imagination is the fact that what is re-created is a (non-imaginative) *internal* experience. An internal experience is essentially or at least normally *de se*, in the following sense: it is supposed to be about a mental or bodily state of oneself. Proprioceptive and agentive experiences are both internal in this sense. At least in normal circumstances, one cannot have a proprioceptive experience of another's body or a sense of agency for another's action. In contrast, all cases of sensory imagination are such that what is re-created is a (non-imaginative) *external* experience. An external experience is typically about the external world and is only accidentally *de se*. For instance, vision is an

⁸ Even if it turns out that motor imagery is constitutively dependent on sensory imagination, it is clearly not fully sensory, as we will shortly show. Note also that if motor imagery can be conceived as the re-creation of an essentially active phenomenon, namely the sense of agency or control, it need not be itself active. Although we cannot dwell on this issue here, imaginings can be either active, when we deliberately imagine something, or passive, as for instance when we are lost in an episode of mind wandering (see footnote 22).

⁹ If proprioception is a case of perception, there must be proprioceptive experiences. This has been contested, especially by Anscombe (1957). However, in our view, Anscombe conflates two different claims. The first claim, which we accept, is that there are no proprioceptive *sensations*. Proprioception is not a case of sensory perception. The second claim, which we reject, is that proprioception does not involve any conscious *experience*. Even if there are no proprioceptive sensations, we are consciously aware of the positions and movements of our body.

¹⁰ The idea that there are "self-informative methods," i.e., ways of finding out about oneself, is pervasive in John Perry's theory of self-knowledge; for a recent statement, see Perry (2011). As Perry makes clear, these methods can be either metaphysically or merely architecturally guaranteed. François Recanati makes use of a similar idea in his account of perspectival thought (Recanati 2007) and mental files (Recanati 2012); for instance, he writes: "In virtue of being a certain individual, I am in a position to gain information concerning that individual in all sorts of ways in which I can gain information about no one else, e.g. through proprioception and kinaesthesia" (Recanati 2007, p. 262).

Objective imagination	Subjective imagination	
Sensory imagination	Proprioception-like imagination	Action-like imagination
<p>I re-create in imagination a visual experience of <i>my fingers running on the keyboard</i></p> <p>I re-create in imagination an auditory experience of <i>music</i></p> <p>I re-create in imagination a multimodal experience of <i>the music as caused by the motions of my fingers</i></p>	<p>I re-create in imagination a proprioceptive experience of <i>my fingers running on the keyboard</i></p>	<p>I re-create in imagination the action of <i>running my fingers on the keyboard</i></p> <p>I re-create in imagination the action of <i>playing the sonata</i></p>

Figure 1: Types of imagining involved in playing a sonata

external experience; it is a way of gaining information about one's immediate surroundings, whether or not one also sees oneself.¹¹

These considerations allow us to give a more fine-grained analysis of the realm of experiential imagination based on the external versus internal contrast, rather than the sensory versus non-sensory contrast. In a nutshell, we

¹¹ This is an oversimplification, since many ordinary experiences have presumably both internal and external aspects. On the one hand, vision might involve both exteroception and interoception (Gibson 1966). On the other hand, proprioception and other forms of bodily experience often rely on visual information (Botvinick & Cohen 1998; de Vignemont 2013). Still, the external aspect of many ordinary visual experiences is clearly dominant, while visually aided proprioception remains essentially a way of gaining information about oneself, and thus is an internal experience in our sense.

can say that experiential imagination comes in two varieties. Experiential imagination can re-create: (a) some external experience—e.g., a way of gaining information about the world (e.g., I imagine *seeing* Superman flying in the air), and (b) some internal experience—e.g., a way of gaining information about oneself (e.g., I imagine *having a proprioceptive experience of* flying in the air). Following Jérôme Dokic (2008), we shall call (a) “objective imagination” and (b) “subjective imagination”; see figure 1.¹²

¹² To make our terminology as clear as possible, the distinction between internal and external experiences concerns the realm of non-imaginative states, while the analogous distinction between subjective and objective imagination concerns the realm of imaginative

We may thus introduce two other hypotheses subordinate to [GH](#), which we call the Objective Hypothesis (ObjH) and the Subjective Hypothesis (SubjH):

ObjH =_{Df} To imagine something objectively is always at least to re-create some external experience.

SubjH =_{Df} To imagine something subjectively is always at least to re-create some internal experience.

Sensory imagination forms an important subclass of experiential imagination, but it can also be seen as a paradigmatic case of objective imagination, since it involves re-creating an *external* experience. Experiential imagination is not merely objective imagination, since another sub-class of experiential imagination, namely subjective imagination, is constituted by cases in which an *internal* experience is re-created. For instance, imagining having one's legs crossed or driving a Ferrari may involve re-creating some internal non-sensory experience, namely a proprioceptive and/or agentive experience as of having one's legs crossed or driving a Ferrari.

To sum up, we have identified two important varieties of imagination that seem to exhaust the domain of experiential imagination: objective and subjective imagination.¹³ We have argued that this distinction, which gives rise to phenomenologically different imaginings, traces back to an independent distinction within the domain of non-imaginative experiences, between external and internal experiences. We have also claimed that sensory imagination, which is the variety of experiential imagination most commonly recognized, should be seen as a paradigmatic example of objective imagination. More should be said about the distinction between objective and subjective imagination. For instance, questions arise as to whether sensory imagination exhausts the field of objective imagination and as to whether

subjective imagination encompasses more than proprioceptive or agentive experiences.

The remainder of the paper is devoted to further clarification of the notions of objective and subjective imagination. We shall begin with a comparison between our own proposal and Zeno Vendler's observations about imagination.

4 Vendler's varieties of imagination

A well-informed reader might think that our distinction between objective and subjective imagination is the same as a homonymous distinction introduced by [Vendler \(1984\)](#). Certainly Vendler intends to capture two phenomenologically different ways of imagining, which potentially correspond to our distinction between external and internal experiential perspectives (perspectives on the world and perspectives on oneself). However, he also gives a *prima facie* interpretation of the distinction between objective and subjective imagination, which has more to do with the way the self is involved in our imaginings than with the distinction between external and internal experiences. On this interpretation, Vendler's notions of objective and subjective imagination arguably diverge from ours. Let us start with Vendler's interpretation of these notions (section 4.1) and then move to a deeper analysis of the contrast examples offered by Vendler in order to motivate his distinction (section 4.2). In so doing, we shall show that our construction of the objective versus subjective distinction is more helpful in order to map the realm of experiential imagination.

4.1 Two kinds of self-involvement

[Vendler \(1984\)](#) suggests that the phrase "S imagines doing A" invites what he calls "subjective" imagination, while the phrase "S imagines herself/himself doing A" can be used to describe "objective" imagination. *Prima facie*, Vendler seems to interpret the distinction between subjective and objective imagination in terms of two ways in which the self can be involved in our imaginings—implicitly or explicitly.

Subjective imagination concerns cases in which the self is implicitly involved in the imagining, whereas objective imagination concerns

states. The question of whether imaginings themselves can be said to be internal or external is not raised in this essay.

¹³ Note that our definition leaves open the possibility that a particular imagining is both objective and subjective, to the extent that the re-created experience has both external and internal aspects (see footnote 11).

cases in which the self is explicitly involved in the imagining. This is why the phrase “imagining doing A”, which does not explicitly mention the agent of the action A, is best used to describe subjective imagination, whereas the phrase “imagining *myself* doing A”, which explicitly mentions myself as the agent of the action A, is more suitable to the description of objective imagination.

The self is implicitly involved in an imagining when it fixes the point of view internal to the imagined scene without being a constituent of that scene. One can imagine seeing the Panthéon from the other end of rue Soufflot without imagining oneself as another object in the scene. Still, the scene is imagined from a specific point of view, as defined by a virtual self. One can also imagine seeing oneself in front of the Panthéon. In such a case, the self is a constituent of the imagined scene—it is explicitly represented as a part of the imagining’s content.

Of course, when one imagines seeing oneself in front of the Panthéon, one’s imagining also involves the self implicitly. One imagines a scene from the perspective of a virtual self, which is distinct from oneself as a constituent of the scene. As a consequence, Vendler makes clear that subjective and objective imagination are not mutually exclusive. Commenting on Vendler’s distinction, François Recanati concurs, writing that “the objective imagination is a particular case of the subjective” (Recanati 2007, p. 196).

It should be sufficiently apparent that the distinction between implicit and explicit self-involvement is a matter of the imagining’s *content* and more precisely deals with the issue of how the self is involved in imagination. In contrast, the distinction between internal and external experiential perspectives has to do with the *mode* re-created in imagination, respectively an external and an internal experience. Therefore, the two distinctions answer different questions and turn out to be orthogonal.

First, objective imagination can involve the self either implicitly or explicitly (but not both at the same time). This is easily seen by considering the Panthéon example. Peacocke

himself suggests another relevant case. He observes that the phrase “imagining being seated on a horse” is ambiguous between adopting the point of view of the rider (namely oneself) and adopting the point of view of someone else who could see the rider (see Peacocke 1985, p. 23). If the relevant perspective is that of the rider (namely oneself), the self need not be a constituent of the imagined scene—in this case (where the rider does not see any part of her body), it is implicitly involved in the imagining. In contrast, if the relevant perspective embraces oneself as the rider, the self is explicitly involved; it figures in the content of the imagining. However, both interpretations involve *visual* (i.e., external) perspectives, so what is at stake is a distinction within *objective* imagination rather than a contrast between subjective and objective imagination.¹⁴

Second, it is at least arguable that subjective imagination can involve the self either implicitly or explicitly. Suppose that one subjectively imagines swimming in the ocean. One may re-create the internal experience of what Marc Jeannerod & Elisabeth Pacherie (2004) call a “naked” intention (in action), which precisely does not involve an explicit representation of the agent. In this case, no self is part of the representational content of one’s imagining. One subjectively imagines swimming without imagining the agent as such, whether oneself or anyone else. However, one might also re-create a more complex internal experience, whose content embraces oneself as the agent of the action of swimming. Accordingly, in this case, the self (oneself) is explicitly represented in the content of one’s subjective imagining. One subjectively imagines a particular agent swimming; in Vendler’s example, that particular agent is oneself.

One might object to the last point and claim that the self is never an object of internal experience. One can have at best internal experiences of particular mental states, such as inten-

¹⁴ One might object that both cases involve subjective imagination, since the visual perspective of the rider, even if she does not see her own body, is tied to her proprioceptive experience; see the *caveat* voiced in footnote 11 above. Again, it might be that the distinction between subjective and objective imagination has really to do with the distinction between re-creating predominantly internal and re-creating predominantly external experiences.

Experiential Imagination		
	Explicit self-involvement	Implicit self-involvement
Subjective	I re-create in imagination a proprioceptive and/or agentive experience of <i>myself flying in the air</i>	I re-create in imagination a proprioceptive and/or agentive experience of <i>flying in the air</i>
Objective	I re-create in imagination a visual experience of <i>myself being seated on a horse</i>	I re-create in imagination a visual experience of <i>being seated on a horse</i>

Figure 2: Explicit and implicit self-involvement in subjective and objective imagination

tions in action, but never of oneself having those mental states. However, this is a substantial claim that certainly needs to be backed up by careful arguments. Note that the assumption that the self can figure in the content of an internal experience is in principle compatible with the Humean point that the self cannot be introspected. Introspection, conceived as a form of inner perception, is only one type of internal experience. Perhaps there are non-introspective cases of internal experience whose explicit contents cannot be fully specified except by using the first-person pronoun. For instance, one might argue that at least some cases of proprioception as well as internal experiences of controlling one's body as a whole give us access to one's self, or at least to the boundaries between oneself and the rest of the environment.¹⁵

Consider other examples offered by Vendler. When you imagine yourself eating a lemon by imagining your pinched face, your imagining is

explicitly self-involving and might be fulfilled via objective imagination, such as visual imagination, but also via subjective imagination, such as proprioceptive imagination, at least to the extent that it recreates an internal experience of your bodily self. What about imagining implicitly involving the self? If while imagining eating a lemon, the subject imagines the action of eating a lemon and nothing else, she is exploiting her subjective imagination, insofar as she is re-creating an agentive perspective. It seems possible to imagine eating a lemon via objective imagination too, for instance by re-creating a visual experience as of an action independently of any identification of the agent.

To sum up, while the distinction between subjective and objective imagination seems to capture two forms or modalities of imagination, the distinction between two kinds of self-involvement, although important in itself, is less relevant to a taxonomy of experiential imagination. The orthogonality of these distinctions is shown again in figure 2. In the following sub-

¹⁵ For relevant discussion, see e.g., Cassam (1999), Bermúdez et al. (1995), Bermúdez (1998), Metzinger (2003), and Peacocke (2014).

section we shall further motivate our hypothesis that Vendler's own contrast examples are best understood in terms of the independently motivated distinction between internal and external experiences.

4.2 Vendler's examples revisited

Aside from his interpretation of subjective imagination as implicitly self-involving and objective imagination as explicitly self-involving, Vendler clearly draws our attention to two ways of imagining a given action, which have quite different phenomenological profiles. In his own words:

We are looking down upon the ocean from a cliff. The water is rough and cold, yet there are some swimmers riding the waves. 'Just imagine swimming in that water' says my friend, and I know what to do. 'Brr!', I say as I imagine the cold, the salty taste, the tug of the current, and so forth. Had he said 'Just imagine yourself swimming in that water', I could comply in another way, too: by picturing myself being tossed about, a scrawny body bobbing up and down in the foamy waste. (Vendler 1984, p. 43)

As some of Vendler's other examples show, the relevant distinction is not restricted to imagining actions:

In order to familiarize yourselves with this distinction, imagine eating a lemon (sour taste), and then imagine yourself eating a lemon (pinched face); imagine being on the rack (agony), and then yourself being on the rack (distorted limbs); imagine whistling in the dark (sensation of puckered lips), and then yourself whistling in the dark (distance uncertain, but coming closer); and so forth. (Vendler 1984, p. 43)

It is not immediately clear what is common to all cases of subjective or objective imagination in Vendler's examples. Consider the suggestion

that the relevant distinction can be explained at the level of the *states* represented by the imaginings. Subjective imagination would involve imagining states that *cannot* be imagined objectively. For instance, in imagining swimming in the water, I also imagine proprioceptive experiences, which (one might argue) cannot be imagined objectively. How could we *visually* imagine such experiences, which are essentially *felt*?

However, it is not obvious that the essence of the distinction between subjective and objective imagination can be fully captured by reference to the imagined states. One can imagine having one's legs crossed via subjective imagination, but also via objective imagination. The first type of imagining is akin to proprioception (one imagines feeling one's legs crossed), while the second type of imagining is akin to vision (one visualizes oneself with one's legs crossed). Yet these imaginings are about the same bodily condition—having one's legs crossed.

Similarly, the very same action of swimming in the ocean can be imagined subjectively or objectively. The case of pain is more controversial, but if one can be visually aware that someone is in pain (by observing pain-related behavior), then one can imagine the very same pain state either subjectively or objectively. The difference between the relevant imaginings must lie elsewhere.

We are now in the position to see that we were on the right track and that Vendler's contrast examples are plausibly construed as involving different experiential perspectives on a given scene, either internal (perspectives on oneself) or external (perspectives on the world). Subjective imagination has to do with the former, and objective imagination with the latter. This is easily seen by considering the example of imagining whistling in the dark. Vendler contrasts the subjective case, in which the subject imagines the sensation of puckered lips, with the objective case, in which the subject imagines the distance uncertain, but coming closer. In other words, what Vendler seems to contrast is proprioception-like imagination with auditory imagination or, in our terminology, an internal experiential perspective with an external one.

More generally, Vendler seems to be concerned with the difference between, on the one hand, imagining doing an action (e.g., swimming, eating, whistling, etc.) or having pain (e.g., agony), where what the imaginer re-creates is the relevant experience and, on the other hand, imagining pieces of behaviour that reveal the very same experience (e.g., visualizing an eating mouth or a body in agony), where what the imaginer re-creates is an external perspective on the relevant experience.¹⁶

Let us note that, in order to make his contrast more realistic, Vendler gives us complex examples, where more than one experience is involved. So for instance, his example of imagining swimming in the ocean clearly belongs to subjective imagination, since the re-creation of a proprioceptive and/or agentive experience is involved. As Vendler suggests, though, when you fulfill this imagining you can also re-create various external experiences, such as “the cold, the salty taste, the tug of the current, and so forth”. The same is true in the case of imagining eating a lemon. When you imagine eating a lemon, you re-create in imagination an internal experience (e.g., the proprioceptive and/or agentive experience of eating), but your imagining can be accompanied by others that re-create external experiences (e.g., the sour taste, the yellow lemon).

The discussion of Vendler’s distinction has led us to strengthen our taxonomy of experiential imagination. So far we have seen that, first, all cases covered by *SenH* seem to be cases of objective imagination (and thus covered by *ObjH*), which involves re-creating some external experience. Second, all cases covered by *SubjH* arguably involve re-creating some internal experience.

However, another important type of imagination emerges from the literature on imagin-

ation, namely cognitive imagination, which has been defined as belief-like and typically contrasted with sensory or even experiential imagination.

5 Cognitive imagination

Many authors contrast sensory imagination with cognitive imagination (“imagining that,” or “propositional imagination”), which has been defined as belief-like (Mulligan 1999; Currie & Ravenscroft 2002; McGinn 2004; Goldman 2006; Weinberg & Meskin 2006b; Arcangeli 2011a).¹⁷ Cognitive imagination seems to be relatively autonomous from sensory imagination. For instance, one can imagine that poverty has been reduced in the world independently of re-creating any visual, auditory, tactile, etc., experience. Of course the autonomy of cognitive imagination relative to sensory imagination echoes the autonomy of belief relative to sensory perception (one can believe that poverty must be reduced in the world without perceiving anything).

Cognitive imagination is by essence non-sensory, but given our previous discussion, it does not exhaust the field of non-sensory imaginings. Re-creating in imagination some internal experience is presumably non-cognitive (in the relevant sense of being belief-like), but it is non-sensory as well. Thus we have, at least *prima facie*, three types of potentially dissociable imagination: sensory non-cognitive imagination (e.g., I imagine hearing a piece of music, such as Ravel’s *Concerto pour la main gauche*), non-sensory non-cognitive imagination (e.g., I imagine having the proprioceptive experience of being one-armed), and non-sensory cognitive imagination (e.g., I imagine that Maurice Ravel has created a piano piece especially for me).

One might argue that cognitive imagination is not only non-sensory but non-experiential as

¹⁶ A similar point is made by Mike Martin when he draws a distinction between “cases in which there is just an itch in the left thigh” in imagination and cases “in which one imagines some person whose behaviour reveals that they have an itch” (Martin 2002, p. 406, fn. 35; see also Dorsch 2012). However, according to his terminology, only the former cases count as being “from the inside”. Very often in the literature, the phrase “imagining from the inside” is used in this narrow sense (to refer to subjective imagination in our terminology) more than the broad sense meant by Peacocke (which refers to experiential imagination as a whole).

¹⁷ In fact, Mulligan speaks of a judgement-like, rather than a belief-like, type of imagination, which he calls “supposition”. It is not entirely clear whether his notion of supposition can be equated with what we call “cognitive imagination.” Very often in the literature, supposition is taken to be belief-like and, as such, nothing but cognitive imagination (Nichols & Stich 2003; McGinn 2004; Goldman 2006). An alternative view is that supposition is a *sui generis* type of imagination akin to *acceptance* rather than belief (Arcangeli 2011b). However, for present purposes we will skip this issue and consider only belief-like imagination.

well and as such lies outside the scope of [GH](#). According to a standard view, beliefs, even if they can be occurrent, are not conscious experiences strictly speaking. On this view, an occurrent belief may be accompanied by various experiences (mental images, feelings, emotions, etc.), but there is nothing it is like to have a belief.¹⁸ Now this view has recently come under attack by philosophers who acknowledge the existence of a doxastic phenomenology, i.e., a kind of phenomenology characteristic of belief (see the debates on cognitive phenomenology in [Bayne & Montague 2011](#)). On this alternative view, there is something it is like to have an occurrent belief, which is reducible to neither sensory nor affective phenomenology. At least some occurrent beliefs would be *sui generis* conscious experiences.¹⁹

If the alternative view is broadly correct, some beliefs lie within the scope of [GH](#).²⁰ In order to capture cognitive imagination as a putative form of experiential imagination, let us introduce another specific hypothesis subordinate to [GH](#), which we call the Cognitive Hypothesis (C):

CogH =_{Df} To imagine something cognitively is always at least to re-create a conscious occurrent belief.

For instance, cognitively imagining that quantum physics is false or that this pen is an alien involves re-creating the conscious occurrent belief that quantum physics is false or that this pen is an alien. In general, one may surmise that anything that can be consciously believed can be cognitively imagined.

We have suggested that experiential imagination divides into two sub-domains only, namely subjective and objective imagination (covered by [SubjH](#) and [ObjH](#), respectively). In addition, sensory imagination (covered by [SensH](#))

emerged as a species of objective imagination and non-sensory non-cognitive types of imagination (e.g., proprioception-like and agentive-like imagination) have been described as paradigmatic cases of subjective imagination. What about cognitive imagination (covered by [CogH](#))? Is it a type of objective or of subjective imagination? Or should we acknowledge a third class of experiential imaginings that are neither objective nor subjective?²¹

We have introduced the distinction between objective and subjective imagination as the imaginative analogue of the distinction between external and internal experience. As we have seen, many external experiences are ways of gaining information about the world, and many internal experiences are ways of gaining information about oneself. Now one might claim that belief, unlike perceptual or introspective experience, is not individuated in terms of ways of gaining information. Of course some of our beliefs result from various ways of gaining information about the world and ourselves, but it is logically possible to have a belief that is not the result of any source of information. Does it follow that belief as an experience is neither external nor internal? Not really, for an external experience has been more fundamentally defined as being accidentally *de se*, whereas an internal experience is essentially or at least normally *de se*. In this more fundamental sense, if belief is an experience, it is clearly an external experience: one can believe all sorts of states of affairs that do not involve or concern oneself. It follows that cognitive imagination, as the re-creation of an external doxastic experience, is better seen as a sub-species of objective imagination, along with sensory imagination. Objective imagination then emerges as a heterogeneous domain, but where at least two clearly different types of imagining can be distinguished (see figure 3).

¹⁸ See [Metzinger \(2003\)](#), [Tye \(2009\)](#), and [Carruthers & Veillet \(2011\)](#). Note that the standard view can lead to different attitudes toward the notion of cognitive imagination. On one attitude, cognitive imagination exists but is non-experiential. On another attitude, cognitive imagination does not exist or wholly reduces to sensory imagination (if, for instance, it is construed as auditory verbal imagination).

¹⁹ [Crane \(2013\)](#) defends a closely related view, according to which episodes of thinking, although not beliefs themselves, are phenomenally conscious. [CogH](#) can easily be adapted to accommodate Crane's view.

²⁰ In conversation, Peacocke confirmed that he intends [GH](#) to cover at least some cases of belief-like imagination.

²¹ Moreover, the question of whether these varieties of imagination exhaust the field of experiential imagination remains open. In order to answer it we would have to inquire as to whether there are other types of imagination, such as desiderative or desire-like imagination (see [Currie & Ravenscroft 2002](#) and [Doggett & Egan 2007](#) for a positive view, and [Weinberg & Meskin 2006a](#) and [Kind 2011](#) for a critical view), affective or emotion-like imagination (see [Goldman 2006](#) for a positive view, and [Currie & Ravenscroft 2002](#) for a critical view) and judgement-like or acceptance-like imagination (see footnote 17). For lack of space, we have to defer this inquiry to another occasion.

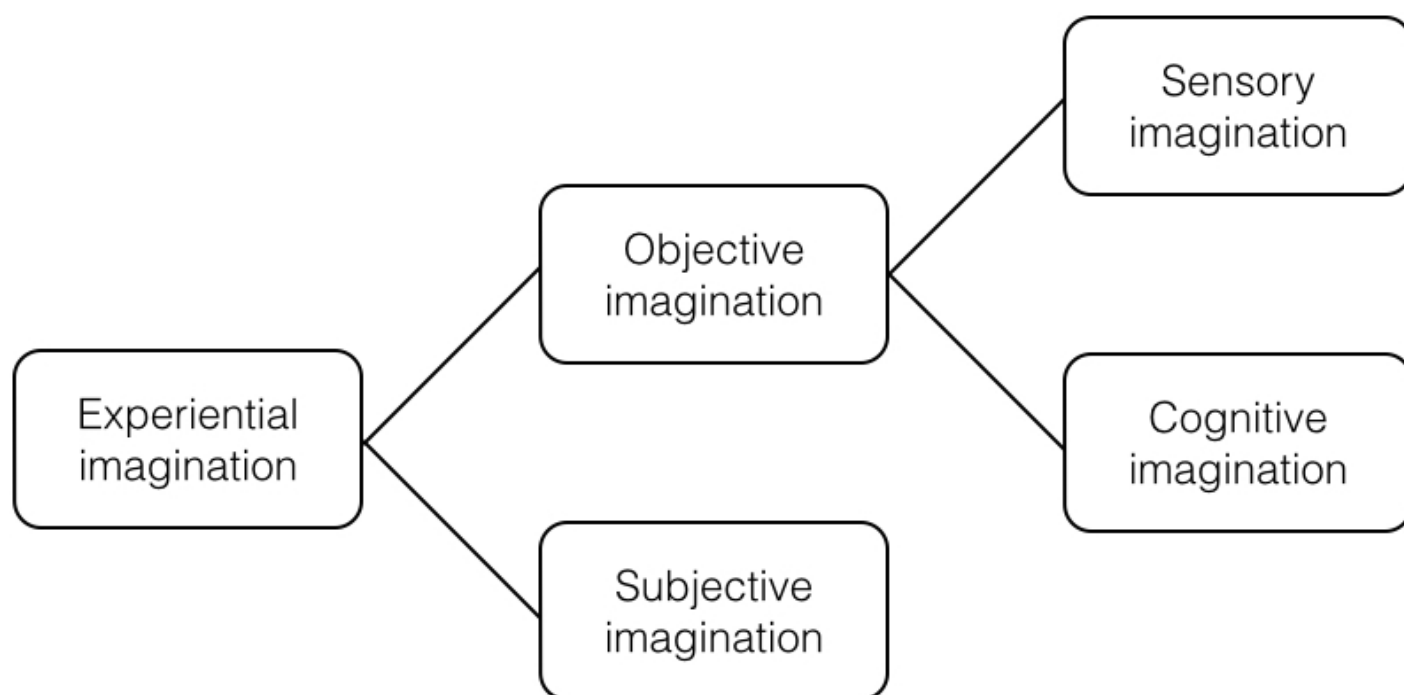

Figure 3: The varieties of experiential imagination

6 The scope of subjective imagination

As we have seen, subjective imagination involves re-creating various ways of gaining information about ourselves, such as proprioceptive or agentive experience. Now we also have ways of gaining information about our own sensory experiences, as well as about our own beliefs. We seem to be able to form self-ascriptions of the form “I see x ” or “I believe that p ” without relying on independent background beliefs. The nature of this ability is controversial. Some philosophers claim that both sensory experiences and beliefs can be introspected (e.g., [Goldman 2006](#)). Thus, we should be open to the possibility of re-creating in imagination an introspective experience of a visual experience or an occurrent belief. Other philosophers reject the notion of introspection altogether and consider that self-ascription of sensory experience or belief can follow a purely theoretical procedure known as an “ascent routine” (see [Evans 1982](#) and [Gordon 1995](#) for the case of belief, and [Byrne 2010](#) for suggestions about how to extend the ascent routine to sensory experience).

The question arises as to what types of internal experience can be re-created in imagination, i.e., what the scope of subjective imagination is. In a sense, this question is hostage to an

independent theory of internal experience, appropriate to sensory experience or belief. Obviously, we cannot settle the matter in this exploratory essay. Still, before moving to the penultimate section, we would like to suggest that phenomenologically accessible distinctions within the realm of imagination might be conceived as (usually neglected) constraints on a correct theory of internal experience. We shall focus on belief, but similar observations can be made for the case of sensory experience.

There is some phenomenological evidence that subjective imagination can capture an internal perspective on at least some beliefs. Consider an atheist who tries to imagine what it is like to believe in God. One might argue that this involves re-creating some internal experience of an occurrent belief in God. At least the atheist’s imagining seems different from two other types of imagining, namely imagining believing in God and imagining believing that one believes in God.

First, it is different from re-creating in imagination an occurrent belief in God, which would be an example of cognitive imagination. The latter imagining does not have belief as a constituent of its content; one cognitively imagines God himself, rather than some belief in

his existence. In general, an imagining that re-creates the non-imaginative state *M* need not have *M* as part of its content; the imagining itself is an imaginative re-creation of *M*, but it is not about *M* (Currie & Ravenscroft 2002, p. 27; see also Burge 2005, p. 63, for the corresponding point about sensory imagination). In contrast, the atheist's imagining essentially has belief as one of the constituents of its content; one imagines a particular belief in God. A related difference is that re-creating an occurrent belief in God is re-creating an external experience of a God-involving world. However, the atheist might want to imagine what it is like to believe in God without taking a stance on the presence of God in the imaginary world. Her imagining is focused on the belief in God, independently of whether it is true or false (even though as an atheist she believes it to be false).

Second, the atheist's imagining is different from re-creating an occurrent higher-order belief that one believes in God, i.e., imagining that one believes in God. Intuitively, the former imagining is more specific than the latter (which is another example of cognitive imagination). Imagining having the higher-order belief that one believes in God involves re-creating an external experience of one's belief in God. However, the atheist is not merely imagining that she or someone else has a belief in God. She wants to get into the believer's mind and re-create in imagination an *internal* perspective on some occurrent belief in God.

In the context of GH, the apparent existence of cases of subjective imagination where the re-created experience is an internal experience of belief can be seen as a constraint on a correct account of the way we gain information about our own beliefs. The introspective account can offer a straightforward explanation of the atheist's imagining as involving the re-creation of an introspective experience, as opposed to a mere higher-order belief, about the belief in God. *Prima facie*, the ascent-routine account has fewer resources to give justice to the relevant phenomenology. It might not be impossible to do so, though, if experiential imagination can also re-create complex cognitive processes such as going through an ascent routine. Again, we

have to leave the discussion for another occasion. It is enough for our purposes to gesture toward the possibility of extending the scope of subjective imagination to encompass more or less specific internal perspectives on beliefs, even if further argument is certainly needed.

7 Some applications

In this penultimate section, we would like to briefly illustrate how the fate of important claims about imagination made by philosophers and scientists depends on something like our taxonomy of experiential imagination. Although we believe that this taxonomy has philosophical value in its own right, we also would like to show that it is connected to central issues in philosophy and cognitive science. These issues concern, respectively, modal epistemology (section 7.1), cognitive resonance (section 7.2), mindreading (section 7.2), and imaginative identification (section 7.4). Our discussion in what follows, though, can only be rather programmatic in contrast to the rest of the essay.²²

7.1 Modal epistemology

Imagination has been traditionally construed as providing evidence for modal claims. For instance, many philosophers since Descartes have suggested that what can be imagined is metaphysically possible. On the other hand, imagination has been shown to produce various sorts of modal illusions (Kripke 1980; Gendler & Hawthorne 2002). The main challenge faced by proponents of an internal relation between imagination and possibility (perhaps via conceivability) is thus to distinguish proper and improper

²² This is only a selection of issues where we think our phenomenological and conceptual distinctions are relevant. We wish we had space to discuss other topics of relevance to the theory of imagination, such as mental time travel (Schacter & Addis 2007), dreams (Windt 2014), and mind wandering (Metzinger 2013). For instance, there are interesting issues having to do with the apparent lack of reflexivity of mind wandering episodes, and the tendency for the mind wanderer to identify herself with imagined protagonists (Metzinger 2013). A speculative hypothesis is that the passivity of mind wandering episodes causes various metacognitive errors, such as the error of confusing a case of subjective imagination with a genuine case of internal experience, which leads the imaginer to self-identify with the subject of the imagined mental state. Again, we have to leave this fascinating issue to another occasion.

uses of imagination, i.e., those uses that provide, and those that do not provide, evidence for modal claims. One might suggest, for instance, that proper uses of imagination require a certain format that other uses lack (Nichols 2006; Weinberg & Meskin 2006b).

In our view, there is an additional criterion that must be taken into account in these debates, which concerns the type of non-imaginative state that is re-created by the relevant imaginings. It might be that only some types of imagination are internally related to modal properties. For instance, it is not clear that cognitive imagination is essentially related to possibility. Assuming the correctness of our claim that cognitive imagination re-creates belief, the fact that one can cognitively imagine that p is no more evidence that p is possible than the mere fact that one believes that p . After all, one can believe all sorts of metaphysically impossible states of affairs (such as that Hesperus and Phosphorus are distinct celestial bodies).

The challenge is then to identify the types of imagination, if any, that are essentially or at least reliably related to what is metaphysically possible. One hypothesis, voiced by Dokic (2008), is to focus on types of imagination that re-create states of (actual or potential) knowledge. On this hypothesis, some uses of imagination are guides to possible contents because they are guides to the possibility of *knowing*. To the extent that sensory perception is commonly thought to be a source of knowledge, sensory imagination could be reliably linked to the possibility of what is imagined in this way (see also Williamson 2008).

This is not to say that cognitive imagination has no role to play in providing evidence for modal claims. Just as belief can be grounded on sensory perception and thereby be counted as knowledge, a single imagining might re-create not only belief and perception separately, but the complex mental state of believing that p on the basis of suitable sensory evidence (see Dokic 2008). The resulting imagining would be neither purely sensory nor purely cognitive, but to the extent that it re-creates a non-imaginative state of knowledge, its content might be bound to what is metaphysically possible.

7.2 Cognitive resonance

If we are right, there is a phenomenologically accessible distinction between objective and subjective imagination. What it is like to visually imagine an action or a painful experience is typically different from what it is like to subjectively imagine acting or having pain. However, this distinction is rarely made explicit in the scientific literature on the neural underpinnings of imagination. Let us consider the case of action. It has been a remarkable discovery that observing and executing an action involve (at least sometimes) the same resonance system in the brain, and more precisely the same “mirror neurons,” corresponding to types of action such as grasping, reaching, or eating (Rizzolatti et al. 1996; Rizzolatti et al. 2001). What about imagining an action? Marc Jeannerod claims that “imagining a movement relies on the same mechanisms as actually performing it, except for the fact that execution is blocked” (Jeannerod 2006, p. 28). Does this claim concern objective imagination, subjective imagination, or both? On the one hand, his notion of “motor imagery”, defined as “the ability to generate a conscious image of the acting self” (p. 23), strongly suggests that he is talking about subjective imagination. Motor imagery seems to underlie the imaginative recreation of an internal experience of action, such as the intimate experience we have while executing an action or controlling our bodily movements. On the other hand, Jeannerod makes clear that the “action representations” involved in motor imagery can also operate during action observation (p. 39). To the extent that visually imagining an action is analogous to observing an action, one may surmise that objective imagination too involves the relevant action representations.²³

What we would like to know, of course, is which action representations are common to both objective and subjective imagination of an action, and which action representations are specific to

²³ There is also the interesting case of observing one’s own action in a mirror. The question here is whether the observer is aware that she is observing her own action. If the answer is negative, then the re-creation of the relevant experience belongs to objective imagination. If the answer is positive, as for instances when one uses visual information to control one’s action (think of a man shaving in front of the mirror), then the re-creation of the relevant experience may also belong to subjective imagination (see footnote 11).

subjective imagination. Here as elsewhere, we think that phenomenological considerations can at least guide scientific investigations into the neural underpinnings of our ability to imagine actions, whether imaginatively observed or imaginatively executed.

7.3 Mindreading

We also think that much of the once-hot debate between the “theory theory” and the “simulation theory” of mindreading has missed the distinction between objective and subjective imagination, or at least its significance. Mindreading is often described as involving ways of “putting oneself in another person’s shoes” (Goldman 2006). However, as many have observed, that colloquial phrase can be used to refer to two different projects. One might try to understand either what one would do if one were in the other’s situation or what the other will do. The difference between these meanings has been conceived as depending on whether one performs the right “egocentric shift” and succeeds in mimicking the other’s mind (Gordon 1995). If we are right, there is another distinction that is crucial to simulation-based mindreading, namely the objective versus subjective imagination distinction. We might perform the right egocentric shift but imaginatively re-create only the other’s external experiences. For instance, we might imaginatively adopt the other’s visual point of view and try to understand what he or she is actually seeing. In doing so, though, we imaginatively adopt a perspective that is not necessarily the other’s perspective. Visual perspectives can be shared. It is only if we re-create at least some of the other’s internal experiences that we imaginatively adopt a perspective that can only be that of the agent. Unlike external experiences, internal experiences cannot be shared.

Why is it important for the success of mindreading that the mindreader re-creates also internal experiences of the other person? Let us consider the case of pain. To the extent that both objectively and subjectively imagining another person in pain may trigger the same resonance (affective) mechanisms, we can argue

that they are on par with respect to the imaginer’s *understanding* of the other’s experience (Gallese 2003). We surmise that the relevant difference between objectively and subjectively imagining the same painful experience concerns the *dynamics* of mindreading. Recreating an internal perspective on pain will spontaneously give rise to other subjective imaginings involving the recreation of the mental consequences of pain in the other. Objective imagination of another person in pain will likely develop in different directions. For instance, if we re-create a visual experience as of someone in pain, we will be inclined to re-create other visual experiences of the consequences of pain. More generally, someone who would be able to re-create only external experiences of pain would be blind to the internal consequences of pain. In contrast, subjective imagination promises to yield a better view of the other’s inner life as it unfolds in time.

7.4 Imaginative identification

In this essay, we did not explicitly mention an intriguing phenomenon in the field of imagination, namely our ability to *imagine being someone else*, or imaginative identification. For instance, we can imagine being Napoleon seeing the desolation at Austerlitz and being vaguely aware of one’s short stature (Williams 1976, p. 43). Recanati calls such cases “quasi-de se imaginings”:

I will, therefore, coin the term ‘quasi-de se’ to refer to the first person point of view type of thought one entertains when one imagines, say, being Napoleon. The type of imagining at stake is clearly first personal, yet the imaginer’s self is not involved [...]. The properties that are imaginatively represented are not ascribed to the subject who imagines them, but to the person whose point of view she espouses. (Recanati 2007, pp. 206–207)

How can an imagining be both first-personal and not genuinely (but only “quasi”) *de se*? If we can imagine being Napoleon just by recreat-

ing his visual experience of the desolation at Austerlitz, it is not obvious that quasi-*de se* imagination is necessarily first-personal. Since visual perspectives can be shared, our visual imagining can re-create anyone's perspective. In other words, objective imagination (i.e., the re-creation of external perspectives) would not be sufficient to generate quasi-*de se* imaginings. Perhaps Recanati implicitly ties quasi-*de se* imagination to subjective imagination so that imagining being someone else involves the recreation of at least some internal experience. Again, in contrast to external perspectives, internal perspectives cannot be shared. For instance, a subject imagining to be Napoleon might, on the one hand, see in imagination the desolation at Austerlitz (i.e., an external perspective is re-created) and, on the other hand, be vaguely aware of his short stature and his hand in his tunic (i.e., an internal, proprioceptive perspective is re-created).

In what sense would subjective imagination be first-personal, then? One view is that the quasi-*de se* case somehow derives from the genuine *de se* case, in which we imagine ourselves having various external and internal experiences. On this view, there is an asymmetrical dependence between quasi-*de se* and genuine *de se* imagination: even if the former is not merely a type of the latter, imagining being someone else having such-and-such experiences depends on the ability to imagine oneself having these experiences.

However, our account of subjective imagination suggests an alternative view, according to which the identity of the subject need not be built into a subjective imagining. Consider the case of action again. The constraint imposed on subjective imagination, that the imagined perspective on the action can only be that of the agent, leaves open whose self is involved. That the action is my action, or someone else's, is an additional fact in the imaginary world. In other words, subjective imagination can be neutral as to the identity of the self that occupies the relevant internal perspective. As a consequence, the same neutral imagining can give rise to either quasi-*de se* or genuine *de se* imagination, depending on

the imaginary project at stake.²⁴ Subjectively imagining oneself swimming and subjectively imagining another person swimming both rest on the same type of imagining, i.e., the recreation of an internal experience of the action of swimming. We take this neutrality to be a potential advantage for our analysis of subjective imagination. Subjective imagination can be seen as a basis for the introduction of a notion of self that is conceptually on a par with other selves. In this respect, imagination acts as an antidote to solipsism.

8 Conclusion

In this essay, we have tried to clarify what it means to claim that imagination is experiential. As we have seen, the notion of experiential imagination is not unitary and refers to a variety of phenomena. We have focused our attention on four aspects of this notion.

- First, experiential imagination broadly means that different kinds of experiential states are re-created in the imagination (although we have remained silent about the precise way in which the experiential states are re-created).
- Second, the distinction between external and internal experiences, which is independently motivated in the literature on non-imaginative mental states, has given rise to a helpful sub-division of experiential imagination into two different ways of imagining: objectively and subjectively. *Pace* Vendler, we have argued that this contrast cannot be straightforwardly aligned with two ways in which the self is involved in our imaginings (respectively, explicitly, or implicitly).
- Third, the literature commonly acknowledges two other varieties of imagination, namely sensory and cognitive imagination.

²⁴ The notion of imaginative project comes from Williams (1976). Imaginings are particular mental states, whereas imaginative projects can bind several imaginings in a coherent endeavour of imaginative world-making. The distinction is relevant even when a single imagining is at stake. Typically, an imaginative project will impose constraints, e.g., of an intentional or stipulative sort, on what is the case in the imagined world in addition to what is explicitly represented in an imagining.

We have pointed out that they should be considered as two sub-varieties of objective imagination, insofar as they both re-create external experiences (respectively, the five senses and at least some occurrent beliefs).

- Fourth, we suggested, more tentatively, that subjective imagination too may be further divided. There would be, on the one hand, the imaginative re-creation of *non-cognitive* non-sensory internal experiences (e.g., proprioception, agentive experiences, introspection, feeling pain) and, on the other hand, the imaginative re-creation of *cognitive* non-sensory internal experiences (e.g., ascent routines).

Of course, more has to be said about the precise domain of experiential states that can be re-created in the imagination, beyond those that we have introduced in this essay. Another question is whether there is something like non-experiential imagination. It might well be that, at the end of the journey, every type of imagining can be shown to belong to experiential imagination. This would have to include the state of imagining being a descendant of Napoleon, which, as we have seen, Walton rates as non-experiential. For instance, one might suggest that it is the state of imagining believing that one is a descendant of Napoleon (understood as representing in imagination a world in which one is a descendant of Napoleon).

Eventually, an analysis of experiential imagination on the lines suggested above should throw light not only on imagination *per se*, but on connected phenomena. As we have tried to illustrate, we believe that traditional and contemporary discussions about the relationship between imagination and possibility, the nature of mindreading, and the ability to imagine being someone else, often rely on oversimplified conceptions of imagination, and that a more fine-grained taxonomy of experiential imagination is needed. We suspect that our taxonomy is beneficial to still other applications of the notion of imagination, but we have to leave the task of justifying our suspicion to another occasion.

Acknowledgements

We thank the audience of the workshop “Self and Agency” in Liège (April 2014) for valuable feedback, two anonymous referees, and the editors Thomas Metzinger and Jennifer Windt for most helpful comments on earlier drafts of this essay.

Imagination and Experience

A Commentary on Jérôme Dokic & Margherita Arcangeli

Anne-Sophie Brüggén

Jérôme Dokic and Margherita Arcangeli develop a taxonomy of the mental states classified as experience-like imaginings in their paper “The Heterogeneity of Experiential Imagination”. Experience-like imaginings are thought to *re-create* experiences. Therefore, the taxonomy of the Experiential Imagination suggested by the authors mirrors a taxonomy of the underlying, re-created experiences. In this commentary, I will focus on the notion of re-creation that is invoked, and argue that this notion must either be fleshed out further or omitted from the taxonomy. Two further points follow this discussion: first I will discuss the idea of different kinds of self-involvement in objective and subjective imagination and suggest an alternative view. Then I raise some doubts about the classification of cognitive imaginings as experiential imaginings. To summarise, I will suggest an alternative interpretation of these findings by claiming that we can obtain a useful taxonomy of imaginative states based on our pre-theoretical opinions. Furthermore, I will explore the idea that experiential imaginings involve an empty point of view.

1 Introduction

In their paper “The Heterogeneity of Experiential Imagination”, Jérôme Dokic and Margherita Arcangeli offer a taxonomy of the various mental states subsumed by them under the label Experiential Imagination. Experiential Imagination is introduced as the re-creation of non-imaginative, conscious mental states. Since experiential imaginings re-create experiential mental states, they can be classified according to the underlying taxonomy of the conscious mental states that they re-create. Dokic and Arcangeli

argue that there are two types of Experiential Imagination: objective imagination and subjective imagination. Objective imagination re-creates experiences about the external world, while subjective imagination re-creates experiences about mental or bodily states of oneself. Furthermore, the authors refine the category of the objective imagination by dividing it into sensory imagination and cognitive imagination. This taxonomy of the Experiential Imagination suggested by Dokic and Arcangeli provides a struc-

ture within which to understand the vast spectrum of mental states classified as experiential imaginings by referring to the notions of subjective and objective imagination. The authors additionally suggest an attractive perspective on cognitive imaginings, which relies on the idea that these have a phenomenal character as well.

I would like to discuss three aspects of Dokic and Arcangeli's paper and close with my own reflections on the topic. I will start with a point concerning the definition of Experiential Imagination as re-creating other mental states (section 2). Two points about the taxonomy itself will follow this discussion: the second point deals with the notions of objective and subjective imagination (section 3). A third point with which I will be concerned is the classification of cognitive imaginings within the suggested taxonomy (section 4). It is unclear whether and in what sense the notion of *re-creation* is helpful for delineating the suggested taxonomy of Experiential Imagination. The taxonomy faces certain issues that are partly grounded in the notion of *re-creation*.

Given these considerations, I will present my own take on a classification of imaginings that does not involve the notion of re-creation and is based on our pre-theoretical opinions about imaginings. In addition to this, I explore the notion of an *empty perspective* to describe a phenomenological difference in the perspectival character of imaginings and non-imaginative experiences (see section 5).

2 Re-creating experiences in imagination

I would like to focus first on the notion of Experiential Imagination itself. Dokic and Arcangeli want to develop a taxonomy of Experiential Imagination, and they therefore start by exploring the mental states that fall under this category. The authors introduce the subject of their taxonomy, the Experiential Imagination, as follows (see Dokic & Arcangeli [this collection](#), p. 2): Experiential Imagination is first of all imagination that is *experience-like*. Whether all instances of imaginings are of this kind or whether there may be kinds of imagination that do not fall under this category is left open

(Dokic & Arcangeli [this collection](#), p. 2). The notion of Experiential Imagination is spelled out further by referring to Christopher Peacocke's so-called General Hypothesis (GH):

To imagine something is always at least to imagine, from the inside, being in some conscious state (see Peacocke 1985, p. 21).

According to this definition, Experiential Imagination is imagining something *from the inside*, which is defined as involving "the perspective of a conscious experience" (Dokic & Arcangeli [this collection](#), p. 3). An example would be visually imagining a white sandy beach, which involves a certain experiential perspective (Dokic & Arcangeli [this collection](#), p. 3). The authors call this kind of imagination "X-like" imagination or "re-creating X" in imagination (Dokic & Arcangeli [this collection](#), p. 3), with X standing for the non-imaginative mental state that is re-created (Dokic & Arcangeli [this collection](#), p. 3). Following this terminology, visually imagining a white sandy beach is vision-like imagination or re-creating a visual experience of a white sandy beach in the imagination. The authors sum up these considerations in a brief discussion on the notion of *re-creation*: Experiential Imagination is, according to the authors, imagination that re-creates non-imaginative conscious states (Dokic & Arcangeli [this collection](#), p. 3). The idea that imaginative states re-create other mental states allows Dokic & Arcangeli to ground their taxonomy of the Experiential Imagination on a classification of such re-created mental states. A taxonomy of these underlying non-imaginative mental states can therefore serve as a basis for a taxonomy of the corresponding imaginative states ([this collection](#), p. 3). Dokic and Arcangeli do not commit themselves to any existing account that explains the imagination in terms of *re-creation* or *simulation* (Dokic & Arcangeli [this collection](#), p. 3). The notion of re-creating a non-imaginative mental state is not explored further, since "it is enough for our purposes to accept the idea that a phenomenologically useful taxonomy of imagination can be guided

by a corresponding taxonomy of non-imaginative mental states” (Dokic & Arcangeli [this collection](#), p. 3).

Even if the authors wish to remain as neutral as possible with respect to the notion of re-creation, it is important to spell it out. There are two main reasons why I think that this notion should be explored further: first, the notion of re-creation is crucial to the nature and scope of the taxonomy in which it is involved. Second, it seems to me that the authors oscillate to some extent between different notions of re-creation, rather than actually remaining neutral about it.

Concerning the first point, there seem at least three options available for understanding the idea that imaginings re-create other mental states, assuming that *re-creating* is not used to specify sub-personal processes but deals instead with mental states on a personal level:

- (1) As a *mere way of speaking* to refer to x-like imaginings
- (2) As the claim that imaginings re-create an experiential *mode*
- (3) As the claim that imaginings re-create experiences as part of their *contents*

The first way to understand the notion of re-creating is to use it synonymously with the notion of x-like imagination. What I mean by this is that we may use the notion of *re-creating X in imagination* to refer to *having an imagining with an x-like phenomenology*. In which case, for example, *re-creating a visual experience in imagination* would be synonymous with *having a vision-like phenomenology*. Understood like this, the notion of re-creating is simply used to refer to imaginings with an experience-like phenomenology. This is merely a way of speaking or a terminological stipulation. If the notion is used like this, it does not assume or specify any relation between imagination and experience in general (or between particular imaginings and experiences). That is, using the notion in this way does not commit us to the claim that imaginings are related to or dependent on experi-

ences in any sense. However, if the notion of re-creation is used as a mere way of speaking, it would be better to omit it from the taxonomy altogether, since it does not play any explanatory role or add any technical term. Instead, we could simply speak of *x-like* imagination and thereby refer to imaginings that have an x-like phenomenology.

The other two ways of spelling out the notion of re-creating are more substantial than just synonyms for x-like imaginings: in these versions, the notion of re-creation is a *metaphysical notion* that is used to indicate a relation between imaginings and experiences. Used like this, the notion of re-creation involves a claim about the metaphysical structure of imaginings (or the imagination), since it endorses the idea that imaginings are related to experiences in a specific way. The nature of this relation can be spelled out differently. Version (2) claims that imaginings re-create experiences in the following sense: for every type of experience there is a respective *imaginative mode*. There is a visual mode of imagination, an auditory mode of imagination, a proprioceptive mode of imagination, and so forth. In this sense, every type of experience is re-created by a specific type of Experiential Imagination. Version (3) claims something else, namely that different experiences are re-created as part of the contents of imaginings: if I visually imagine an object O, for example, the imagining has as part of its content a visual experience of O.

These two notions of re-creation yield different taxonomies with different metaphysical underpinnings: a taxonomy based on (2) differentiates imaginings according to their *mode*, while a taxonomy based on (3) classifies imaginings according to their *contents*. If re-creation is understood as specified in (2), such that for every experience-type there is an imaginative type that re-creates this experience-type, this is a different metaphysical claim to the one sketched in (3). As such, one could claim that there is one type of imagination that re-creates various experience-types by taking them up as parts of their contents. The nature of the relation called *re-creation* therefore has consequences for what is taxonomised: this can be,

for example, the mode or the content of an imagining. Neglecting this notion (if it is considered to be a substantial metaphysical notion) therefore means neglecting the metaphysical basis of the taxonomy. Thus, it seems to me that from a methodological point of view it is indeed important to clarify which notion of re-creation is in play.

The second worry I want to raise about the notion of re-creation is that the authors do not in fact remain neutral with regard to this notion. First, it seems that the notion of re-creating that the authors have in mind is not only a synonym for the expression *x-like imaginings*. One reason to think so is that Dokic and Arcangeli use the notion of re-creation in crucial definitions such as, for example, to formulate the various versions of the General Hypothesis. One example is as follows:

SensH: To imagine something sensorily is always at least to re-create some sensory experience. (Dokic & Arcangeli [this collection](#), p. 4)

If *to re-create some sensory experience* is synonymous with *having an imagining with a sensory phenomenology*, the hypothesis and its variants are no longer interesting claims. This indicates that the notion is more than what I called a mere way of speaking, but instead refers to (and thereby stipulates) a relation between imaginings and experiences or imagination and experience in general.

Additionally, it seems to me that the suggested taxonomy oscillates between different notions of re-creation. On the one hand, Dokic and Arcangeli sometimes seem to sympathise with the mode-sense of the notion of re-creation (as in (2)). When introducing the distinction between objective and subjective imagination, they claim, for example, that this distinction is concerned with the mode of the experience and not with the content (Dokic & Arcangeli [this collection](#), p. 9). I address this point in more detail in section 3, below. On the other hand, Dokic and Arcangeli employ the General Hypothesis and develop various variants of it. As a reminder, the General Hypothesis claims that

“to imagine something is always at least to imagine, from the inside, being in some conscious state” (Peacocke 1985, p. 21). This thesis is put forward by Christopher Peacocke (1985, p. 21) and Michael Martin (2002), who call it the “Dependency Thesis” (Martin 2002). It is usually considered to be a claim about what an imagining represents (see e.g., Dorsch 2012, pp. 294 and pp. 314; see also Paul Noordhof’s exploration and criticism of the thesis in Noordhof 2002). The idea behind these claims is that imaginings are experiential in nature because what we imagine in the imagining are experiences: “sensory imagining is experiential or phenomenal precisely because what is imagined is experiential or phenomenal” (Martin 2002: 406). This means that my visual imagining of an object *O* *represents* an experience of *O* and therefore is experiential. The General Hypothesis hence seems to imply, at least implicitly, a specific conception of re-creation: it endorses the idea that imaginings involve experiences as part of their contents, which is the notion of re-creation I formulated in version (3). Therefore, this view is not neutral about the nature of re-creating: relying on the General Hypothesis brings with it a certain commitment about the notion of re-creation involved (given that one adopts the suggested reading of the General Hypothesis and its variants).

In this section, I (1.) discussed three interpretations of the notion of re-creation that I take to be the most relevant in the given context, since they are alluded to by the authors. It seems that the notion of re-creation needs to be fleshed out further if it is to play some explanatory role in the taxonomy (otherwise it can be dismissed); and (2.) argued that the background assumptions of the taxonomy are committed to differing interpretations of the notion of re-creation. Therefore, the authors do not remain neutral about the notion of re-creation that is involved here but seem to implicitly adopt different notions of re-creation. One way of solving these issues would be to address them and commit to a specific notion of re-creation. Another solution would be to eliminate the notion of re-creation from the taxonomy, which is what I will suggest in the final section of this commentary.

3 Subjective and objective imagination and the self

One central aspect of the taxonomy that Dokic & Arcangeli propose is the distinction between subjective imagination and objective imagination (see [this collection](#), pp. 4). Subjective imagination re-creates internal experiences: experiences that are “supposed to be about a mental or bodily state of oneself” (Dokic & Arcangeli [this collection](#), p. 6). As an example, the authors point to “proprioceptive and agentic experiences” (Dokic & Arcangeli [this collection](#), p. 6) such as imagining the movements of swimming in the sea. In contrast, objective imagination re-creates external experiences. These are experiences that are “typically about the external world” (Dokic & Arcangeli [this collection](#), p. 6)—such as, for example, visual experiences of objects. Dokic & Arcangeli claim that experiential imaginings in general can be divided into subjective and objective imaginings ([this collection](#), p. 6). In a second step, this differentiation is then distinguished from Zeno Vendler’s distinction between imaginings that either implicitly or explicitly involve the self (Dokic & Arcangeli [this collection](#), pp. 7). The authors argue that Vendler’s categorisation differs from their own by providing four examples of cases of subjective and objective imagination that involve the self either implicitly or explicitly (Dokic & Arcangeli [this collection](#), p. 8).

I have a number of worries about some of the ideas and notions that the authors put forward along this line of thought. My first worry concerns the claim that the suggested differentiation of objective and subjective imagination concerns the *mode* of the respective state and therefore differs from Vendler’s distinction, which is thought to be about the state’s *content* (Dokic & Arcangeli [this collection](#), p. 8). Internal and external experiences are equally *internal* in some sense, since they are experiences that are *internal to some subject*. As I understand the authors here, the difference between internal and external experiences is that they are usually about internal or external entities, respectively. Thus, in the given context, the notions *internal* and *external* apparently specify

what the experiences are about. On the level of imagination, subjective and objective imagination re-creates these different types of experiences. The authors specify this idea by spelling out two versions of the General Hypothesis adapted for objective and subjective imagination, called *ObjH* and *SubjH* (Dokic & Arcangeli [this collection](#), p. 6). As I specified above in section 2, one can read the General Hypothesis and its variants as claiming that imaginings re-create experiences in the sense that they represent experiences as part of their contents. If one accepts this interpretation, it is not obvious to me why and how re-creating internal and external experiences in the imagination yields imaginings that are different in *mode* (namely subjective and objective imaginings) and not in terms of what they represent. This point is an exemplification of the issue I raised in section 2: it depends on how one spells out the notion of re-creation whether or not the line of argument that the authors present to distinguish their notions from Vendler’s is convincing.

My second worry concerns the notion of *implicitly involving the self*. It seems to me that there is room to argue that both objective and subjective imagination as defined by Dokic and Arcangeli always involve the self implicitly (the authors briefly address this point in footnote 13). If this were the case it is unclear how their notions are different from Vendler’s. The self is implicitly involved in an imagining if “it fixes the point of view internal to the imagined scene without being a constituent of that scene” (Dokic & Arcangeli [this collection](#), p. 7). An example is imagining seeing the Pantheon: there is a specific point of view involved in this imagining (Dokic & Arcangeli [this collection](#), p. 7). This, however, seems to be the definition of Experiential Imagination *in general* that the authors propose in the beginning of the paper. They explain (by referring to Peacocke) that Experiential Imagination always involves an experiential perspective (Dokic & Arcangeli [this collection](#), p. 3). If involving an experiential perspective is sufficient to implicitly involve the self, and if experiential imaginings are defined as imaginings that involve an experiential perspective, then every experiential imagining in-

volves the self implicitly. If this is indeed how the authors conceive of Experiential Imagination, a notion introduced by Michael Martin may be helpful for dismissing certain difficulties (though I am aware that he uses this notion in a context with different argumentative aims). [Martin](#) argues (similarly to Peacocke) that at least some sensory imaginings involve a point of view, and thereby implicitly represent experiences (2002, pp. 40). However, as he explains, the presence of a point of view in the imagining does not imply that I myself occupy this point of view: “[t]he point of view within the imagined scene is notoriously empty enough that one can in occupying that point of view imagine being someone other than one actually is” ([Martin 2002](#), p. 411). I take this to be a promising way of differentiating imaginings from non-imaginative experiences, since they involve different kinds of points of view or perspectivalness (I will say more on this in section 5).

Maybe this notion of an *empty* point of view can also be helpful for further sharpening the notions of objective and subjective imagination. One could argue that objective experiential imaginings involve a point of view—but an empty one. Thus, imagining seeing the Pantheon involves a point of view, but this point of view is empty in the sense that it must not be myself occupying this point of view. In this sense, objective imaginings may not involve the self at all. This observation could also serve to set the subjective/objective distinction apart from Vendler’s. But it is probably more difficult to transfer the notion of an empty point of view to subjective imagination, given that it is defined as re-creating experiences about oneself. Maybe this is close to what the authors have in mind when they loosen the notion of subjective imagination towards the end of the paper by claiming that subjective imaginings may be neutral about the identity of the self involved ([Dokic & Arcangeli this collection](#), p. 16). Thus, to conclude, considering the notion of an empty point of view at least seems to be an interesting option to be explored in order to strengthen the objective/subjective distinction and the notion of subjective imagination. Apart from this suggestion, I will come back to the notion of an

empty point of view in the final section of this commentary and on this basis offer an additional perspective.

4 The phenomenal character of cognitive imaginings

My third and final point concerns the classification of cognitive imaginings. Cognitive imaginings are usually considered to be non-sensory in the sense of not having a sensory phenomenal character or indeed any phenomenal character at all. An example of cognitive imagination is to imagine that there is a largest prime number. [Dokic](#) and [Arcangeli](#) suggest that this orthodox classification may be misguided, since one can plausibly argue that cognitive imaginings have a certain phenomenology, namely a cognitive one ([this collection](#), pp. 10–11). Therefore, the authors claim, we could classify them as experiential imaginings as well.

I think the idea of ascribing a certain cognitive phenomenology to cognitive imaginings is very attractive, since it acknowledges the idea of a cognitive phenomenology in general and allows us to classify all kinds of imaginings according to one single feature, which is their phenomenal character (see also section 5). However, I am unsure about the classification of cognitive imaginings as experiential imaginings. Here is why: in the beginning of the paper, the authors define one important feature of the kinds of imaginings that they consider experiential: they involve an “experiential perspective” and are (in this sense) “from the inside” (see [Dokic & Arcangeli this collection](#), p. 3). It is not spelled out in detail how we should understand the notion of an experiential perspective but, as I interpret it, this involves at least that things are oriented “within egocentric space” ([Martin 2002](#), p. 408), to use Martin’s expression. Martin only speaks about visual perceptual experiences, but it seems to me that one can plausibly expand this notion to all kinds of experiences: they involve an egocentric perspective. As I understand Dokic and Arcangeli, they consider this egocentric perspective to be a defining feature of the phenomenology of experiential imaginings that re-create experiences.

If cognitive imaginings are considered to be experiential imaginings, and if experiential imaginings are considered to involve an egocentric perspective, one would expect cognitive imaginings to also have this egocentric perspective. However, it seems to me that the phenomenal character of cognitive imaginings does not involve the *perspective of an experience*. If I imagine that the earth is flat (and according to the authors thereby re-create the belief that the earth is flat) it seems that imagining this does not involve any egocentric perspective in the sense given above. If at all, cognitive imaginings incorporate a very specific kind of perspective that is distinct from any experiential *perspective*. Consequently, even if cognitive imaginings have a phenomenal character, this seems quite different from the phenomenal character of experiences (given that the latter is considered to involve an experiential perspective). If the authors endorse a different notion of experiential phenomenal character and *having an experiential phenomenal character* is, for example, just a synonym for *having a phenomenal character*, then my point is not valid. However, if Dokic and Arcangeli indeed think that having an experiential phenomenal character means that an egocentric perspective is involved (as in the case of experiences), I suggest that we need to reconsider the classification of cognitive imaginings as provided here. While I find the idea that cognitive imaginings may have some kind of phenomenal character convincing, it seems less convincing to me that they have an experiential phenomenal character in the sense discussed here. Therefore, I propose that we instead classify cognitive imaginings as a different kind of imagination with a specific cognitive phenomenal character.

5 Conclusion

The issues I raised in the previous sections can probably all be met in order to maintain the taxonomy suggested by Dokic and Arcangeli and to develop it further. Nevertheless, I think that the points I raised also allow for an alternative interpretation that offers a different perspective on a taxonomy of imaginings. Before

summarising the results of this commentary, I would like to explore this alternative perspective on the topic. My two main claims are: (1.) that it is not helpful to involve the notion of recreation in a taxonomy of imaginings, and that the taxonomy can be yielded without it; and (2.) that the specific way the self is (not) involved in imaginings *distinguishes* them from experiences rather than mirroring experiences.

Concerning the first point, it is neither necessary nor helpful to involve the notion of recreation or any other metaphysical notion if the aim is to yield a *phenomenological taxonomy* of imaginative states (and I take this to be one of the aims of Dokic and Arcangeli's paper). In order to yield such a phenomenological taxonomy, we can simply rely on our pre-theoretical classifications of imaginings as vision-like or action-like, and so forth. The notion *vision-like* and its cognates *x-like* can be understood as phenomenological notions here: to the imagining subject, what it is like to visually imagine an object is similar to what it is like to visually experience an object. That there are such similarities in phenomenal character is an interesting observation that allows us to build a phenomenological taxonomy. If one additionally accepts the idea of a cognitive phenomenology, this account allows us to capture cognitive imaginings as well, and to classify them according to their (cognitive) phenomenal character. Explaining *why* imaginings are vision-like or action-like, and what the metaphysical underpinnings of this phenomenological taxonomy may be is another task. These tasks should not be entangled.

One may worry that these pre-theoretical notions (such as *vision-like*) and opinions are too imprecise and not apt to yield a taxonomy of imaginative states that can ground further philosophical theorising. One answer to this worry is to expand a line of thought suggested by Fabian Dorsch. He considers the fact that we stably, effortlessly, and consistently “do group together a large variety of mental occurrences in the class of imaginings, while excluding many others” (Dorsch 2012, p. 6) to justify the idea that imaginings form a unified class of mental states. This line of thought can be adapted to ground a more fine-grained taxonomy of ima-

imaginings, based on our pre-theoretical opinions: we also stably, effortlessly, and consistently classify various imaginings as vision-like, audition-like, movement-like, and so forth. There are certainly borderline cases or instances of imaginings that combine several phenomenological aspects, but nevertheless this pre-theoretical classification is stable in the way described by Dorsch. I consider therefore this intuitive and pre-theoretical classification a helpful taxonomy of imaginings that can serve as a sufficiently justified *starting point* for further philosophical reflection. This pre-theoretical classification of imaginings that I suggest probably does not yield essentially different categories to the taxonomy suggested by Dokic and Arcangeli. It classifies imaginings according to their phenomenal character as vision-like, action-like, and so forth, which are all categories acknowledged by the authors. What I wish to claim is that in order to ground this taxonomy, it is not necessary or helpful to involve a metaphysical notion such as re-creation. It is sufficient to recur to our pre-theoretical classification of imaginative states.

The only category that is probably not reflected in this phenomenological taxonomy is the distinction between subjective and objective imagination, which, according to the authors, also “gives rise to phenomenologically different imaginings” (Dokic & Arcangeli [this collection](#), p. 6). The reason for this is that there is a difference between the more fine-grained phenomenology and the more coarse-grained phenomenology of a mental state. By this I mean that we can distinguish various aspects of a mental state’s phenomenal character. Two different visual experiences of a red apple and a green apple respectively share the coarse-grained phenomenal character of being visual, but they differ in terms of their fine-grained phenomenal character: perceiving a red apple is phenomenally different from perceiving a green apple. The taxonomy I suggest above is concerned with the rather coarse-grained phenomenal character of imaginings that allows us to classify them as vision-like, action-like, and so forth. An even more coarse-grained phenomenal character would be the one which all types of

imaginings have in contrast to cognitive state, for example. The distinction between objective and subjective imagination seems to reflect more fine-grained phenomenological categories than those that classify imaginings according to what their phenomenal character resembles. I am not sure whether there is a *phenomenology of objectiveness* (as opposed to subjectiveness) that, for example, unifies sensory imagination and cognitive imagination as opposed to proprioceptive imagination (as suggested by Dokic and Arcangeli). This shows that the account and methodology that I propose also faces certain challenges. One challenge would be to single out exactly which aspects of the phenomenology we take to be defining marks for a categorisation. Another challenge, for example, would be to point out that for this account we have to rely on introspective findings, whose epistemic status and reliability may be controversial. Nevertheless I think that pre-theoretical reflection based on phenomenological findings is an appropriate way to lay out a taxonomy of the mental states we classify as imaginings, since in principle it can be done stably, effortlessly, and consistently (see again [Dorsch 2012](#), p. 6).

The second aspect I would like to address is the distinction between subjective and objective imagination. These notions introduced by Dokic and Arcangeli are very helpful, since they reveal the particular ways in which the self (or aspects of the self) is involved in imaginings. However, I think one can draw different conclusions from these observations than those presented by the authors. As I suggested in [section 3](#), I think the best way to describe the point of view involved in imaginings is by adopting and expanding the notion of an *empty point of view*. It seems to me that imaginings do not involve the self in the same way as, for example, experiences do. I will explore this line of thought by pointing to the example of visual experiences as opposed to visual imaginings. The perspectival character of a visual experience has several aspects: it involves a distinct point of view that locates the perceiving subject in a determinate relation to its surrounding objects. Objects are therefore perceived as being close, far away, to

the left, above, and so forth (see also [Martin 2002](#), p. 408). In this sense the self is involved, since there is always an egocentric perspective. However, in imagination this kind of perspectivalness need not be fully realised. It seems possible to imagine an object without imagining it at a certain distance or at a certain position. If I perceive a tree, I perceive it far away to the left, for example. If I imagine a tree I can simply imagine the tree. I *can* imagine a tree in the distance to the left but this is something I deliberately add to the imagining. This thought can be expanded to other forms of imaginings as well. One way to capture this particular perspectival character of imaginings is to adopt the proposed notion of an empty point of view: while experiences involve the self in the sense of involving an egocentric perspective (which is a non-empty point of view), imaginings involve an *empty point of view*. This does not mean that one adopts, in imagining, the point of view of someone else (as opposed to the point of view of myself), but that this point of view is *empty*. One important difference between this notion of an empty point of view and Dokic and Arcangeli's account is that it *differentiates* imaginings from experiences: regarding the point of view that is involved, imaginings differ importantly from non-imaginative experiential states, since the former may involve an empty point of view. In contrast to this, Dokic and Arcangeli seem to think that imaginings mirror non-imaginative states with respect to the nature of the point of view involved (again probably partly due to the notion of re-creation). Again, the approach that I suggest certainly faces challenges. One challenge is to demand that we spell out the notion of an empty point of view in more detail. So far, I have only pointed in the direction of how to capture certain particular features of imaginings. However, investigating this difference further seems like a promising way to clarify the nature of imaginings.

To sum up, I will briefly repeat the points I discussed in this commentary:

1. I suggested that we explore the notion of re-creation further, since it occupies a central place in the suggested taxonomy of Experien-

tial Imagination. As I argued, this notion must either be spelled out or omitted from the taxonomy, since as an underdetermined notion it does not add to the explanatory basis. Furthermore, I showed that the authors seem to implicitly rely on different notions of re-creation instead of remaining neutral about it.

2. I pointed to some worries about the distinction between subjective and objective imagination. I suggested that we adopt the notion of an empty point of view to characterise the kind of self-involvement we find in experiential imaginings.
3. I formulated my doubts about the classification of cognitive imaginings as experiential imaginings due to their phenomenal character, which does not seem to be experiential in the sense that it does not involve an experiential perspective.

I concluded these considerations with my own interpretation of the findings. As I suggested, we can develop a phenomenological taxonomy of different types of imaginings by basing it on our pre-theoretical opinions about imaginings. We do not need to involve the notion of re-creation (or other non-phenomenological notions) in order to do this. Clarifying the metaphysical underpinnings of this taxonomy is a different task. Additionally, I interpreted reflections on the various ways the self is involved in imaginings as yielding the conclusion that imaginings differ from experiences in terms of how the self is (not) involved, rather than mirroring experiences, in this respect. Imaginings involve an empty point of view, while experiences have an egocentric point of view. I consider both these aspects relevant for any theory of imaginings.

Dokic and Arcangeli's taxonomy has essentially contributed to further developing a theory of imaginings by revealing and illuminating relevant aspects of the nature of imaginings. Their observations have clearly uncovered a neuralgic aspect of imaginings, which is how the self is involved (or not involved) in imaginings. Furthermore, their taxonomy allows us to classify cognitive imaginings in terms of their phenomenal character and not, for example, with respect to

what these are about. Although the taxonomy reveals how heterogeneous imaginings are, it therefore nevertheless offers a unified take on imaginings. Adopting Dokic and Arcangeli's observations as a starting point for further investigations will certainly be very fruitful, and is sure to advance our understanding of the nature of imaginings.

Acknowledgements

I want to thank the editors of this volume and the anonymous reviewers for their valuable comments, which have all been very helpful.

The Importance of Being Neutral: More on the Phenomenology and Metaphysics of Imagination

A Reply to Anne-Sophie Brügger

Jérôme Dokic & Margherita Arcangeli

In this reply to Anne-Sophie Brügger's comments to our target paper, we focus on three main issues. First, we explain that although our account of imaginative re-creation is in many respects metaphysically neutral, it allows for a taxonomy of imaginings that goes beyond mere phenomenological observations and pre-theoretical intuitions. Second, we defend our interpretation of the distinction between objective and subjective imagination and compare it with Brügger's own suggestions involving the notion of an empty point of view. Third, we insist that the notion of experiential perspective should be construed broadly and include cognitive or belief-like imagination.

Keywords

Cognitive imagination | Empty point of view | Objective imagination | Phenomenology | Re-creation | Subjective imagination

We would like to thank Anne-Sophie Brügger for her very interesting comments on our paper. In what follows, we try to respond to what we see as the central points raised in her discussion.

1 On the notion of re-creation

In our target paper, we use a notion of re-creation in order to set up a sophisticated taxonomy of experiential imagination. We also profess a certain neutrality with respect to this notion. Anne-Sophie

Brügger argues that our neutrality is only apparent, and that we in fact oscillate between two substantial notions of re-creation, which have quite different implications for the ontology of imaginings.

Our professed neutrality concerns only the subpersonal underpinnings of imagination. We do not want to commit ourselves to the view that imaginings and their non-imaginative counterparts share neural or functional resources. We do not explicitly vindicate any neutrality with respect to the notion of re-creation at the personal level. However, we intend to be neutral at that level too, in the following respect. In our account, the phrase “X re-creates Y” should be used synonymously with the phrase “X is Y-like”, to mean that an imagining of type X has a phenomenal character analogous to the phenomenal character of a non-imaginative state of type Y. For instance, visual imagination is visual-like in the sense that its phenomenal character is more similar to visual perception than, say, auditory perception or belief. In general, what matters for our purposes is that there is a systematic correspondence between the imaginative and the non-imaginative realms; the metaphysical nature of this correspondence is left open.

Now, Brüggen raises an interesting question, namely whether (notwithstanding our intentions) our account shows an oscillation between two different metaphysical conceptions of re-creation. On the first (mode-based) conception, there are different imaginative *modes* corresponding to kinds of experience in the non-imaginative realm. On the second (content-based) conception, which Brüggen attributes to Mike Martin, all imaginings belong to a single imaginative mode but represent different kinds of experience as part of their *contents*.

Brüggen suggests (following Martin’s 2002 interpretation) that Peacocke’s General Hypothesis (1985) already carries a commitment to the content-based conception. We disagree. The phrase “imagining being in some conscious state” (Peacocke 1985, p. 21) does not obviously entail that the conscious state is represented in the content of the imagining. It is compatible with taking the expression “being in some conscious state” to be a modifier of “imagining”, just as the internal accusative “a song” is a modifier of “singing” in “singing a song”. Perhaps we are wrong about Peacocke’s intentions, but we insist that our use of the General Hypo-

thesis can be metaphysically neutral in this sense.

What about the mode-based conception of re-creation? We concede that some of our formulations, especially when we introduce the distinction between objective and subjective imagination, evoke such a conception. As it happens, we have both rejected the content-based conception in other works (Dokic 2008; Arcangeli 2011a, 2011b). However, many aspects of our taxonomy can be re-formulated in terms more amenable to the latter conception. For instance, the distinction between objective and subjective imagination might be construed as a distinction between imaginings that represent external experiences and imaginings that represent internal experiences as part of their contents. Whether all aspects of our taxonomy can be re-formulated in this way is indeed something that should be explored further.

Brüggen eventually recommends getting rid of the notion of re-creation, and going for a purely phenomenological taxonomy based on pre-theoretical intuitions. It is worth contrasting our methodology with hers. In many respects, our taxonomy rests on well-identified phenomenological types. For instance, all visual imaginings are clearly unified under a single phenomenological type. The latter can then easily be related to a kind of experience in the non-imaginative realm, namely visual experiences. In other cases, identifying non-imaginative counterparts is more difficult because the relevant imaginings do not form a well-identified phenomenological type. We agree with Brüggen that there may not be a phenomenology of objective (as opposed to subjective) imagination. Still, there is no need to introduce a metaphysically-loaded conception of re-creation (either mode-based or content-based) to ground the distinction between objective and subjective imagination. It is enough that phenomenological contrasts can be drawn between particular cases of objective imagination and particular cases of subjective imagination in various domains. This is exactly how Vender (1984) introduces the distinction in the domain of imagining actions. At this point, our method departs from phenomenology and becomes abductive and specu-

lative. In our view, the best explanation of the relevant phenomenological contrasts is that the imaginings correspond to different kinds of experience in the non-imaginative realm, namely external and internal experiences. We need not rely exclusively on pre-theoretical intuitions. Our taxonomy is indeed grounded in particular phenomenological contrasts, but it is also informed by (controversial) theoretical notions, such as the notion of an external (as opposed to an internal) experience.

2 On the distinction between objective and subjective imagination

Brüggen finds our distinction between objective and subjective imagination “very helpful” ([this collection](#), p. 9), but she is worried about the way we flesh out the distinction. We have already answered one of her worries, which is that our account of the distinction carries a commitment to the mode-based conception of re-creation. As we have suggested, our account is compatible with the alternative, content-based conception. Another worry of Brüggen’s is that it is unclear how our notions of objective and subjective imagination differ from Vendler’s. Brüggen grounds this worry in the fact that our account leaves room for the claim that both objective and subjective imagination always involve the self implicitly ([this collection](#), p. 5).

As far as objective imagination is concerned, our examples certainly suggest that when one objectively (e.g., visually) imagines oneself in an explicit way (e.g., as a rider or as showing a pinched face), one’s imagining can also be implicitly self-involving. This does not mean that the imaginer’s self is involved twice. Here the imaginer’s self is involved only in an explicit way (as we point out all too briefly in the beginning of section 4.1 of our target paper, our definition of implicit self-involvement excludes that the same self that is involved both implicitly and explicitly in a single imagining). The claim that objective imagination is *always* implicitly self-involving does not immediately follow from these examples, but it is admittedly consistent with our account.

Things are more complicated with respect to subjective imagination. We argue that the latter can be either implicitly or explicitly self-involving, although we also acknowledge that the latter is controversial, since it assumes that we can have an internal experience that explicitly represents the self as such. Taking for granted that some subjective imaginings can explicitly involve the self, it is hard to see how they can also be implicitly self-involving. This is so because of the very nature of the re-created internal experience. An internal experience can only be about a (physical or mental) state whose bearer is identical with the bearer of the experience itself. It is not possible to have a proprioceptive experience of another’s body, or to introspect someone else’s mental states. When a subjective imagining re-creates an internal experience that explicitly represents the self (the imaginer’s or someone else’s), the latter cannot but be the self of the re-created experience. Thus the imagining is not implicitly self-involving, according to our definition.

Moreover, even granting Brüggen’s claim that objective and subjective imagination always involve the self implicitly, we do not see how this leads us back to Vendler’s account of the distinction. For us, the key to the distinction is not the distinction between explicit and implicit self-involvement, but rather the distinction between external and internal experiences. Indeed, the latter distinction has to do with aspects of the self, since we have defined an internal experience as being normally *de se*; but, as we have seen, the *de se* nature of internal experiences can be explained independently of whether the self is explicitly or implicitly involved in the relevant imaginings.

Brüggen introduces the notion of an empty point of view as an additional tool for the theory of imagination. For instance, when a subject visually imagines the Panthéon, her imagining involves a perspective that is not occupied by herself or anyone else. In other words, it is not required that there be an observer *in the imaginary world* (the subject can visualize an unseen Panthéon). If this is the right interpretation of Brüggen’s notion of an empty point of view, we already have it in our toolbox. For we claim that

the first-person perspective from which the subject is imagining the Panthéon can remain virtual or counterfactual, in the sense that she is imagining a situation from a spatial perspective that a normally-sighted subject *would* have if she were suitably oriented in the imaginary world.

Brüggen suggests that we could use the notion of an empty point of view to “further sharpen” the distinction between objective and subjective imagination ([this collection](#), p. 6). The idea seems to be that objective imagination always involves an empty point of view, while subjective imagination never does. Let us grant that this idea is broadly correct. We still think that our account of objective and subjective imagination as re-creating external and internal experiences can provide a more fundamental explanation. One might claim that subjective imagination creates more ontological constraints on the imaginary world than objective imagination. A subjective imagining represents a state whose bearer can only be that of the re-created internal experience itself. If such a state is ontologically dependent on a bearer, one cannot imagine the former in a world in which the latter does not exist. Thus, subjective imagination imposes the existence of a self in the imaginary world, whether or not the self in question is explicitly represented. In contrast, since objective imagination re-creates an external experience, one might argue that it is free from the specific constraints of subjective imagination, and need not impose the existence of any self in the imaginary world.

Toward the end of her commentary, Brüggen also suggests that the notion of an empty point of view can help us to distinguish between imaginings and non-imaginative experiences. If we understand her correctly, her suggestion is that in contrast to imaginings, non-imaginative experiences *must* involve an occupied point of view. This is an interesting suggestion, and we do not see why we cannot take it on board. Brüggen thinks otherwise and writes: “Dokic and Arcangeli seem to think that imaginings mirror non-imaginative states with respect to the nature of the point of view involved (again probably partly due to the notion of re-creation)” ([this collection](#), p. 9). However, as de-

tailed above, our account is more neutral and does not carry such a commitment. We do not posit a specific relationship between imaginings and non-imaginative states, but for the sake of argument let us put in a good word for a less neutral view. Even if one claims that imaginings mirror (or simulate) non-imaginative states in the sense that they are dependent on the latter, thus holding an asymmetrical relationship between those kinds of mental states, one is not committed to the conclusion that imaginings mirror every aspect of non-imaginative states (e.g., the nature of the point of view). Further specifications are needed about what precisely is preserved and according to which mapping function ([Arcangeli 2011b](#)).

3 On cognitive imagination

Brüggen is hesitant about our classification of cognitive imaginings as experiential imaginings. Her main reason for being hesitant is not that the notion of cognitive phenomenology is ill-conceived. On the contrary, she is attracted by the view that beliefs have a special phenomenal character. She thinks that cognitive imaginings do not involve an experiential perspective because she construes the notion of experiential perspective quite narrowly, as a spatial egocentric perspective. In our view, Brüggen’s construal of the notion of experiential perspective is too narrow. On this construal, many non-cognitive imaginings turn out to be non-experiential as well. Some cases of sensory imaginings, involving auditory, olfactory, or gustatory imagination, do not always clearly involve a spatial egocentric perspective. Many imaginings that re-create internal experiences (excluding perhaps proprioception) do not involve such a perspective either. For our part, we do not see why the notion of experiential perspective should be restricted to the spatial egocentric case.

4 Conclusion

We have not tried to be exhaustive and answer every point raised in Brüggen’s rich commentary here. But we still hope that we have dealt with her main concerns. Despite the fact that

our minimal notion of re-creation does not introduce a substantial metaphysical relation between the imaginative and the non-imaginative realms, it should be conceived as a placeholder for such a relation. Our taxonomy can then be taken as a starting-point for, and perhaps a constraint on, a full-blooded theory of the ontology of imagination.

On the Eve of Artificial Minds

Chris Eliasmith

I review recent technological, empirical, and theoretical developments related to building sophisticated cognitive machines. I suggest that rapid growth in robotics, brain-like computing, new theories of large-scale functional modeling, and financial resources directed at this goal means that there will soon be a significant increase in the abilities of artificial minds. I propose a specific timeline for this development over the next fifty years and argue for its plausibility. I highlight some barriers to the development of this kind of technology, and discuss the ethical and philosophical consequences of such a development. I conclude that researchers in this field, governments, and corporations must take care to be aware of, and willing to discuss, both the costs and benefits of pursuing the construction of artificial minds.

Prediction is difficult, especially about the future
– Danish Proverb

1 Introduction

The prediction game is a dangerous one, but that, of course, is what makes it fun. The pitfalls are many: some technologies change exponentially but some don't; completely new inventions, or fundamental limits, might appear at any time; and it can be difficult to say something informative without simply stating the obvious. In short, it's easy to be wrong if you're specific. (Although, it is easy to be right if you're Nostradamus.) Regardless, the purpose of this essay is to play this game. As a consequence, I won't be pursuing technical discussion on the finer points of what a mind is, or how to build one, but rather attempting to paint an abstract portrait of the state of research in fields related to machine intelligence broadly construed. I think the risks of undertak-

ing this kind of prognostication are justified because of the enormous potential impact of a new kind of technology that lies just around the corner. It is a technology we have been dreaming about—and dreading—for hundreds of years. I believe we are on the eve of artificial minds.

In 1958 [Herbert Simon](#) & [Allen Newell](#) claimed that “there are now in the world machines that think” and predicted that it would take ten years for a computer to become world chess champion and write beautiful music ([1958](#), p. 8). Becoming world chess champion took longer, and we still don't have a digital Debussy. More importantly, even when a computer became world chess champion it was not generally seen as the success that Simon and

Newell had expected. This is because the way in which Deep Blue beat Gary Kasparov did not strike many as advancing our understanding of cognition. Instead, it showed that brute force computation, and a lot of careful tweaking by expert chess players, could surpass human performance in a specific, highly circumscribed environment.

Excitement about AI grew again in the 1980s, but was followed by funding cuts and general skepticism in the “AI winter” of the 1990s (Newquist 1994). Maybe we are just stuck in a thirty-year cycle of excitement followed by disappointment, and I am simply expressing the beginning of the next temporary uptick. However, I don’t think this is the case. Instead, I believe that there are qualitative changes in methods, computational platforms, and financial resources that place us in a historically unique position to develop artificial minds. I will discuss each of these in more detail in subsequent sections, but here is a brief overview.

Statistical and brain-like modeling methods are far more mature than they have ever been before. Systems with millions (Garis et al. 2010; Eliasmith et al. 2012) and even tens of millions (Fox 2009) of simulated neurons are suddenly becoming common, and the scale of models is increasing at a rapid rate. In addition, the challenges of controlling a sophisticated, nonlinear body are being met by recent advances in robotics (Cheah et al. 2006; Schaal et al. 2007). These kinds of methodological advances represent a significant shift away from classical approaches to AI (which were largely responsible for the previously unfulfilled promises of AI) to more neurally inspired, and brain-like ones. I believe this change in focus will allow us to succeed where we haven’t before. In short, the conceptual tools and technical methods being developed for studying what I call “biological cognition” (Eliasmith 2013), will make a fundamental difference to our likelihood of success.

Second, there have been closely allied and important advances in the kinds of computational platforms that can be exploited to run these models. So-called “neuromorphic” computing—hardware platforms that perform brain-

style computation—has been rapidly scaling up, with several current projects expected to hit millions (Choudhary et al. 2012) and billions (Khan et al. 2008) of neurons running in real time within the next three to four years. These hardware advances are critical for performing efficient computation capable of realizing brain-like functions embedded in and controlling physical, robotic bodies.

Finally, unprecedented financial resources have been allocated by both public and private groups focusing on basic science and industrial applications. For instance, in February 2013 the European Union announced one billion euros in funding for the Human Brain Project, which focuses on developing a large scale brain model as well as neuromorphic and robotic platforms. A month later, the Obama BRAIN initiative was announced in the United States. This initiative devotes the same level of funding to experimental, technological, and theoretical advances in neuroscience. More recently, there has been a huge amount of private investment:

Google purchased eight robotics and AI companies between Dec 2013 and Jan 2014, including industry leader Boston Dynamics Stunt (2014).

Qualcomm has introduced the Zeroth processor, which is modeled after how a human brain works (Kumar 2013). They demonstrated an Field-Programmable Gate Array (FPGA) mock-up of the chip performing a reinforcement learning task on a robot.

Amazon has recently expressed a desire to provide the Amazon Prime Air service, which will use robotic quadcopters to deliver goods within thirty minutes of their having been ordered (Amazon 2013).

IBM has launched a product based on Watson, which famously beat the best human Jeopardy players (<http://ibm.com/innovation/us/watson/>). The product will provide confidence based responses to natural language queries. It has been opened up to allow developers to use it in a wide variety of applications. They are also developing a neuromorphic platform (Esser et al. 2013).

In addition, there are a growing number of startups that work on brain-inspired computing including Numenta, the Brain Corporation, Vi-

carious, DeepMind (recently purchased by Google for \$400 million) and Applied Brain Research, among many others. In short, I believe there are more dollars being directed at the problem than ever before.

It is primarily these three forces that I believe will allow us to build *convincing* examples of artificial minds in the next fifty years. And, I believe we can do this without necessarily defining what it is that makes a “mind”—even an artificial one. As with many subtle concepts—such as “game,” to use Wittgenstein’s example, or “pornography,” to use Supreme Court Justice Potter Stewart’s example—I suspect we will avoid definitions and rely instead on our sophisticated, but poorly understood, methods of classifying the world around us. In the case of “minds,” these methods will be partly behavioural, partly theoretical, and partly based on judgments of similarity to the familiar. In any case, I do not propose to provide a definition here, but rather to point to reasons why the artifacts we continue to build will become more and more like the natural minds around us. In doing so, I survey recent technological, theoretical, and empirical developments that are important for supporting our progress on this front. I then suggest a timeline over which I expect these developments to take place. Finally, I conclude with what I expect to be the major philosophical and societal impacts on our being able to build artificial minds. As a reminder, I am adopting a somewhat high-level perspective on the behavioural sciences and related technologies in order to make clear where my broad (and likely wrong) predictions are coming from. In addition, if I’m not entirely wrong, I suspect that the practical implications of such developments will prove salient to a broad audience, and so, as researchers in the area, we should consider the consequences of our research.

2 Technological developments

Because I take it that brain-based approaches provide the “difference that makes a difference” between current approaches and traditional AI, here I focus on developments in neuromorphic and robotic technology. Notably, all of the de-

velopments in neuromorphic hardware that I discuss below are inspired by some basic features of neural computation. For instance, all of the neuromorphic approaches use spiking neural networks SNNs to encode and process information. In addition, there is unanimous agreement that biological computation is in orders of magnitude more power efficient than digital computation (Hasler & Marr 2013). Consequently, a central motivation behind exploring these hardware technologies is that they might allow for sophisticated information processing using small amounts of power. This is critical for applications that require the processing to be near the data, such as in robotics and remote sensing. In what follows I begin by providing a sample of several major projects in neuromorphic computing that span the space of current work in the area. I then briefly discuss the current state of high-performance computing and robotics, to identify the roles of the most relevant technologies for developing artificial minds.

To complement its cognitively focused Watson project, IBM has been developing a neuromorphic architecture, a digital model of individual neurons, and a method for programming this architecture (Esser et al. 2013). The architecture itself is called TrueNorth. They argue that the “low-precision, synthetic, simultaneous, pattern-based metaphor of TrueNorth is a fitting complement to the high-precision, analytical, sequential, logic-based metaphor of today’s of von Neumann computers” (Esser et al. 2013, p. 1). TrueNorth has neurons organized into 256 neuron blocks, in which each neuron can receive input from 256 axons. To assist with programming this hardware, IBM has introduced the notion of a “corelet,” which is an abstraction that encapsulates local connectivity in small networks. These act like small programs that can be composed in order to build up more complex functions. To date the demonstrations of the approach have focused on simple, largely feed-forward, standard applications, though across a wide range of methods, including Restricted Boltzmann Machines (RBMs), liquid state machines, Hidden Markov Model (HMMs), and so on. It should be noted that the proposed chip does not yet exist, and

current demonstrations are on detailed simulations of the architecture. However, because it is a digital chip the simulations are highly accurate.

A direct competitor to IBM's approach is the Zeroth neuromorphic chip from Qualcomm. Like IBM, Qualcomm believes that constructing brain-inspired hardware will provide a new paradigm for exploiting the efficiencies of neural computation, targeted at the kind of information processing at which brains excel, but which is extremely challenging for von Neumann approaches. The main difference between these two approaches is that Qualcomm has committed to allowing online learning to take place on the hardware. Consequently, they announced their processor by demonstrating its application in a reinforcement learning paradigm on a real-world robot. They have released videos of the robot maneuvering in an environment and learning to only visit one kind of stimulus (white boxes: <http://www.youtube.com/watch?v=8c1Noq2K96c>). It should again be noted that this is an FPGA simulation of a digital chip that does not yet exist. However, the simulation, like IBM's, is highly accurate.

In the academic sphere, the Spinnaker project at Manchester University has not focused on designing new kinds of chips, but has instead focused on using low-power ARM processors on a massive scale to allow large-scale brain simulations (Khan et al. 2008). As a result, the focus has been on designing approaches to routing that allow for the high bandwidth communication, which underwrites much of the brain's information processing. Simulations on the Spinnaker hardware typically employ spiking neurons, like IBM and Qualcomm, and occasionally allow for learning (Davies et al. 2013), as with Qualcomm's approach. However, even with low power conventional chips, the energy usage is projected to be higher on the Spinnaker platform per neuron. Nevertheless, Spinnaker boards have been used in a wider variety of larger-scale embodied and non-embodied applications. These include simulating place cells, path integration, simple sensory-guided movements, and item classification.

There are also a number of neuromorphic projects that use analog instead of digital implementations of neurons. Analog approaches tend to be several orders of magnitude more power efficient (Hasler & Marr 2013), though also more noisy, unreliable, and subject to process variation (i.e., variations in the hardware due to variability in the size of components on the manufactured chip). These projects include work on the Neurogrid chip at Stanford University (Choudhary et al. 2012), and on a chip at ETH Zürich (Corradi, Eliasmith & Indiveri 2014). The Neurogrid chip has demonstrated larger numbers of simulated neurons—up to a million—while the ETH Zürich chip allows for online learning. More recently, the Neurogrid chip has been used to control a nonlinear, six degree of freedom robotic arm, exhibiting perhaps the most sophisticated information processing from an analog chip to date.

In addition to the above neuromorphic projects, which are focused on cortical simulation, there have been several specialized neuromorphic chips that mimic the information processing of different perceptual systems. For example, the dynamic vision sensor (DVS) artificial retina developed at ETH Zürich performs real-time vision processing that results in a stream of neuron-like spikes (Lichtsteiner et al. 2008). Similarly, an artificial cochlea called AEREAR2 has been developed that generates spikes in response to auditory signals (Li et al. 2012). The development of these and other neuronal sensors makes it possible to build fully embodied spiking neuromorphic systems (Galluppi et al. 2014).

There have also been developments in traditional computing platforms that are important for supporting the construction of models that run on neuromorphic hardware. Testing and debugging large-scale neural models is often much easier with traditional computational platforms such as Graphics Processing Unit (GPUs) and supercomputers. In addition, the development of neuromorphic hardware often relies on simulation of the designs before manufacture. For example, IBM has been testing their TrueNorth architecture with very large-scale simulations that have run up to 500 billion

neurons. These kinds of simulations allow for designs to be stress-tested and fine-tuned before costly production is undertaken. In short, the development of traditional hardware is also an important technological advance that supports the rapid development of more biologically-based approaches to constructing artificial cognitive systems.

A third area of rapid technological development that is critical for successfully realizing artificial minds is the field of robotics. The success of recent methods in robotics have entered public awareness with the creation of the Google car. This self-driving vehicle has successfully navigated hundreds of thousands of miles of urban and rural roadways. Many of the technologies in the car were developed out of DARPA's Grand Challenge to build an autonomous vehicle that would be tested in both urban and rural settings. Due to the success of the first three iterations of the Grand Challenge, DARPA is now funding a challenge to build robots that can be deployed in emergency situations, such as a nuclear meltdown or other disaster.

One of the most impressive humanoid robots to be built for this challenge is the Atlas, constructed by Boston Dynamics. It has twenty-eight degrees of freedom, covering two arms, two legs, a torso, and a head. The robot has been demonstrated walking bipedally, even in extremely challenging environments in which it must use its hands to help navigate and steady itself (<http://www.youtube.com/watch?v=zkBnFPBV3f0>). Several teams in this most recent Grand Challenge have been awarded a copy of Atlas, and have been proceeding to competitively design algorithms to improve its performance.

In fact, there have been a wide variety of significant advances in robotic control algorithms, enabling robots—including quadcopters, wheeled platforms, and humanoid robots—to perform tasks more accurately and more quickly than had previously been possible. This has resulted in one of the first human versus robot dexterity competitions being recently announced. Just as IBM pitted Watson against human Jeopardy champions, Kuka has pitted its high-speed arm against the human

ping-pong champion Timo Boll (http://www.youtube.com/watch?v=_mbdtupCbc4). Despite the somewhat disappointing outcome, this kind of competition would not have been thought possible a mere five years ago (Ackerman 2014).

These three areas of technological development—neuromorphics, high-performance conventional computing, and robotics—are progressing at an incredibly rapid pace. And, more importantly, their convergence will allow a new class of artificial agents to be built. That is, agents that can begin processing information at very similar speeds and support very similar skills to those we observe in the animal kingdom. It is perhaps important to emphasize that my purpose here is predictive. I am not claiming that current technologies are sufficient for building a new kind of artificial mind, but rather that they lay the foundations, and are progressing at a sufficient rate to make it reasonable to expect that the sophistication, adaptability, flexibility, and robustness of artificial minds will rapidly approach those of the human mind. We might again worry that it will be difficult to measure such progress, but I would suggest that progress will be made along many dimensions simultaneously, so picking nearly any of dimensions will result in some measurable improvement. In general, multi-dimensional similarity judgements are likely to result in “I’ll know it when I see it” kinds of reactions to classifying complicated examples. This may be derided by some as “hand-wavy”, but it might also be a simple acknowledgement that “mindedness” is complex. I would like to be clear that my claims about approaching human mindful behaviour are to be taken as applying to the vast majority of the many measures we use for identifying minds.

3 Theoretical developments

Along with these technological developments there have been a series of theoretical developments that are critical for building large-scale artificial agents. Some have argued that theoretical developments are not that important: suggesting that standard back propagation at a sufficiently large scale is enough to capture

complex perceptual processing (Krizhevsky et al. 2012). That is, building brain-like models is more a matter of getting a sufficiently large computer with enough parameters and neurons than it is of discovering some new principles about how brains function. If this is true, then the technological developments that I pointed to in the previous section may be sufficient for scaling to sophisticated cognitive agents. However, I am not convinced that this is the case.

As a result, I think that theoretical developments in deep learning, nonlinear adaptive control, high dimensional brain-like computing, and biological cognition *combined* will be important to support continued advances in understanding how the mind works. For instance, deep networks continue to achieve state-of-the-art results in a wide variety of perception-like processing challenges (http://rodrigob.github.io/are_we_there_yet/build/classification_datasets_results.html#43494641522d3130). And while deep networks have traditionally been used for static processing, such as an image classification or document classification, there has been a recent, concerted move to use them to model more dynamic perceptual tasks as well (Graves et al. 2013). In essence, deep networks are one among many techniques for modeling the statistics of time varying signals, a skill central to animal cognition.

However, animals are also incredibly adept at *controlling* nonlinear dynamical systems, including their bodies. That is, biological brains can *generate* time varying signals that allow successful and sophisticated interactions with their environment through their body. Critically, there have been a variety of important theoretical advances in nonlinear and adaptive control theory as well. New methods for solving difficult optimal control problems have been discovered through careful study of biological motor control (Schaal et al. 2007; Todorov 2008). In addition, advances in hierarchical control allow for real-time computation of difficult inverse kinematics problems on a laptop (Khatib 1987). And, finally, important advances in adaptive control allow for the automatic learning of both kinematic and dynamic models even in highly nonlinear and

high dimensional control spaces (Cheah et al. 2006).

Concurrently with these more abstract characterizations of brain function there have been theoretical developments in neuroscience that have deepened our understanding of how biological neural networks may perform sophisticated information processing. Work using the Neural Engineering Framework (NEF) has resulted in a wide variety of spiking neural models that mirror data recorded from biological systems (Eliasmith & Anderson 1999, 2003). In addition, the closely related liquid computing (Maass et al. 2002) and FORCE learning (Sussillo & Abbott 2009) paradigms have been successfully exploited by a number of researchers to generate interesting dynamical systems that often closely mirror biological data. Together these kinds of methods provide quantitative characterizations of the computational power available in biologically plausible neural networks. Such developments are crucial for exploiting neuromorphic approaches to building brain-like hardware. And they suggest ways of testing some of the more abstract perceptual and control ideas in real-world, brain-like implementations.

Interestingly, several authors have suggested that difficult perceptual and control problems are in fact mathematical duals of one another (Todorov 2009; Eliasmith 2013). This means that there are deep theoretical connections between perception and motor control. This realization points to a need to think hard about how diverse aspects of brain function can be integrated into single, large-scale models. This has been a major focus of research in my lab recently. One result of this focus is Spaun, currently the world's largest functional brain model. This model incorporates deep networks, recent control methods, and the NEF to perform eight different perceptual, motor, and cognitive tasks (Eliasmith et al. 2012). Importantly, this is not a one-off model, but rather a single example among many that employs a general architecture intended to directly address integrated biological cognition (Eliasmith 2013). Currently, the most challenging constraints for running models like Spaun are technological—computers are not fast enough. However, the

neuromorphic technologies mentioned previously should soon remove these constraints. So, in some sense, theory currently outstrips application: we have individually tested several critical assumptions of the model and shown that they scale well (Crawford et al. 2013), but we are not yet able to integrate full-scale versions of the components due to limitations in current computational resources.

Taken together, I believe that these recent theoretical developments demonstrate that we have a roadmap for how to approach the problem of building sophisticated models of biological cognition. No doubt not all of the methods we need are currently available, but it is not evident that there are any major conceptual roadblocks to building a cognitive system that rivals the flexibility, adaptability, and robustness of those found in nature. I believe this is a unique historical position. In the heyday of the symbolic approach to AI there were detractors who said that the perceptual problems solved easily by biological systems would be a challenge for the symbolic approach (Norman 1986; Rumelhart 1989). They were correct. In the heyday of connectionism there were detractors who said that standard approaches to artificial neural networks would not be able to solve difficult planning or syntactic processing problems (Pinker & Prince 1988; Fodor & Pylyshyn 1988; Jackendoff 2002). They were correct. In the heyday of statistical machine learning approaches (a heyday we are still in) there are detractors who say that mountains of data are not sufficient for solving the kinds of problems faced by biological cognitive systems (Marcus 2013). They are probably correct. However, as many of the insights of these various approaches are combined with control theory, integrated into models able to do efficient syntactic and semantic processing with neural networks, and, in general, become conceptually *unified* (Eliasmith 2013), it is less and less obvious what might be missing from our characterization of biological cognition.

4 Empirical developments

One thing that might be missing is, simply, knowledge. We have many questions about how

real biological systems work that remain unanswered. Of course, complete knowledge of natural systems is not a prerequisite for building nearly functionally equivalent systems (see e.g., flight). However, I believe our understanding of natural cognitive systems will continue to play an important role in deciding what kinds of algorithms are worth pursuing as we build more sophisticated artificial agents.

Fortunately, on this front there have been two announcements of significant resources dedicated to improving our knowledge of the brain, which I mentioned in the introduction. One is from the EU and the other from the US. Each are investing over \$1 billion in generating the kind of data needed to fill gaps in our understanding of how brains function. The EU's Human Brain Project (HBP) includes two central subprojects aimed at gathering mouse and human brain data to complement the large-scale models being built within the project. These subprojects will focus on genetic, cellular, vascular, and overall organizational data to complement the large-scale projects of this type already available (such as the Allen Brain Atlas, <http://www.brain-map.org/>). One central goal of these subprojects is to clarify the relationship between the mouse (which is highly experimentally accessible) and human subjects.

The American "brain research through advancing innovative neurotechnologies" (BRAIN) initiative is even more directly focused on large-scale gathering of neural data. Its purpose is to accelerate technologies to provide large-scale dynamic information about the brain that demonstrates how both single runs and larger neural circuits operate. Its explicit goal is to "fill major gaps in our current knowledge" (<http://www.nih.gov/science/brain/>). It is a natural complement to the human connectome project, which has been mapping the structure of the human brain on a large-scale (<http://www.humanconnectomeproject.org/>). Even though it is not yet clear exactly what information will be provided by the BRAIN initiative, it is clear that significant resources are being put into developing technologies that draw on nanoscience, informatics, engineering, and other fields to measure the brain at a level of detail and scale not previously possible.

Table 1

Within (years)	Von Neumann (real-time neurons)	Neuromorphic (real-time neurons)	Behaviours
5	10^8	10^7	constrained environment navigation; uncluttered vision/audition recognition; simple language understanding; slow, robust motor control
10	10^9	10^8	good open world large-scale navigation; learn simple few-step cognitive tasks; rapid single limb motor control; general, shallow semantics and syntax
15	10^{10}	10^9	literal natural language (4-5 year old equivalent); learn new many step tasks; near human quality perceptual skills (categorization and recognition in arbitrary, moving scenes)
25	10^{11}	10^{11}	arbitrary autonomous navigation; highly tunable cognitive system for task specialization, generally exceeding human ability on gross manual tasks, basic problem solving, etc.; human quality perception
50	10^{13}	10^{14}	human level full body agility; above average IQ; nuanced natural language; better than human perception

While both of these projects are just over a year old, they have both garnered international attention and been rewarded with sufficient funding to ensure a good measure of success. Consequently, it is likely that as we build more sophisticated models of brain function, and as we discover where our greatest areas of ignorance lay, we will be able to turn to the methods developed by these projects to rapidly gain critical information and continue improving our models. In short, I believe that there is a confluence of technological, theoretical, and empirical developments that will allow for bootstrapping detailed functional models of the brain. It is precisely these kinds of models that I expect will lead to the most convincing embodiments of artificial cognition that we have ever seen—I am even willing to suggest that their sophistication will rival those of natural cognitive systems.

5 A future timeline

Until this point I have been mustering evidence that there will soon be significant improvements in our ability to construct artificial cognitive agents. However, I have not been very specific about timing. The purpose of this section is to provide more quantification on the speed of development in the field.

In Table 1, the first column specifies the timeframe, the second suggests the number of neurons that will be simulatable in real-time on standard hardware, the third suggests the number of neurons that will be simulatable in real-time on neuromorphic hardware, and the last identifies relevant achievable behaviours within that timeframe.

I believe that several of the computational technologies I have mentioned, as well as empir-

ical methods for gathering evidence, are on an exponential trajectory by relevant measures (e.g., number of neurons per chip, number of neurons recorded [Stevenson & Kording 2011](#)). On the technological side, if we assume a doubling every eighteen months, this is equivalent to an increase of about one order of magnitude every five years. I should also note that I am assuming that real-time simulation of neurons will be embedded in an interactive, real-world environment, and that the neuron count is for the whole system (not a single chip). For context, it is worth remembering that the human brain has about 10^{11} neurons, though they are more computationally sophisticated than those typically simulated in hardware.

Another caveat is that it is likely that large-scale simulations on a digital Von Neumann architecture will hit a power barrier, which makes it likely that the suggested scaling could be achieved, but will be cost-prohibitive in fifty years. Consequently, a neuromorphic alternative is most likely to be the standard implementational substrate of artificial agents.

Finally, the behavioural characterizations I am giving are with a view to functions necessary for creating a convincing artificial mind in an artificial body. Consequently, my comments generally address perceptual, motor, and cognitive skills relevant to reproducing human-like abilities.

6 Consequences for philosophy

So suppose that, fifty years hence, we have developed an understanding of cognitive systems that allows us to build artificial systems that are on par with, or, if we see fit, surpass the abilities of an average person. Suppose, that is, that we can build artificial agents that can move, react, adapt, and think much like human beings. What consequences, if any, would this have for our theoretical questions about cognition? I take these questions to largely be in the domain of philosophy of mind. In this section I consider several central issues in philosophy of mind and discuss what sorts of consequences I take building a human-like artificial agent to have for them.

Being a philosopher, I am certain that, for any contemporary problem we consider, at least some subset of those who have a committed opinion about that problem will not admit that any amount of technical advance can “solve” it. I suspect, however, that their opinions may end up carrying about as much weight as a modern-day vitalist. To take one easy example, let us think for a moment about contemporary dualism. Some contemporary dualists hold that even if we had a complete understanding of how the brain functions, we would be no closer to solving the “hard problem” of consciousness ([Chalmers 1996](#)). The “hard problem” is the problem of explaining how subjective experience comes from neural activity. That is, how the phenomenal experiences we know from a first-person perspective can be accounted for by third-person physicalist approaches to understanding the mind. If indeed we have constructed artificial agents that behave much like people, share a wide variety of internal states with people, are fully empirically accessible, and report experiences like people, it is not obvious to what extent this problem will not have been solved. Philosophers who are committed to the notion that no amount of empirical knowledge will solve the problem will of course dismiss such an accomplishment on the strength of their intuitions. I suspect, however, that when most people are actually confronted with such an agent—one they can interrogate to their heart’s content and one about which they can have complete knowledge of its functioning—it will seem odd indeed to suppose that we cannot explain how its subjective experience is generated. I suspect it will seem as odd as someone nowadays claiming that we cannot expect to explain how life is generated despite our current understanding of biochemistry. Another way to put this is that the “strong intuitions” of contemporary dualists will hold little plausibility in the face of actually existing, convincing artificial agents, and so, I suspect, they will become even more of a rarity.

I refer to this example as “easy” because the central reasons for rejecting dualism are only strengthened, not *generated*, by the existence of sophisticated artificial minds. That is,

good arguments against the dualist view are more or less independent of the current state of constructing agents (although the existence of such agents will likely sway intuitions). However, other philosophical conundrums, like Searle's famous Chinese room (1980), have responses that depend fairly explicitly on our ability to construct artificial agents. In particular, the "systems reply" suggests that a sufficiently complex system will have the same intentional states as a biological cognitive system. For those who think that this is a good rejection of Searle's strong intentionalist views, having systems that meet all the requirements of their currently hypothetical agents would provide strong empirical evidence consistent with their position. Of course, the existence of such artificial agents is unlikely to convince those, like Searle, who believe that there is some fundamental property of biology that allows intentionality to gain a foothold. But it does make such a position seem that much more tenuous if every means of measuring intentionality produces similar measurements across non-biological and biological agents. In any case, the realization of the systems reply does ultimately depend on our ability to construct sufficiently sophisticated artificial agents. And I am suggesting that such agents are likely to be available in the next fifty years.

More immediately, I suspect we will be able to make significant headway on several problems that have been traditionally considered philosophical *before* we reach the fifty-year mark. For example, the frame problem—i.e., the problem of knowing what representational states to update in a dynamic environment—is one that contemporary methods, like control theory and machine learning, struggle with much less than classical methods. Because the dynamics of the environment are explicitly included in the world-model being exploited by such control theoretic and statistical methods, updating state representations naturally includes the kinds of expectations that caused such problems for symbolic approaches.

Similarly, explicit quantitative solutions are suggested for the symbol-grounding problem through integrated models that incorporate as-

pects of both statistical perceptual processing and syntactic manipulation. Even in simple models, like Spaun, it is clear how the symbols for digits that are syntactically manipulated are related to inputs coming from the external world (Eliasmith 2013). And it is clear how those same symbols can play a role in driving the model's body to express its knowledge about those representations. As a result, the tasks that Spaun can undertake demonstrate both conceptual knowledge, through the symbol-like relationships between numbers (e.g., in the counting task), and perceptual knowledge, through categorization and the ability to drive its motor system to reproduce visual properties (e.g., in the copy-drawing task).

In some cases, rather than resolving philosophical debates, the advent of sophisticated artificial agents is likely to make these debates far more empirically grounded. These include debates about the nature of concepts, conceptual change, and functionalism, among others. However these debates turn out, it seems clear that having an engineered, working system that can generate behaviour as sophisticated as that that gave rise to these theoretical ideas in the first place will allow a systematic investigation of their appropriate application. After all, there are few, if any, limits on the empirical information we can garner from such constructed systems. In addition, our having built the system explicitly makes it unlikely that we would be unaware of some "critical element" essential in generating the observed behaviours.

Even without such a working system, I believe that there are already hints as to how these debates are likely to be resolved, given the theoretical approaches I highlighted earlier. For instance, I suspect that we will find that concepts are explained by a combination of vector space representations and a restricted class of dynamic processes defined over those spaces (Eliasmith 2013). Similarly, quantifying the adaptive nature of those representations and processes will indicate the nature of mechanisms of conceptual change in individuals (Thagard 2014). In addition, functionalism will probably seem too crude a hypothesis given a detailed understanding of how to build a wide variety of

artificial minds. Perhaps a kind of “functionalism with error bars” will take its place, providing a useful means of talking about degrees of functional similarity and allowing a quantification of functional characterizations of complex systems. Consequently, suggestions about which functions are or are not necessary for “mindedness” can be empirically tested through explicit implementation and experimentation. This will not solve the problem of mapping experimental results to conceptual claims (a problem we currently face when considering non-human and even some human subjects), but it will make functionalism as empirically accessible as seems plausible.

In addition to these philosophical issues that may undergo reconceptualization with the construction of artificial minds, there are others that are bound to become more vexing. For example, the breadth of application of ethical theory may, for the first time, reach to engineered devices. If, after all, we have built artificial minds capable of understanding their place in the universe, it seems likely we will have to worry about the possibility of their suffering (Metzinger 2013). It does not seem that understanding how such devices work, or having explicitly built them, will be sufficient for dismissing them as having no moral status. While current theories of non-human ethics have been developed, it is not clear how much or little theories of non-biological ethics will be able to borrow from them.

I suspect that the complexities introduced to ethical theory will go beyond adding a new category of potential application. Because artificial minds will be designed, they may be designed to make what have traditionally been morally objectionable inter-mind relationships seem less problematic. Consider, for instance, a robot that is designed to gain maximal self-fulfillment out of providing service to people. That is, unlike any biological species of which we are aware, these robots place service to humans above all else. Is a slave-like relationship between humans and these minds still wrong in such an instance? Whatever our analysis of why slavery is wrong, it seems likely that we will be able to design artificial minds that bypass that

analysis. This is a unique quandary because while it is currently possible for certain individuals to claim to have such slave-aligned goals, it is always possible to argue that they are simply mistaken in their personal psychological analysis. In the case of minds whose psychology is designed in a known manner, however, the having of such goals will at least seem much more genuine. This is only one among many new kinds of challenges that ethical theory will face with the development of sophisticated artificial agents (Metzinger 2013).

I do not take this surely unreasonably brief discussion of any of these subtle philosophical issues to do justice to them. My main purpose here is to provide a few example instances of how the technological developments discussed earlier are likely to affect our theoretical inquiry. On some occasions such developments will lead to strengthening already common intuitions; on others they may provide deep empirical access to closely related issues; and on still other occasions these developments will serve to make complex issues even more so.

7 The good and the bad

As with the development of many technologies—cars, electricity, nuclear power—the construction of artificial minds is likely to have both negative and positive impacts. However, there is a sense in which building *minds* is much more fraught than these other technologies. We may, after all, build agents that are themselves capable of immorality. Presumably we would much prefer to build Commander Data than to build HAL or the Terminator. But how to do this is by no means obvious. There have been several interesting suggestions as to how this might be accomplished, perhaps most notably from Isaac Asimov in his entertaining and thought-provoking exploration of the three laws of robotics. For my purposes, however, I will sidestep this issue—not because it is not important, but because more immediate concerns arise from considering the development of these agents from a technological perspective. Let me then focus on the more immediately pressing consequences of constructing intelligent machines.

The rapid development of technologies related to artificial intelligence has not escaped the notice of governments around the world. One of the primary concerns for governments is the potentially massive changes in the nature of the economy that may result from an increase in automatization. It has recently been suggested that almost half of the jobs in the United States are likely to be computerized in the next twenty years (Rutkin 2013). The US Bureau of Labor and Statistics regularly publishes articles on the significant consequence of automation for the labour force in their journal *Monthly Labor Review* (Goodman 1996; Plewes 1990). This work suggests that greater automatization of jobs may cause standard measures of productivity and output to increase, while still increasing unemployment.

Similar interest in the economic and social impacts of automatization is evident in many other countries. For instance, Policy Horizons Canada is a think-tank that works for the Canadian government, which has published work on the effects of increasing automatization and the future of the economy (Arshad 2012). Soon after the publication of our recent work on Spaun, I was contacted by this group to discuss the impact of Spaun and related technologies. It was clear from our discussion that machine learning, automated control, robotics, and so on are of great interest to those who have to plan for the future, namely our governments and policy makers (Padbury et al. 2014).

This is not surprising. A recent McKinsey report suggests that these highly disruptive technologies are likely to have an economic value of about \$18 trillion by 2025 (Manyika et al. 2013). It is also clear from the majority of analyses, that lower-paid jobs will be the first affected, and that the benefits will accrue to those who can afford what will initially be expensive technologies. Every expectation, then, is that automatization will exacerbate the already large and growing divide between rich and poor (Malone 2014; “The Future of Jobs: The On-rushing Wave” 2014). Being armed with this knowledge now means that individuals, governments, and corporations can support progressive policies to mitigate these kinds of potentially

problematic societal shifts (Padbury et al. 2014).

Indeed, many of the benefits of automatization may help alleviate the potential downsides. Automatization has already had significant impact on the growth of new technology, both speeding up the process of development and making new technology cheaper. The human genome project was a success largely because of the automatization of the sequencing process. Similarly, many aspects of drug discovery can be automatized by using advanced computational techniques (Leung et al. 2013). Automatization of more intelligent behaviour than simply generating and sifting through data is likely to have an even greater impact on the advancement of science and engineering. This may lead more quickly to cleaner and cheaper energy, advances in manufacturing, decreases in the cost and access to advanced technologies, and other societal benefits.

As a consequence, manufacturing is likely to become safer—a trend already seen in areas of manufacturing that employ large numbers of robots (Robertson et al. 2005). At the same time, additional safety considerations come into play as robotic and human workspaces themselves begin to interact. This concern has resulted in a significant focus in robotics on compliant robots. Compliant robots are those that have “soft” environmental interactions, often implemented by including real or virtual springs on the robotic platform. As a result, control becomes more difficult, but interactions become much safer, since the robotic system does not rigidly go to a target position even if there is an unexpected obstacle (e.g., a person) in the way.

As the workplace continues to become one where human and automated systems co-operate, additional concerns may arise as to what kinds of human-machine relationships employers should be permitted to demand. Will employees have the right not to work with certain kinds of technology? Will employers still have to provide jobs to employees who refuse certain work situations? These questions touch on many of the same subjects highlighted in the previous section regarding

the ethical challenges that will be raised as we develop more and more sophisticated artificial minds.

Finally, much has been made of the possibility that the automatization of technological advancement could eventually result in machines designing themselves more effectively than humans can. This idea has captured the public imagination, and the point in time where this occurs is now broadly known as “The Singularity,” a term first introduced by von Neumann (Ulam 1958). Given the vast variety of functions that machines are built to perform, it seems highly unlikely that there will be anything analogous to a mathematical singularity—a clearly defined, discontinuous point—after which machines will be superior to humans. As with most things, such a shift, if it occurs, is likely to be gradual. Indeed, the earlier timeline is one suggestion for how such a gradual shift might occur. Machines are already used in many aspects of design, for performing optimizations that would not be possible without them. Machines are also already much better at many functions than people: most obviously mechanical functions, but more recently cognitive ones, like playing chess and answering trivia questions in certain circumstances.

Because the advancement of intelligent machines is likely to continue to be a smooth, continuous one (even if exponential at times), we will likely remain in a position to make informed decisions about what they are permitted to do. As with members of a strictly human society, we do not tolerate arbitrary behaviour simply because such behaviour is possible. If anything, we will be in a *better* position to specify appropriate behaviour in machines than we are in the case of our human peers. Perhaps we will need laws and other societal controls for determining forbidden or tolerable behaviour. Perhaps some people and machines will choose to ignore those laws. But, as a society, it is likely that we will enforce these behavioural constraints the same way we do now—with publicly sanctioned agencies that act on behalf of society. In short, the dystopian predictions we often see that revolve around the development of intelligent robots seem no more or less likely

because of the robots. Challenges to societal stability are nothing new: war, hunger, poverty, weather are constant destabilizing forces. Artificial minds are likely to introduce another force, but one that may be just as likely to be stabilizing as problematic.

Unsurprisingly, like many other technological changes, the development of artificial minds will bring with it both costs and benefits. It may even be the case that deciding what is a cost and what is a benefit is not straightforward. If indeed many jobs become automated, it would be unsurprising if the average working week becomes shorter. As a result, a large number of people may have much more recreational time than has been typical in recent history. This may seem like a clear benefit, as many of us look forward to holidays and time off work. However, it has been argued that fulfilling work is a central to human happiness (Thagard 2010). Consequently, overly limited or unchallenging work may end up being a significant cost of automation.

As good evidence for costs and benefits becomes available, decision-makers will be faced with the challenge of determining what the appropriate roles of artificial minds should be. These roles will no doubt evolve as technologies change, but there is little reason to presume that unmanageable upheavals or “inflection points” will be the result of artificial minds being developed. While we, as a society, must be aware of, and prepared for, being faced with new kinds of ethical dilemmas, this has been a regular occurrence during the technological developments of the last several hundred years. Perhaps the greatest challenges will arise because of the significant wealth imbalances that may be exacerbated by limited access to more intelligent machines.

8 Conclusion

I have argued that we are at a unique point in the development of technologies that are critical to the realization of artificial minds. I have even gone so far as to predict that human-level intelligence and physical ability will be achieved in about fifty years. I suspect that for many famil-

iar with the history of artificial intelligence such predictions will be easily dismissed. Did we not have such predictions over fifty years ago? Some have suggested that the singularity will occur by 2030 (Vinge 1993), others by 2045 (Kurzweil 2005). There were suggestions and significant financial speculation that AI would change the world economy in the 1990s, but this never happened. Why would we expect anything to be different this time around?

In short, my answer is encapsulated by the specific technological, theoretical, and empirical developments I have described above. I believe that they address the central limitations of previous approaches to artificial cognition, and are significantly more mature than is generally appreciated. In addition, the limitations they address—such as power consumption, computational scaling, control of nonlinear dynamics, and integrating large-scale neural systems—have been more central to prior failures than many have realized. Furthermore, the financial resources being directed towards the challenge of building artificial minds is unprecedented. High-tech companies, including Google, IBM, and Qualcomm have invested billions of dollars in machine intelligence. In addition, funding agencies including DARPA (Defense Advanced Research Projects Agency), EU-IST (European Union—Information Society Technologies), IARPA (Intelligence Advanced Research Projects Agency), ONR (Office of Naval Research), and AFOSR (Air Force Office of Scientific Research) have contributed a similar or greater amount of financial support across a wide range of projects focused on brain-inspired computing. And the two special billion dollar initiatives from the US and EU will serve to further deepen our understanding of biological cognition, which has, and will continue, to inspire builders of artificial minds.

While I believe that the alignment of these forces will serve to underpin unprecedented advances in our understanding of biological cognition, there are several challenges to achieving the timeline I suggest above. For one, robotic actuators are still far behind the efficiency and speeds found in nature. There will no doubt be advances in materials science that will help overcome these limitations, but how long that will take is not yet

clear. Similarly, sensors on the scale and precision of those available from nature are not yet available. This is less true for vision and audition, but definitely the case for proprioception and touch. The latter are essential for fluid, rapid motion control. It also remains to be seen how well our theoretical methods for integrating complex systems will scale. This will only become clear as we attempt to construct more and more sophisticated systems. This is perhaps the most fragile aspect of my prediction: expecting to solve difficult algorithmic and integration problems. And, of course, there are myriad other possible ways in which I may have underestimated the complexity of biological cognition: maybe glial cells are performing critical computations; maybe we need to describe genetic transcription processes in detail to capture learning; maybe we need to delve to the quantum level to get the explanations we need—but I am doubtful (Litt et al. 2006).

Perhaps it goes without saying that, all things considered, I believe the timeline I propose is a plausible one.¹ This, of course, is predicated on there being the societal and political will to allow the development of artificial minds to proceed. No doubt researchers in this field need to be responsive to public concerns about the specific uses to which such technology might be put. It will be important to remain open, self-critical, and self-regulating as artificial minds become more and more capable. We must usher in these technologies with care, fully cogniscent of, and willing to discuss, both their costs and their benefits.

Acknowledgements

I wish to express special thanks to two anonymous reviewers for their helpful feedback. Many of the ideas given here were developed in discussion with members of the CNRG Lab, participants at the Telluride workshops, and my collaborators on ONR grant N000141310419 (PIs: Kwabena Boahen and Rajit Manohar). This work was also funded by AFOSR grant FA8655-13-1-3084, Canada Research Chairs, and NSERC Discovery grant 261453.

¹ It is quite different from that proposed by the HBP, for example. For further discussion of the differences in perspective between the HBP and my lab's work, see Eliasmith & Trujillo (2013).

Future Games

A Commentary on Chris Eliasmith

Daniela Hill

In this commentary, the future of artificial minds as it is presented by the target article will be reconstructed. I shall suggest two readings of Eliasmith's claims: one regards them as a thought experiment, the other as a formal argument. While the latter reading is at odds with Eliasmith's own remarks throughout the paper, it is nonetheless useful because it helps to reveal the implicit background assumptions underlying his reasoning. For this reason, I begin by "virtually reconstructing" his claims as an argument—that is, by formalizing his implicit premises and conclusion. This leads to my second claim, namely that more than technological equipment and biologically inspired hardware will be needed to build artificial minds. I then raise the question of whether we will produce *minds* at all, or rather functionally differentiated, fragmented derivatives which might turn out not to be notably relevant for philosophy (e.g., from an ethical perspective). As a potential alternative to artificial minds, I present the notion of postbiotic systems. These two scenarios call for adjustments of ethical theories, as well as some caution in the development of already-existing artificial systems.

1 Introduction

This commentary has two main aims: First, it aims to reconstruct the major important predictions and claims Eliasmith presents in his target article as well as his reasons for endorsing them. Second, it plays its own version of "future games"—the "argumentation game"—by taking some suggestions presented by Eliasmith maximally seriously and then highlighting problems that might arise as a consequence. Of course, these consequences are of a hypothetical nature. Still, they are theoretically relevant for the question of what will be needed to build full-fledged artificial cognitive agents.

Chris Eliasmith discusses recent technological, theoretical, and empirical progress in re-

search on Artificial Intelligence and robotics. His position is that current theories on cognition, along with highly sophisticated technology and the necessary financial support, will lead to the construction of sophisticated-minded machines within the coming five decades ([Eliasmith this collection](#), p. 2). And also vice versa: artificial minds will inform theories on biological cognition as well. Since these artificial agents are likely to transcend humans' cognitive performance, theoretical (i.e., philosophical and ethical) as well as pragmatic (e.g., legal and cultural laws etc.) consequences have to be considered throughout the process of developing and constructing such machines.

The ideas Eliasmith presents are derived from developments in three areas: technology, theory, and funding; and I will demonstrate the background assumptions underlying these. In this way, I want to demonstrate that if we read Eliasmith as defending a formal argument (rather than a thought experiment), this argument has the form of a *petitio principii*. To illustrate this very clearly, a formal reconstruction of the (not explicitly endorsed, but implicitly assumed) arguments will be conducted. I then argue that even though they are constructed as arguments, and Eliasmith's claims fail, his suggestions provide an insightful contribution to the philosophical debate on artificial systems and the near future of related research. I further want to stress that we should perhaps confine ourselves to talking about less radical alternatives that do not necessarily include the mindedness of artificial agents, but have some element of biological cognition (architecture or software) in them. A number of subordinate questions have to be looked at in order to arrive at a point where a justified statement about the possibility of phenomenologically convincing artificial minds can be made. These considerations include more possibilities than simply the dichotomy of human-like vs. artificial. This is due to our *having* to think about possibilities that lie between or beyond these two extremes, such as fragmented minds and postbiotic systems, since they might soon emerge in the real world. The way in which these will be relevant to philosophy will be largely a question of their psychological make-up—most notably, their ability to suffer.

To start with, the following two sections will present some relevant aspects of the position expressed in the target article. They will summarize, and highlight some of the article's many informative and noteworthy suggestions. I shall also bring in some additional thoughts that I consider important. Afterwards, I will play a kind of future game of my own: I take Eliasmith's predictions very seriously and point at some of the problems that might arise if we were to take his suggestions as arguments. To be fair, [Eliasmith](#) himself says that what he presents are “likely wrong” predictions ([this col-](#)

[lection](#), p. 3). So on a more charitable reading, his claims are not intended to be arguments at all. Yet the attempt to reconstruct them as a formal argument has the advantage of showing that his claims are based on a reasoning that is itself problematic.

2 Are artificial minds just around the corner?

[Eliasmith's](#) perspective on the architecture of minds is a functionalist one ([this collection](#), p. 2, p. 6, pp. 6–7, pp. 9–11, p. 13). The thread running through his paper is his interest in “understanding how the brain functions” and realizing “detailed functional models of the brain” ([ibid.](#), p. 9). The basic idea is that if we construct artificial minds and endow them with certain functions (such as natural language and human-like perceptual abilities), we can examine empirically, in a process comparable to reverse engineering, what it is that constitutes so-called mindedness ([ibid.](#), p. 11). But in their striving to unearth the nature of mindedness, it is not the task of artificial intelligence research or biology to deliver comprehensive and full-fledged theories on biological cognition in general and human cognition in particular. Rather, a very interesting reciprocal relationship between the two parties, in which one learns from the other, is what will propel forward our understanding of biological cognitive systems. In the following I give an overview of the most relevant points that are presented in the target article. They will be divided up into the original sections (technical, theoretical, and empirical).

First, in the technical area and according to Eliasmith, we are fairly far advanced—although there are certain hindrances to successfully implementing theories on this technology. The main obstacle is the size of artificial neuronal systems and, connected to that, their power consumption. Even though neuromorphic chips are being improved steadily, the number of neurons that can be reproduced artificially is still much lower than the number of neurons a human brain has. Thus, the processing of information is significantly slower than in natural cognitive systems ([Eliasmith this collection](#), p.

14). Consequently, what can be realized in the field is still far from the complexity displayed by natural, biological cognition. However, as Eliasmith argues, since we are already in possession of the theoretical groundwork, the main barrier to overcome are technological advances (*ibid.*, p. 9). Throughout the paper, Eliasmith informs the reader that in case we had the technologies needed, artificial minds would immediately be created (*ibid.*, e.g., p. 7, p. 9, p. 11). However, where Eliasmith emphasizes technological barriers, I would like to point out that *theoretical* obstacles exist as well. These mainly revolve around the fact that a system of ethics has to be created *before* we encounter artificial agents. Eliasmith also comments on the consequences for philosophy, arguing that some major positions in the philosophy of mind, such as functionalism, will receive more empirical grounding (*ibid.*, p. 11).

It seems as if the tacit understanding that [Eliasmith](#) has of the function of artificial minds is that they serve as shared research objects of biology and artificial research science in order to gain a better understanding of biological cognition ([this collection](#), p. 9). That is of course only true if indeed the functional architecture of the artificial agent produces convincing behavior, similar to that of biological cognitive systems (humans and animals alike). To illustrate possible problems, one can think of the fact that in research, we learn from animal experiments, even though these animals are quite different from us in many ways. They are, however, similar or at least comparable in one epistemically relevant and specific aspect, i.e., the one that is to be examined, for example in certain aspects of metabolism used to test whether a new drug causes liver failure in humans ([Shanks et al. 2009](#), p. 5). It is the same with artificial agents: they are similar to us in their behavior and thus a worthwhile research object. As such, we could formulate the underlying reasoning as a variant of analytical behaviorism. Analytical behaviorists suppose that intrinsic states of a system are mirrored in certain kinds of behavior. Two systems displaying identical behavior on the outside can be investigated in order to detect whether they do so on the inside

as well ([Graham 2010](#)). This means that we could gain insight on the origin of mental states from a functionally isomorphic system, i.e., an artificially constructed system that is identical in organization and behavior to the natural system copied.

Last, since it seems that it will be possible in the future, given the required hardware, to design artificial agents according to our needs, it does not appear far-fetched to assume that the quality of human life might consequently be improved to a great extent ([Eliasmith this collection](#), p. 11). This requires, however, that we make up our own minds about how to interact with such agents, which rights to grant and which to deny them. And also the opposite case may not be disregarded: it is imaginable that the artificial agents will at some point turn the tables and be the ones to decide on *our* rights (cf. [Metzinger 2012](#)). In highlighting aspects from different areas to be considered, Eliasmith reminds us of the possibilities that lie ahead of us, but also of the challenges that might show up and have to be faced. I want to suggest that we also take into consideration alternative outcomes that are not minds in the biological sense, but rather derivatives of minds. I will therefore put the notion of postbiotic systems into play as a way of escaping the dichotomy “human-like” vs. “artificial” ([Metzinger 2013](#)). The philosophical point here is that the conceptual distinction between “natural” and “artificial” may well turn out to be non-exhaustive and non-exclusive: there might well, as Metzinger points out, be future systems that are neither artificial nor biological. By no means do I intend to argue against the use of scientific models, since they are what good research needs. Rather, I wish to draw attention to the possible emergence of intermediate systems, rather than only the extremes (i.e., human-like vs. artificial agents), or classes of systems that go beyond our traditional distinctions, but which nevertheless count as “minded”. As mentioned above, this is due to these intermediate or postbiotic systems being possible much earlier—probably preceding full-blown minded agents.

I will end this section by drawing attention to some of the author’s thoughts on the crucial elements of artificially-minded systems. According

to Eliasmith, three types of skills are vital in building artificial minds: cognitive, perceptual, and motor skills have to be combined to create a certain behavior of the minded artificial agent. This behavior will then serve as the basis for us humans to judge whether we perceive the artificial agent as “convincing” or not (Eliasmith this collection, p. 9). Unfortunately, no closer specification of what it is to be “convincing” is given in the target article. No theoretical demarcation criterion is offered. What we can say with great certainty, however, is that in the end our subjective *perception* of the artificial agents will be the decisive criterion. One could speculate on whether it is merely an impression, or even an illusion, that leads us to concluding that we are facing a *minded* agent. According to Eliasmith, any system that produces a robust social hallucination in human observers will count as possessing a mind.

3 Playing the “argumentation game”

In the following I will play the “argumentation game” and for a moment assume that what Eliasmith presents us with actually is argumentation. The goal of this section is not to claim that Eliasmith really *argues* for the emergence of artificial minds in the classical way. Rather, I wish to highlight that possibly more than technological equipment and biologically inspired hardware need to be taken into account before research can present us with a mind, as outlined by Eliasmith. If we deconstruct his line of reasoning and virtually formalize the *argument*, we don’t find valid argumentation but rather a set of highly educated—and certainly informative—claims about the future, which doubtlessly help us prepare for a future not too far ahead of us. I will utilize the terms “argumentation”, “argument”, “premise”, and “conclusion” in the following, but it should always be remembered that these terms are only “virtually” or hypothetically. So let us see how Eliasmith proceeds:

If we play the argumentation game, a first result is that Eliasmith’s virtual argument becomes problematic at the moment he starts elaborating on theoretical developments that have been made and that will propel forward the development of “brain-like models” (this collection,

p. 6). From the perspective of an incautious reader, the entire section “Theoretical developments” could be seen as resulting in a claim that can be traced back to a *petitio principii*. This means that the conclusion drawn at the end of the argumentative line is identical with at least one of the implicit premises. The implicit argumentation is made up of three relevant parts and unfolds as follows: first, building brain-like models is not only a matter of the available technological equipment (*ibid.*, first paragraph; cf. premise 1). Instead, if we face a convincing artificially-minded agent, it is characterized by both sophisticated technological equipment and by our discovery of principles of how the brain functions, such as learning or motor control (*ibid.*; cf. premise 2). And so, in conclusion, it follows that if biological understanding and technological equipment come together, we will be able to build brain-like models and implement them in highly sophisticated cognitive agents (*ibid.*).

The incautious reader would now have to believe that Eliasmith is confusing necessary and sufficient conditions. Let us look at this assumed argument in some more detail. Formulated as a complete argument we would get: “If it is not the case that technological equipment *alone* leads to the building of brain-like models for artificial cognitive agents, but we face a good artificial minded agent which is endowed with certain technology as well as biologically inspired hardware, we have to conclude that this certain technology and biologically inspired hardware are not only necessary, but also sufficient for building brain-like models for artificial cognitive agents.”

The formal expression of this argument would be the following:

T: We have developed sophisticated technological equipment.

B: We have developed biologically-inspired hardware.

M: We can build brain-like models which can be implemented in artificial cognitive agents.

$$\begin{array}{l} \neg(T \rightarrow M) \\ M \rightarrow (T \ \& \ B) \\ \hline (T \ \& \ B) \rightarrow M \end{array}$$

As is obvious from how the argument is constructed, it is invalid. So, what we can say at this point is that the combination of both technical features and biologically-inspired neuromorphic hardware very likely does get us some way, but we might have to consider which elements are missing so that we really end up building what will be perceived as minds. I shall propose some possibilities in the following section. The author even supposes that we will be able to build artificial agents ready to rival humans in cognitive ability (Eliasmith [this collection](#), p. 9). I am convinced that it is not cognitive artificial agents that will be the crucial hurdle, but rather their mindedness. I am also convinced that the huge amount of money spent on certain research projects will most likely result in improved models of the brain, as suggested by Eliasmith ([ibid.](#), p. 8), but it is not obvious to me how investing a vast amount of money necessarily results in relevant findings. It is also possible that no real progress will be made. Stating the opposite, which Eliasmith does not, resembles a claim based on expertise as bulletproof evidence. Sure enough, monetary sources are needed to make progress, but they are no *guarantee*. So possibly technology, biological theories on the brain's functioning, and money, essentially, might not lead to sophisticated cognitive agents being built ([ibid.](#)). The point is not that we should not invest money unless a positive outcome is guaranteed. Rather, we need a theoretical criterion for mindedness that is philosophically convincing—and not only robust, but epistemically unjustified social hallucinations. This theoretical criterion is what we lack.

4 What could artificial minds be?

In this section, I intend to sketch some important issues and questions for the future debate on artificial minds. I shall examine whether predictions on the concept of *artificial minds* can be made at the present state of the debate and based on the empirical data we currently have. This involves knowledge about what a mind is, and knowledge about how an *artificial* mind is characterized. In reconstructing Eliasmith's un-

derstanding of what a mind is, we may find the following statement informative: he relies on behavioral, theoretical, and similarity-based methods ([this collection](#), p. 3). The possible problem with this approach is that the characterization of the methods is very limited. To point to some relevant questions: what is the behavior of a mind? What about the fact that *mind* is not even close to being well understood theoretically? How do similarity-based methods avoid drawing problematic conclusions from analogies (cf. Wild 2012)? Importantly, at this point we are only talking about natural, biologically-grounded minds. Answers as to what an *artificial* mind is supposed to be might exceed the concept of mind in ways we are unable to tell at the present moment.

Let us see how Eliasmith characterizes artificial *minds*. One can see this as a judgment based on the similarity of behavior originating from two types of agents: humans and artificial. Functions need to be developed that are necessary for building an artificial mind. These functions lead to a certain kind of behavior. This behavior is achieved by perceptive, motor, and cognitive skills, which are needed to make the behavior seem human-like. Thus, the functions implemented on sophisticated kinds of technology will, in the end, lead to human-like behavior (Eliasmith [this collection](#), p. 9). The reason why the argumentative step from cognition, perception, and motor skills to mindedness can be made is the underlying assumption that the behavior resulting from these three types of skills is *convincing* behavior in our eyes (Eliasmith [this collection](#), p. 10). Similarity judgments, so Eliasmith argues, might appear “hand-wavy”. Still, he uses them to reduce the complexity that mindedness brings with it ([ibid.](#), pp. 5–6), and he certainly succeeds in drawing attention to a whole range of important issues. However, it could well be that the reduction to human-like behavior as the benchmark for assessing mindedness is too simple. After all, analytical behaviorism today counts as a failed philosophical research program. There could be much more to mindedness than behavior. We just do not know what this is yet. As a possible candidate we might consider the previously

mentioned psychological make-up of artificial agents, such as their being endowed with internal states like ours. One might think of robust first-person perspectives, but also about emotions like pain, disappointment, happiness, fear, and the ability to react to these. Other options include interoceptive awareness or the ability to interact socially—and much more.

5 What should we brace ourselves for?

Given the complexity of mindedness and our very limited understanding of what constitutes it, what else can we talk about? We could consider further possibilities of artificial systems that might arise, thereby enlarging the set of constraints that has to be satisfied. Some of them seem much more likely than artificial minds, and they might precede minds chronologically. I would like to focus on the idea of *fragmented minds* on the one hand and of *postbiotic systems* on the other, as two versions of artificial systems. An artificially-constructed fragmented mind is characterized by only partial satisfaction of the constraints fulfilled by a human mind. It could thus, very much like autistic persons with savant syndrome (i.e., more than average competence in a certain domain, e.g., language learning or music), and possess only some of our cognitive functions, but be strikingly better at them than normal humans are and ever could be, given their biological endowment.¹ Postbiotic minds, on the other hand, could satisfy additional constraints that are not yet apparent presently. I will conclude with some reflections on the new kind of ethics that will have to be created in order to approach new kinds of cognitive agents. As pointed out above, I assume that cognitive agents will be possible much earlier than truly minded agents. Learning, remembering, and other cognitive functions can already be recreated in artificial systems like *Spaun*. Still, human cognition is very versatile and complex. A fully minded agent, in contrast to a merely cognitive agent, might also be able to experience herself as a cognitive agent.

Therefore, I propose that cognitive systems could be created that do not yet qualify as a copy of our cognitive facilities, but which cover only parts of our cognitive setup. I call these *fragmented minds*. Importantly, the word *minds* does not refer here to the artificiality of the system at all. There are human beings with fragmented minds, too, such as babies, who do not yet display the cognitive abilities we ascribe to adult humans in general, or the aforementioned autistic humans with savant syndrome. Fragmented minds are contrasted with what we experience as normal human minds. *Fragmented* means that the created system possesses only part of the abilities that our mind displays. The term *mind* delineates the—historically contingent—point of reference that is human beings. How are fragmented minds further characterized? Eliasmith himself gives us an example: we could design a robot (an artificial mind) that gains fulfillment from serving humans ([this collection](#), p. 11). This would only be possible if aspects of our own minds were not part of the mental landscape of this robot. We could roughly formulate such an aspect, such as the will to design one's own life. Folk psychology would most likely regard this robot as lacking a free will, which is in conformity with the idea of slavery that Eliasmith acknowledges (*ibid.*). So a fragmented mind is an artificial system that possesses part of a biological cognitive system's abilities instead of the rich landscape most higher animals (e.g., some fishes and birds, certainly mammals), as well as humans, display.

Related to the aspect of fragmented minds is the idea that we could refrain from creating minds that might cause us a lot of moral and practical trouble, and instead focus on building sophisticated robots designed to carry out specific kinds of tasks. Why do we need to create artificial *minds*? What is the additional value gained? If these robots are not mindful, we will circumvent the vast majority of conceptual and ethical problems, such as legal questions (What is their legal status compared to ours?) or ethical considerations (If I am not sure whether an artificial agent can perceive pain, how should I treat it in order to not cause harm?). In which case, they

¹ In that case, the variable **B** from above (biologically inspired hardware) would not be a necessary condition for finding out more about mindedness.

would only be more capable technology than what we know at present, and most likely be of no major concern for the philosophy of mind. However, if they *are* mindful, we doubtlessly have to think about new ways of approaching them ethically.

Also ethically relevant are intermediate systems, systems that are not clearly either natural or artificial. These systems have been called *postbiotic systems* (Metzinger 2012, p. 268). What characterizes postbiotic systems is the fact that they are made up of both natural and artificial parts, thus belonging to neither of the exhaustive categories “natural” or “artificial”. In that way a natural system, e.g., an animal, could be controlled by artificially-constructed hardware (as in hybrid bio-robotics); or, in the opposite case, artificial hardware could be equipped with biologically-inspired software, which works in very much the same way as neuronal computation (Metzinger 2012, pp. 268–270; Metzinger 2013, p. 4). Perhaps Eliasmith’s own brain-like model *Spaun* is a postbiotic system in this sense, too. In what way would these systems become ethically relevant? Although the postbiotic systems in existence today do not have the ability to subjectively experience themselves and the world around them, they might have it in the future. In being able to subjectively experience their surroundings, they are probably also able to experience the state of suffering (Metzinger 2013, p. 4). Everything that is able to consciously experience a frustration of preferences as a frustration of its *own* preferences automatically becomes an object of ethical consideration, according to this principle. For such cases, we have to think of ethical guidelines *before* we are confronted with a suffering postbiotic mind, which could be much earlier than we expect. Before thinking about how to implement something as complex and unpredictable as an artificial *mind*, one should consider what one does *not* want to generate. This could, for example, be the ability to suffer, the inability to judge and act according to ethical premises, or the possibility of developing itself further in a way that is not controllable by and potentially dangerous for humans.

6 Conclusion

In this commentary, I have played the “argumentation game” as my own version of Eliasmith’s “future game”. The intention behind this was to demonstrate that we very likely need more than sophisticated technology and biologically-inspired hardware to build brain-like models ready to be applied in artificial cognitive agents. As such, I playfully took Eliasmith’s considerations on the future of artificial minds as arguments, and demonstrated that they would result in a *petitio principii*. In so doing, I highlighted that necessary conditions do not have to be sufficient as well. While this is common philosophical currency, it is instructive to spell this out in the case of artificial agents. So in the present case, what constitutes artificial cognitive systems and what is needed to gain a deeper understanding of how the mind works might include more factors than the two crucial ones Eliasmith outlines, namely biological understanding and its implementation in highly-sophisticated technology. I proposed some possibilities that might turn out to be informative for future considerations on what constitutes an artificial mind. In particular, I mentioned experiential aspects, such as the perception of emotions and reactions to them, as well as internal perceptions like interoceptive awareness. In general, this means that we need theoretical criteria that are convincing for philosophy in order to overcome referring to robust yet convincing social hallucinations. Further, to illustrate that the distinction between natural and artificial systems might not be exhaustive, I pointed to the notions of fragmented minds and postbiotic systems as possible developments for the nearer future. They have to be considered, in particular with respect to their ethical implications, before they are developed and implemented in practice.

Even though we lack a more fine-grained, deeper understanding of what constitutes minds, Eliasmith shows us that it is worth thinking about what we already *do* have at hand for constructing artificially-minded systems. He demonstrates vividly that two factors—technology and biology—are of major import-

ance on the route to artificially-cognitive, if not minded, agents. And he brings into discussion a number of far-reaching consequences that will apply in case we do succeed in building artificial minds within the next five decades. These will inform the development of these artificial systems as well as philosophical debate, both on an ethical, as well as theoretical level. In this way, Eliasmith's contribution has to be regarded as significant in terms of preparing us for the decades to come.

Acknowledgements

First and foremost, I am grateful to Thomas Metzinger and Jennifer M. Windt for letting me be part of this project, thus providing me a unique opportunity to gain valuable experience. Further special thanks go to the two anonymous reviewers, as well as the editorial reviewers for their insightful comments on earlier versions of this paper. Lastly, I wish to express my gratitude to Anne-Kathrin Koch for sharing her expertise with me.

Mind Games

A Reply to Daniela Hill

Chris Eliasmith

In her discussion of my original article, Hill reconstructs an argument I may have been making, argues that the distinction between natural and artificial minds is not exclusive, and suggests that my reliance on behaviour as a determiner of “mindedness” is a dangerous slip back to philosophical behaviourism. In reply, I note that the logical fallacy of which I’m accused (circular reasoning) is not the one present in the reconstruction of my argument (besides the point), and offer a non-fallacious reconstruction. More importantly, I note that logical analysis does not seem appropriate for the discussion in the target article. I then agree that natural and artificial minds do not make up two discrete categories for mindedness. Finally, I note that my research program belies any behaviourist motivations, and reiterate that even though behaviour is typically important for identifying minds, I do not suggest that it is a substitute for theory. However, the target article is not about such theory, but about the near-term likelihood of sophisticated artificial minds

1 Introduction

I think Hill is right to wonder aloud about my methodology in the target article. After all, I just ignored the hard philosophical issue of saying what minds really are. I pretended (somewhat self-consciously) that we all know what minds are, and so that we will simply be able to tell when someone has created one, if they ever do. But, I did that for a reason. The reason was this: I did not want to get lost in the minutiae of metaphysics when my focus was on a technological revolution—one with significant philosophical consequences (which is also not to say I don’t like such minutiae in their proper time and place).

2 A failure of logic

However, Hill was also not especially taken by the reasons I provided for expecting such developments either. Hill’s suggestion is that the best reasonable argument you could construct from my original considerations was fallacious. Though, [Hill](#) is quick to point out that I didn’t take myself to be constructing an argument: “... not to claim that Eliasmith really argues for the emergence of artificial minds” ([this collection](#), p. 4).

Nevertheless, her analysis is that what I have provided is best understood as a *petitio principii* (aka circular argument): “this means that the conclusion drawn at the end of the ar-

gumentative line is identical with at least one of the implicit premises” (Hill [this collection](#), p. 4). Unfortunately, the technical analysis offered (p. 5) is a *non sequitur* (i.e., there is no logical connection between the premises and conclusion). Regardless, one fallacy is as embarrassing as the other.

However, I’d like to suggest that if we wanted to recast the original paper as a logical argument, then a simple *modus ponens* will do: if we have a good theory and the technological innovations necessary to implement the theory, then we can build a minded agent. We have good (and improving) theory and will have the proper technological innovations (in the next 50 years), therefore we will be able to build a minded agent (in the next 50 years). Indeed, most of the paper is arguing for the plausibility of these premises.

More to the point, however, I think that we can take this as an object lesson for when logical inference is really just the wrong kind of analysis of a paper. Instead of trying to provide a logical argument from which the conclusion necessarily follows from the premises, I am providing series of considerations that I believe make the conclusion likely given both the current state of affairs, and expected changes. In short, I think of the original paper as providing something more like a series of inferences to the best explanation: all of which are, technically, fallacious; and all of which are directed at establishing premises.

3 Back to minds

Despite disagreeing with the analysis of the logical structure of the paper, I do appreciate the emphasis that Hill has placed on philosophical and ethical aspects of our attempts to construct minds. In the original article, I only very briefly touch on those issues. However, I would be quick to point out that I do not think, and never intended to suggest, that the distinction between “natural” and “artificial minds” was an absolute, “exhaustive,” or “exclusive” one (Hill [this collection](#), p. 3). Like most interesting and complex features, possession of ‘mindedness’ no doubt comes in degrees. In fact, I think that our

attempts to construct artificial minds will provide a much better sense of the dimensions along which such a continuum is best defined.

Finally, I must admit that I find it somewhat alarming that I’m being characterized as a behaviourist in Hill’s article—*that* has definitely never happened before: “Let us see how Elia-smith characterizes artificial minds. One can see this as a judgment based on the similarity of behaviour originating from two types of agents: humans and artificial” ([this collection](#), p. 5). Hence, I was espousing “analytical behaviorism... a failed philosophical research program” (Hill [this collection](#), p. 6). Indeed, I, like all behavioural scientists, believe that behaviour is one important metric for characterizing the systems of interest. However, the reason I focus on internal mechanisms in my own research – all the way down to the neural – is that I believe those mechanisms give us critical additional constraints for identifying the right class of algorithms that give rise to behaviours. Consequently, I wholeheartedly agree with Hill that “There could be much more to mindedness than behaviour” ([this collection](#), p. 6). So, for the record, I believe that our best theories for how to build minds are going to be highly informed by low-level mechanisms.

That being said, I also think that most people’s judgments of whether or not something counts as being minded is going to come down largely to their being convinced of the naturalness, or “cognitiveness” of the behaviour that is exhibited by agents we construct. Notice that there is a difference between a claim of how people will judge mindedness, and a claim about theories of mindedness or how we ought to best achieve that judgment. Turing was, after all, onto *something* with his test.

4 Conclusion

I noted in the original article (Eliasmith [this collection](#)) that I was attempting to avoid becoming mired in tangential debates regarding what it is to have a mind by simplifying the criteria for mindedness (for the purposes of that article). Exactly the kinds of debates I was attempting to avoid are raised in Hill’s comment-

ary. For example, I don't think we know if there is a clean contrast between a "fully minded agent" and a "merely cognitive agent" ([Hill this collection](#), p. 6). Perhaps there is, and perhaps it is that a fully minded agent can "experience herself as a cognitive agent", ([Hill this collection](#), p. 6) but perhaps not. This does not strike me as a decidable question at present.

So, perhaps my unwillingness to venture into the murky waters of necessary and sufficient conditions for having a mind came off as making me look like a behaviourist. But in truth, my purpose was rather to focus on providing a variety of evidence that I think suggests that artificial minds are not as far away as some have assumed. There is, I believe, a historically unique confluence of theory, technology, and capital happening as we speak.

Can We Be Epigenetically Proactive?

Kathinka Evers

The human brain is an essentially evaluative organ endowed with reward systems engaged in learning and memory as well as in higher evaluative tendencies. Our innate species-specific, neuronally-based identity disposes us to develop universal evaluative tendencies, such as self-interest, control-orientation, dissociation, selective sympathy, empathy, and xenophobia. The combination of these tendencies may place us in a predicament. Our neuronal identity makes us social, but also individualistic and self-projective, with an emotional and intellectual engagement that is far more narrowly focused in space and time than the effects of our actions. However, synaptic epigenesis theories of cultural and social imprinting on our brain architecture suggest that there is a possibility of culturally influencing these predispositions. In an analysis of epigenesis by selective stabilisation of synapses, I discuss the relationships between genotype and brain phenotype: the paradox of non-linear evolution between genome and brain complexity; the selection of cultural circuits in the brain during development; and the genesis and epigenetic transmission of cultural imprints. I proceed to discuss the combinatorial explosion of brain representations, and the channelling of behaviour through “epigenetic rules” and top-down control of decision-making. In neurobiological terms, these “rules” are viewed as acquired patterns of connections (scaffoldings), hypothetically stored in frontal cortex long-term memory, which frame the genesis of novel representations and regulate decision-making in a top-down manner. Against that background I propose the possibility of being epigenetically proactive, and adapting our social structures, in both the short and the long term, to benefit, influence, and constructively interact with the ever-developing neuronal architecture of our brains.

Cultural circuits | Empathetic xenophobia | Epigenetic proaction | Epigenetic rules | Neuroethics | Precaution | Responsibility | Selective sympathy | Species-specific identity | Synaptic epigenesis

1 Introduction

Contemporary neuroscience no longer views the brain as an input-output processing device but as an autonomously active, self-referential, and selectional system operating in a projective style, which is in constant social interaction and in which values are incorporated as necessary constraints. The idea that evolution by natural selection has given rise to an essentially evaluative cerebral architecture raises the question whether, in the human species, such neurobiologically-based predispositions have further developed the means to generate novel specific values on higher cognitive levels. The concept of “value” would then play a central role as something that is taken into account in decision-

making and that influences a choice, selection, or decision, that can occur on many levels—non-conscious as well as conscious—as a basic biological function or as a feature of advanced moral reasoning. But, if we are born evaluators, to what extent can these predispositions with which we are all born be culturally controlled?

In this article, I suggest that our innate species-specific neurally based identity disposes us to develop universal evaluative tendencies, such as self-interest, control-orientation, dissociation, selective sympathy, empathy, and xenophobia. The combination of these tendencies may place us in a practical and moral predicament. Our neuronal identity as persons makes

us social, but also individualistic and self-projective, with an emotional and intellectual engagement that is far more narrowly focused in space and time than the effects of our actions.

However, the neuronal organisation of our adult brain develops in the course of a fifteen year-long period following birth, during which, and, to a lesser extent, after which it is subject to cultural influence, both on the individual level and, at the social group level, across generations (Lagercrantz 2005; Lagercrantz et al. 2010; Collin & van den Heuvel 2013). Synaptic epigenesis theories of cultural and social imprinting on our brain architecture (which differ from less discriminative epigenetic modifications of nuclear chromatin) (Changeux 1985; Kitayama & Uskul 2011) suggest that there is an interesting possibility, which, in my opinion, has hitherto been underestimated. That is, we could potentially be *epigenetically proactive* (Evers 2009) and adapt our social structures, in both the short and the long term, to benefit, influence, and constructively interact with the ever-developing neuronal architecture of our brains.

2 The social individualist

2.1 An egocentric evaluator

The human brain is intrinsically active: it produces electrical and chemical activity both in response to external stimuli and, spontaneously, independently of them. The brain is an autonomously-active motivated neuronal system, genetically equipped with a predisposition to explore the world and to classify what it finds there (Changeux 1985, 2004). On-going spontaneous activity is present throughout the nervous system. In the embryo, spontaneous movements (Narayanan & Hamburger 1971) and waves of endogenous retinal activity (Galli & Maffei 1988; Goodman & Shatz 1993) are thought to play an important role in the epigenesis of neural networks through synapse selection (see below). On-going spontaneous activity is also present in the adult brain, where it is responsible for the highly variable patterns of the electroencephalogram (EEG; Berger 1929; Raichle et al. 2001). Thalamocor-

tical networks generate a variety of oscillations, whose rhythms change across the sleep-wake cycle (Llinas & Paré 1991). Optical imaging methods in anesthetized animals also reveal fast spontaneous states of neuronal activity that, far from being random, exhibit patterns that resemble those evoked by external stimuli. In parallel, functional neuroimaging studies in humans have shown a globally-elevated brain metabolism at rest, with localized patterns suggesting that particular cortical regions are maintained in a high, although variable, state of activity referred to as “default mode” by Raichle et al. (2001).

Hypotheses of knowledge acquisition posit that patterns of spontaneous activity, referred to as “pre-representations”, arise in the brain and are selected by reward signals as “representations” confirmed by both external experience and internal processes of evaluation within a conscious neuronal workspace (Dehaene & Changeux 2011). Such “models of the world” are stabilised through “cognitive games” by analogy with Wittgenstein “language games”, as permanent features of the developing cognitive apparatus, according to a process referred to as “mental Darwinism” (Changeux 2004).

Anticipation of reward signals introduces a delay between the elaboration of tacit plans of action and actual interaction with the world performed by the organism, which presupposes a distinction of temporal states: awareness of the present, remembrance of the past, and anticipation of the future (Barto & Sutton 1982; Schultz et al. 1997; Dehaene & Changeux 2000; Schultz 2006). Without any capacity to evaluate stimuli, the brain could neither learn nor remember: it has to prefer some stimuli to others in order to learn. This classical idea in learning theory has been expressed in neuronal terms by Dehaene & Changeux (1991), and by Edelman in his accounts of primary consciousness (Edelman 1992). In these accounts, learning is a change in actual behaviour, or the storage of a trace subsequently unveiled (Dudai 1989, 2002) through brain categorizations of stimuli. These are given in terms of positive or negative values, understood as something that is taken into account in decision-making and that influences a choice, selection or decision, which can occur on

many levels. Through its intense and spontaneous activity, the brain has also been described as a narrative organ, spinning its own neuronal tale (Evers 2009). The narrations will vary greatly between individuals, but each will be self-projective.

The natural egocentricity or individualism of the human brain appears quite pronounced. In its projection of autonomously-produced images, the brain refers all experiences to itself, that is, to its own individual perspective. This self-projection is a biological predisposition that humans possess innately and that is closely connected to our predisposition for developing self-awareness, which Edelman suggests is a necessary condition for developing higher-order consciousness (Edelman 1992; Denton 2006; see also Tulving 1983). The existence of a self-projecting systems monitoring internal processes in the brain was suggested by an early Positron Emission Tomography (PET) study of self-generated actions showing hemodynamic activity in the posterior cingulate cortex (Blakemore et al. 1998). This observation was confirmed and extended by magneto-encephalography following synchronization in the gamma range (55–100 Hz), thus defining a major network of the brain: the paralimbic interaction between the medial prefrontal/anterior cingulate and medial parietal/posterior cingulate cortices and subcortical regions (Lou et al. 2004; rev. Changeux & Lou 2011). Damasio (1999) distinguished a “core consciousness” (core self) from an “extended consciousness” (extended self) that we consider as analogous to the “minimal self” and “extended self” of Gallagher (2000). Minimal self-awareness is prereflexive, immediate and normally reliable, while still involving a sense of ownership of experience (Gallagher 2000). The “extended self” is a coherent self that persists across time and requires a system that can retrieve long-term memories of personal experiences—namely, episodic memory (Gardiner 2001). Consequently, episodic memory retrieval becomes an indispensable component of the more complex forms of self-awareness and consciousness (Tulving 1983).

In the course of growing up, the infant develops the capacity to focus its attention; it

learns to distinguish between and recognise objects in its environment, such as faces, and becomes aware of itself as standing in various relations to these objects. Conscious processing develops into auto-distinction (when “this-here” is distinguished from “that-there”). When further developed, the individual becomes aware of itself as a subject of experience and ascribes mental states to itself: auto-distinction evolves into self-awareness (when “this-here” becomes “I”) usually at around one and a half years of age (Lagercrantz 2005), and possibly even earlier (Falck-Ytter et al. 2006; see also Rochat 2001). From the age of six to twelve months, the child typically sees a “sociable playmate” in the mirror’s reflection. Self-admiring and embarrassment usually begin at twelve months, and at fourteen to twenty months most children demonstrate avoidance behaviours. Finally, at eighteen months 50% of children recognize the reflection in the mirror as their own and by twenty to twenty-four months this rises to 65%—this is revealed, for instance, by them trying to evince marks on their own nose, taking advantage, in all these instances, of their episodic memory abilities (see Tulving 1983).

An evolved survival function that adds an evaluative element to our brain’s self-projective mode of operation is self-interest, expressed as a desire to survive, to be well-fed, safe, to reproduce, and so on. This is not a defining characteristic, for there are exceptions, for example subjects who have a very poorly developed self-interest (Damasio 1994; Damasio & Carvalho 2013). Nor is it necessarily rational, since biological evolution is circumstantial. There is an abundant literature on the phenomenologically rich concept of self-interest in philosophy and ethics, in terms e.g., of enlightenment, egoism, capacity for altruism, etc. Such issues are relevant and interesting but beyond the scope of this discussion. In the present context, self-interest is understood in a minimalistic sense, as an evolved survival function that adds an evaluative element to our brain’s self-projective mode of operation.

Self-interest is also a source of the urge to control the immediate environment, and of the need for familiarity, security, and preference for

the known. The subjective experience of some level of control and the security that this provides is in fact a necessary condition for the individual to develop in a healthy manner and to consolidate an integrated sense of self (Le-doux 1998). When the external circumstances become severely disturbing, we feel increasingly threatened and have a defence mechanism that is eventually activated: *dissociation*, here understood as a process whereby information—incoming, stored, or outgoing—is actively prevented from integration with its usual or expected associations.

The human being is, in this sense, a “dissociative animal”: we spend a considerable amount of intellectual and emotional energy on distancing ourselves from a wide range of things that we consciously or non-consciously fear or dislike (Evers 2009). When an experience is too painful to accept, we sometimes deliberately do not accept it; instead of integrating it into our ordinary system of associations, we push it away from us, and prevent it from being integrated into our consciousness. Pushed to an extreme, this tendency may become pathological, e.g., in the development of Dissociative Identity Disorder (cf. DSM-IV), but as a non-pathological process it is an important adaptive function, and a valuable evolutionary asset allowing us to survive events that we would otherwise be unable to endure (Putnam 1989; Evers 2001).

So far, I have described the brain as an autonomously active, self-projective, and selectional neural system with innate evaluative tendencies, e.g., self-interest, control-orientation, and dissociation. These cerebral features characterize the individual, but they are also reflected in the social relationships proper to the human species.

2.2 Selective sympathy & empathetic xenophobia

In social animals, self-interest is a source of interest in others. In the case of humans, this social interest focuses primarily on those to whom the self can relate and with whom it identifies, such as the next of kin, the clan, the community, etc. The human brain conjugates op-

posite tendencies: first, embodied in the human subject, it is engaged in highly individualistic and self-projective actions, such as the search for water or food. But it also mediates co-operative social relationships: the “I” is extended to endorse the group, as a “we”, and distinctions are drawn between “us” and “them” (Ricoeur 1992; Changeux & Ricoeur 2000). Sympathy and aid is typically extended to others in proportion to their closeness to us in terms of biology, e.g., face recognition (Michel et al. 2006; Hills & Lewis 2006), racial out-group versus in-group distinctions (Hart et al. 2000; Phelps et al. 2003), culture, ideology, etc.

Imagining an action or actually performing that action both have similar neural circuits (which include the premotor cortex, supplementary motor area, cerebellum, parietal cortex, and basal ganglia) to those activated when one observes, imitates, or imagines actions performed by other individuals (Jeannerod 2006; Decety 2012). The model mechanism suggested is that actions are coded in terms of perceivable effects (Hommel et al. 2001). Performing a movement leaves a memory of the association between the motor pattern by which it was generated and the sensory effects that it produces. Such stored associations can then be used to retrieve a movement by anticipating its effects. This perception-action coupling mechanism, which includes active sensing and motor-sensory loops (Gordon & Ahissar 2012) and to which may be added the motor theory of language (Liberman & Mattingly 1985), offers a mechanism for intersubjective communication and social understanding by creating functional links between first-person and third-person information (Decety & Sommerville 2003; Jackson & Decety 2004).

Functional Magnetic Resonance Imaging and magneto-encephalography among other methods have led to the demonstration that when children or adults watch other subjects in pain, the neural circuits mobilized by the processing of first-hand experience of pain are activated in the observer (Singer et al. 2004; Cheng et al. 2008). This sharing allows mapping of the perceived affective cues of others onto the behaviours and experiences of the self-oriented

response. Decety (2012) argues that, depending on the extent of the overlap in the pain matrix, and complex interactions with personal dispositions, motivation, contextual information, and self-regulation, this can lead to personal distress (i.e., self-centred motivation) or to empathic concern (i.e., an other-oriented response). This basic somatic sensorimotor resonance plays a critical role in the recognition and sharing of others' affective states.

There is an important neural distinction between apprehending and caring that makes it possible to understand the affective state of another without feeling engaged in it. Studies in the neurobiology of empathy (here understood as the ability to apprehend the mental states of others), and sympathy (the ability to care about others) suggest that these abilities involve complex cognitive functions with large individual and contextual variations that depend on both biological and socio-cultural factors (Jackson & Decety 2004; Singer et al. 2004; Singer et al. 2006; Iacoboni et al. 2005; Jackson et al. 2006; Lawrence et al. 2006; Parr & Waller 2006; Engen & Singer 2013). Such results are important, because appreciating the brain's role in apprehending and responding to the affective states of others can help us understand people who exhibit social cognitive disorders and are deficient in experiencing socially relevant emotions such as sympathy, shame, or guilt.

However, even in supposedly healthy human brains the capacity for other-oriented responses, such as sympathy, is pronouncedly selective and limited by spontaneous aggressive tendencies (Panksepp 1998; Lorenz 1963). When sympathy and mutual aid is extended within a group, they are also (de facto) withheld from those that do not belong to this group. In other words, interest in others is ordinarily expressed positively or negatively towards specific groups—but very rarely are attitudes extended to universal coverage, for example as attitudes towards the entire human species, or towards all sentient beings.

Understanding does not entail compassion, but is frequently combined with emotional dissociation from “the other”. We can easily understand, say, that a child in a distant country

probably reacts to hunger or pain in a way that is similar to how children in our own country react to hunger or pain, but that does not mean that we care about those children in equal or even comparable measures. Indeed, if understanding entailed sympathy, the world would be a far more pleasant dwelling place for many of its inhabitants. By nature, we are “empathetic xenophobes” (Evers 2009): we are empathetic by virtue of our intelligence and capacity to apprehend the mental life of a relatively wide range of creatures, but far more sympathetic to the closer group into which are born or choose to join, remaining neutral or hostile to “out-group” individuals.¹

Thus, in spite of our natural capacity for empathy, sympathy, and mutual assistance, the human being can also be described as a self-interested, control-oriented, dissociative xenophobe. In view of their historic prevalence, it is not unlikely that these features have evolved to become a part of our innate neurobiological identity and that any attempt to construe social structures (rules, conventions, contracts, etc.) opposing this identity must, in order to be realistically implemented, take this biological challenge into account in addition to the historically well-known political, social, and cultural challenges.

A major practical problem is that the effects of our actions are not limited, as are our capacities for engagement. The difficulty of wide involvement due to the brain's self-projective egocentricity is matched by a capacity to cause large-scale effects, which poses serious problems whenever large-scale or long-term solutions are needed—say, to improve the global environment, reduce global poverty, or safeguard future generations. Our societies are importantly construed around egocentric and short-term perspectives—political, economical, etc.—making it extremely difficult to put global or long-term thought and foresight into practice. This is of course only to be expected, since our brains'

¹ I am here discussing social attitudes in terms of subjective evaluators, but they can also be discussed in terms of non-conscious non-feeling units. Some current neuroscience literature may prefer to discuss the issue not from the point of view of subjective definitions but rather from the perspective of relevance detection and evaluation that is objectively observed.

neuronal architectures are engaged in social interactions and determine the social structures that we can and do develop.

However, our brain identity incorporates social influence. Culture and nature stand in a relationship of mutual causal influence: whilst the organisation of our brains in part determines who we are and what types of societies we develop, our social structures also have a strong impact on the brain's organisation; notably, they impact upon cultural imprints epigenetically stored in our brains. The genetic control over the brain's development is subject to epigenetic evolutionary processes; that is to say, to a coordinated and organised neuronal development that is the result of learning and experience and that is intermixed with the action of genes. The door to being epigenetically proactive is, accordingly, opened. In the following analysis of epigenesis by selective stabilisation of synapses I shall discuss the relationship between genotype and brain phenotype; the paradox of non-linear evolution between genome and brain complexity; the selection of cultural circuits in the brain during development; and the genesis and epigenetic transmission of cultural imprints.

3 Neuronal epigenesis

3.1 Genotype & brain phenotype: The paradox of non-linear evolution between genome & brain complexity

The comparison between what we presently know about human genomes and the brain phenotype raises the paradox of a non-linear evolution between the complexity of the genome and that of the brain ([Changeux 1985, 2012b](#)). From a molecular neurobiologist's perspective, the cognitive abilities and skills required for the highest functions of the human brain are built from a cascade of events driven by a "genetic envelope", which makes the difference between *Homo sapiens* and the human family's earliest ancestors, but which cannot be simply related to genome size, nor to the number of genes.

The total amount of DNA housed in the haploid genome is approximately 3.1 billion

base pairs, but no more than 20,000–25,000 gene sequences (1.2% of our genome code for exons—the DNA components of genes), and this number does not significantly differ from mouse to human. Moreover, the difference in full DNA sequences are very limited: between humans and chimpanzees they comprise no more than 4% of the genome. However, the total number of neurons in the human brain is in the order of 85 billion, compared to about 70 million in the brain of the mouse ([Azevedo et al. 2009](#)). Yet, notwithstanding the increase in cell numbers, with each neuron possessing its particular connectivity and its set of genes expressed, mammalian brain anatomy has evolved dramatically from a poorly corticalized lissencephalic brain with about 10–20 identified cortical areas to a brain with a very high relative cortical surface, multiple gyri and sulci, and possibly as many as 100 identified cortical areas ([Mountcastle 1998](#)). Thus, there exists a remarkable nonlinear relationship between the evolution of brain anatomy and the evolution of the genome organisation.

Molecular and cellular explanations have been suggested to account for this nonlinear relationship. One is the combinatorial expression of spatio-temporal patterns of genes that affect development ([Changeux 1985; Edelman 1987; Tsigelny et al. 2013](#)). Another, non-exclusive explanation, is the contribution of "epigenetic mechanisms" driven by interaction with the environment in the course of the long postnatal period of brain maturation—circa 15 years in humans—during which critical and reciprocal relationships take place between the brain and its physical, social, and cultural environment. It is on these epigenetic mechanisms that I shall focus here.

3.2 The epigenesis of neuronal networks by selective stabilization of synapses

The word "epigenesis" can be traced back to [William Harvey \(1651\)](#), who stated in contrast to contemporary preformationist views that the embryo arises by "the addition of parts budding out from one another". It was subsequently used by [Conrad Waddington \(1942\)](#) to specify the re-

lationship between the genes and their environment to produce a phenotype. This is also the meaning adopted in the theory of the epigenesis of neuronal networks by selective stabilization of synapses, according to which the environment affects the organisation of connections in an evolving neuronal network through the stabilization or elimination (pruning) of labile synapses, under the control of the state of activity of the network (Changeux et al. 1973). This meaning, which I shall use henceforth, contrasts with the more recent and biochemically distinct meaning of the word *epigenetic*, **which** refers to the status of DNA methylation and histone modification in a particular genomic region. This concerns the neuronal nucleus, but not the diversity of individual synaptic contacts (Sassone-Corsi & Christen 2012). The modulatory role of chromatin modifications in long-term memory has already been described (see e.g., Levenson & Sweatt 2005), but the informational content involved—which relies upon cell bodies—is expected to be in orders of magnitude smaller than that of synaptic epigenesis, based upon the combinatorial power of individual synapses.

During embryonic and postnatal development, the million billion (10^{15}) synapses that form the human brain network do not assemble like the parts of a computer, that is, according to a plan that precisely defines the disposition of all the individual components. If this were the case, the slightest error in the instructions for carrying out this program could have catastrophic consequences. On the contrary, the mechanism appears to rely on the progressive setting of robust interneuronal connections through trial-and-error mechanisms that formally resemble an evolutionary process by variation selection (Changeux et al. 1973; Changeux & Danchin 1976; Edelman 1987; Changeux 2012a). At sensitive periods of brain development, the phenotypic variability of nerve cell distribution and position, as well as the exuberant spreading and the multiple figures of transiently-formed connections originating from the erratic wandering of growth cone behaviour, introduce a maximal diversity of synaptic connections. This variability is then reduced by the selective stabilization of some of the labile con-

tacts and the elimination (or retraction) of others. The crucial hypothesis of the model is that the evolution of the connective state of each synaptic contact is governed globally, and within a given time window, by the overall “message” of signals experienced by the cell on which it terminates (Changeux et al. 1973).

One consequence of this is that particular electrical and chemical spatiotemporal patterns of activity in developing neuronal networks are liable to be inscribed under the form of defined and stable topologies of connections within the frame of the genetic envelope. In humans, about half of all adult connections are formed after birth at a very fast rate. The nesting of these multiple traces directly contributes to forming and shaping the micro- and macroscopic architecture of the wiring network of the adult human brain, thus bringing an additional explanation to the above-mentioned non-linearity paradox.

Another consequence of the synapse-selection model (originally presented as a “theorem of variability”) is that the selection of networks with different connective topologies can lead to the same input-output behavioural relationship (Changeux et al. 1973). This accounts for an important feature of the human brain: the constancy or “invariance” of defined states of behaviour, despite the epigenetic “variability” between individual brains’ connectivity.

Finally, both the spontaneous and the evoked activity may contribute to synapse selection. In this framework, a suggestion has been made that reward signals received from the environment may control the developmental evolution of connectivity (Gisiger et al. 2005; Gisiger & Kerszberg 2006). In other words, reinforcement learning would modulate the epigenesis of the network. The model has been implemented in a case of the learning of a visual delayed-matching-to-sample task (see below). This process of synaptic selection by reward signals may concern the evolution of brain connectivity in single individuals, but it also concerns the exchange of information and shared emotions or rewards between individuals in the social group (Changeux 1985, 2004; Gisiger et al. 2005). This is an important part of our argument; it may

thus play a critical role in social and cultural evolution.

3.3 The selection of cultural circuits in the brain during development & the epigenetic transmission of cultural imprints

There is an abundance of experimental studies that are consistent with, or directly support, the model of synapse selection. In humans the maximum synaptic density is reached within three years, then steadily declines until the total number stabilises around the time of puberty (Huttenlocher et al. 1997; Bourgeois 1997; Petanjek et al. 2011). Yet the process of synaptic refinement goes far beyond puberty: learning is life-long (Petanjek et al. 2011). The observed global decline in synaptic numbers during childhood plausibly reflects a rich cascade of elementary steps of learning by selection. Numerous studies have shown that when neuronal activity is experimentally modified, synaptic elimination is altered (Benoit & Changeux 1975, 1978; Stretavan et al. 1988; Purves & Lichtman 1980; Luo & O'Leary 2005; Innocenti & Price 2005; Collin & van den Heuvel 2013). At variance with the classical Lamarckist-constructivist scheme (Quartz & Sejnowski 1997), blocking the activity maintains a high number of connections: it is activity that enhances synaptic elimination (Benoit & Changeux 1975, 1978; Stretavan et al. 1988; Luo & O'Leary 2005). Thus “to learn is to eliminate” (Changeux 1985).

Among the cortical connections established in post-natal life are the long-range tracts between the frontal areas (Miller & Cohen 2001; Fuster 2008) and other brain cortical areas (including sensory ones) (Goldman-Rakic 1987; Goldman-Rakic 1999; Hagmann et al. 2008; Collin & van den Heuvel 2013). Some years ago, it was suggested, according to the “global neuronal workspace” hypothesis, that these long-range connections, by broadcasting signals to multiple brain areas, yield subjective “conscious” experience by allowing sensory inputs—seeing, hearing and so on—global access to many brain areas (Dehaene et al. 1998; Dehaene

& Changeux 2011). The long-range connections would provide a structural basis for the global experience known as conscious access.

These long-range connections are particularly important in the case of the prefrontal areas which contribute to planning, decision-making, thought, and socialisation. The ontogeny and postnatal development of long-range connectivity expectedly reveal phases of exuberance and phases of selection and axonal pruning (Collin & van den Heuvel 2013). In human newborns evolution is slow, and it has been suggested that the phase of exuberant long axon removal is largely completed at the age of two years, accompanied by increasing information processing and cognitive development (Collin & van den Heuvel 2013). Evolution continues during adolescence until adulthood with decreasing segregation and increasing integration, mainly but not exclusively driven by modulation of connections strength (local synaptic elimination persists in the adult; Petanjek et al. 2011). It is expected to have major consequences on the laying down of cultural imprints including the “epigenetic rules” associated with socialisation.

The acquisition of reading and writing may be viewed as a typical example of epigenetic development of “cultural circuits”. Writing and reading are recent cultural inventions (about 5000 years old) that evolved into distinct sub-systems and put considerable demands on our cognitive system. Historically, the first evidence for specialized writing and reading circuits in the brain was the discovery by the French neurologist Dejerine (1895) of pure alexia, also known as alexia without agraphia. Individuals with pure alexia suffer from severe reading problems while other language-related skills such as naming, oral repetition, auditory comprehension or writing are typically intact. Alexia results from cerebral lesions in circumscribed brain regions including the angular and supramarginal gyri. New specialized sets of connections are present exclusively in individuals that have learned written language and have been selected and consolidated in the course of development at sensitive periods (4–6 years) as a consequence of an intensive period of education.

The human brain did not evolve to learn to read, but possesses enough epigenetic variability in the course of its development (and also—though to a lesser extent—in the adult) to incorporate a cultural invention of this kind. During the acquisition of reading and writing by Western subjects, representations for visual forms of words progressively settle into the occipito-temporal cortex, recruiting a subset of functionally-appropriate object recognition regions in the temporo-parietal junction (Dehaene et al. 2010). The group of illiterate individuals is consistently more right-lateralized than their literate controls (Pettersson et al. 2007). Interestingly, alphabetic writing systems recruit circuits that differ in part from those mobilized by the Chinese ideographic systems. In French readers reading French, activations were enhanced in left-hemisphere visual area V1, with the strongest differences between French words and their controls found at the central and horizontal meridian representations. In contrast, Chinese readers reading Chinese showed enhanced activations in intermediate visual areas V3v/hV4, which was absent in French participants (Szwed et al. 2014). Also, the capacity to read sheet music is selectively altered in music-specific forms of alexia. Neuronal circuits specific to a given culture may thus become epigenetically established in the brains of social group members. Written language-learning is only one of the many cultural imprints acquired during the development of the human brain (Changeux 1985). For instance, cross-cultural differences between Asian and Western participants manifest themselves as differential increases of fMRI in the medial prefrontal cortex with reference to self-judgment (Zhu et al. 2007; Ray et al. 2010) and also to diverse brain recordings in mind reading (Kobayashi et al. 2007), holistic attention (Hedden et al. 2008), or facial photo recognition (Na & Kitayama 2011). The adult human brain thus builds up from a complex intertwining of cultural circuits progressively laid down during development within the framework of a human-specific genetic envelope.

There is no compelling evidence that culturally-acquired phenotypes will sooner or later

be genetically transmitted. What the evidence does show is that they have to be learned by each generation, by children from adults, and epigenetically transmitted from generation to generation, beginning in the mother's womb and up until the adulthood. Teaching reading and writing to circa five-year-old children requires elaborate pedagogic strategies, which in a general manner are absent in non-human primates (Premack 2007).

In short, cultural imprints have a physical reality in the human brain. Cultural imprints have also been demonstrated in non-human brains, e.g., by Peter Marler's work on birds' song-learning (Marler 1970). Yet the importance of cultural imprints on behaviour are comparatively much more important in humans compared to non-humans, in particular due to the long postnatal period of brain maturation. They play a critical role in shaping the brain phenotype in relation with the social group, through oral and written language but also through diverse culture-specific habits, traditions, and symbolic systems, including the ethical and social norms embodied in the adult brain.

I shall now proceed to discuss issues raised by the combinatorial explosion of brain representations and the channelling of behaviour through *epigenetic rules* and top-down control of decision-making.

epigenetic rules =_{Df} In neurobiological terms, these “rules” shall be viewed as acquired patterns of connections (scaffoldings), hypothetically stored in frontal cortex long-term memory. They frame the genesis of novel representations and regulate decision-making in a top-down manner.

4 “Epigenetic rules” and top-down control of decision-making

4.1 The hierarchical architecture of the brain

It has been suggested that ethical and social norms are, from a perspective in which the brain is central, ultimately encoded as spati-

otemporal patterns of neuronal activity that can be mobilized within the conscious neuronal workspace (Dehaene & Changeux 2011). Yet from a neurobiological standpoint, this view hinges upon the classical issue of the combinatorial explosion raised by the immense network of almost a million billion (10^{15}) interconnected synapses of the human brain. The question that arises, then, is how the particular patterns of neuronal activity, which, for instance, encode defined actions or perceptual events and ultimately ethical rules, are selected within this gigantic neural network. In my view, the concept of a hierarchical organisation of the brain needs to be taken into consideration more closely.

Analysis of the neurological deficits caused by lesions discloses hierarchical and parallel neural architectures that help us understand higher brain functions (Shallice & Cooper 2011). Among these is the inhibition of automatic (or reflex) actions and the elaboration of goal-directed behaviours and their control. In the brain, an evolutionary-recent territory of cerebral cortex architecture, the lateral prefrontal cortex, has been shown to play a critical role in the temporal control of behaviour. It serves as a “temporal buffer” between past events and future actions, allowing behaviours that follow internal goals to occur (Fuster 2001; Goldman-Rakic 1987; Petrides 2005). Moreover, the lateral prefrontal cortex exerts top-down control of cognitive processes associated with hierarchically-lower regions distributed in more posterior territories on the basis of internal plans, goals, or what may be referred to as “rules” (Miller & Cohen 2001; Passingham 1993; Shallice 1988; Dehaene & Changeux 1991; Koechlin et al. 2003). It thus contributes to decision-making within the actual context of a given individual history and stored memories (Damasio 1994) and to “neurally encoded rules” that can associate a context with a specific behavioural response and the ability to generalize a rule in novel circumstances.

An early formal model of learning by selection according to a rule was devised in the Wisconsin Card Sorting Task, which is commonly used as a test of the integrity of frontal lobe functions (Dehaene & Changeux 1991). It

requires subjects to infer a “rule” according to which a deck of cards must be sorted, i.e., colour, shape, or number. Feedback from the experimenter takes the form of a simple positive or negative reward (correct or incorrect). The goal for the subject is to get as many “right” responses as possible. Initially, cards must be sorted according to, say, colour. When performance is successful, the “sorting rule” is changed, for example from colour to shape; the subject must notice the change and find the new rule. The global architecture of a network that passes the task comprises two distinct levels of organization: a low level (level 1) that governs the orientation of the organism toward an object with a defined feature and which would correspond to a visuo-motor loop, including visual areas and the premotor cortex; and a high level (level 2) that controls the behavioural task according to a memory rule, and which would be homologous to the prefrontal cortex or closely-related areas (Dehaene et al. 1987; Dehaene & Changeux 1989).

A key feature of the model is that the high level contains a particular category or cluster of neurons, referred to as “rule-coding clusters”, each of which codes a single dimension (e.g., number, colour, or shape). During the acquisition step, the layer of rule-coding neurons is assumed to play the role of a “generator of diversity”. The spontaneous activity then plays a critical role in the activation of a given rule-coding cluster; and because of lateral inhibition only one cluster is active at a time. A search by trial and error takes place, until a positive reward is received from the environment (here the experimenter). Then, the particular cluster active at this precise moment is selected (for discussion see Monchi et al. 2001; Asplund et al. 2010; Fuster 2008). The number of trials necessary to learn the current rule is small (1–2), and single trial learning may occur in normal subjects as it does with the model (Dehaene & Changeux 1991). This learning of short-term rules based upon the fast (millisecond to second) allosteric transitions of synaptic receptors may also be transferred to long-term stores as epigenetically-acquired patterns of connections (see above).

In the course of the modelling of the Wisconsin card-sorting task, an additional architecture was introduced in the form of an auto-evaluation loop, which can short-circuit the reward input from the exterior. It allows for an internal evaluation of covert motor intentions without actualizing them as behaviours, but instead by testing them by comparison with memorized former experiences (Dehaene & Changeux 1991).

In these early formulations, the “rule-coding clusters” were pre-wired in the neuronal network. Subsequent models, however, opened the range of possible epigenetic rules to a brain-wide space of combinations made available within the global neuronal workspace (Baars 1988). This is of importance when we consider the ability to coordinate thoughts or actions in relation to internal goals, which is referred to as “cognitive control” and is a rather infrequent phenomenon. This discussion thus illustrates how rules encoding ethical norms may originate from the brain. Against this background—which shows how ethical rules might be epigenetically built from brain organization—I propose the possibility of being epigenetically proactive, and adapting our social structures, in both the short- and long-term, to benefit, influence, and constructively interact with the ever-developing neuronal architecture of our brains.

4.2 A cascade model of top-down cognitive control

Cognitive control has been further investigated by Koechlin et al. (2003) using a set of more complex tasks than the Wisconsin Card Sorting Task, and which span (at least three) nested levels of complexity. They consist in the presentation of series of coloured visual stimuli (squares or letters) organized into blocks, with an increasing importance of contextual signals: from “sensory control” with little if any contextual signal, to “contextual control” and, at the higher level, to “episodic control”. Brain imaging fMRI recordings with healthy human subjects revealed that the lateral prefrontal cortex contributes to a hierarchical cascade of executive processes that involve at least three nested

levels of processing. These are neurally implemented in distinct regions, from posterior premotor to rostral lateral prefrontal cortex regions (typically Brodman’s area 46; Koechlin et al. 2003; Badre & D’Esposito 2007; Badre et al. 2009). Patients with focal lateral prefrontal cortex lesions performed cognitive tasks with sensory, contextual, and episodic deficits associated with focal damage to Brodman’s areas 6, 45, and 46, respectively—as is expected from the cascade model (Azuar et al. 2014; Kayser & D’Esposito 2013).

By analogy with the Wisconsin Card Sorting Task (WCST) model mentioned above, behavioural rules are also sorted, but at different nested levels of information processing, the highest level rules “controlling” in a top-down manner the underlying rules closer to the senses. Hypothetically, ethical norms may be viewed as some particular kind of “control rules” developed within a social context, though this possibility still deserves to be explored by Koechlin, D’Esposito and colleagues.

Recently Collins & Koechlin (2012) have further suggested a computational model of human executive functioning associated with the prefrontal cortex, which integrates multiple processes during decision-making, such as expectedness of uncertainty, task switching, and reinforcement learning. The model reveals that the human frontal function may monitor up to three or four concurrent behavioural strategies and infers online their ability to predict action outcomes: whenever one appears more reliable than unreliable, this strategy is chosen to guide the selection and learning of actions that maximize rewards (see also Miller & Cohen 2001; Passingham 1993; Shallice 1988; Fuster 2008; Dehaene & Changeux 2011).

In their original paper, Collins and Koechlin do not explicitly mention social interaction. Yet we may consider an extension of their model to the social context by assuming that ethical or social norms are part of the “concurrent behavioural strategies” that they postulate exist in decision-making. The selection and learning of actions would then be more elaborate than the simple maximization of immediate rewards.

The developing baby is exposed very early on to a defined social and cultural environment, possibly even pre-natally (Lagercrantz & Changeux 2009; Lagercrantz et al. 2010). At this stage of development an intense synaptogenesis steadily occurs in the cerebral cortex, and epigenetic selection of neuronal networks accompanies the acquisition of the “maternal” language as well as of the common rules of the social community to which the child’s family belongs. The developing baby/child is “impregnated” with the current ethical rules of the social community, and this is often linked with the symbolic (philosophical/religious) system of representation character of the community to which it belongs. These early traces may last for the lifetime of the individual and sooner or later create conflicting relationships with a fast-evolving environment aggravated by the increased longevity of the individual (Changeux 1985). On the basis of the neurobiological data mentioned above, one may define these rules as epigenetically-acquired patterns of connections (scaffoldings) stored in frontal cortex long-term memory, which frame the genesis of novel representation and “cognitively controlled” decision-making in a top-down manner.

Against this background I propose the possibility of being epigenetically proactive and adapting our social structures, in both the short- and the long-term, to benefit, influence, and constructively interact with the ever-developing neuronal architecture of our brains.

5 A naturalistic responsibility

5.1 Proactive epigenesis

The first sentence in the 1948 Universal Declaration of Human Rights states: “All human beings are born free and equal in dignity and rights.”

Read as a description of the actual situation of human beings, this is blatantly and tragically false. Read as a normative ideal that we should strive for, it is noble but tragically unrealistic: considering our present cerebral structure, we are not likely to acknowledge in actual social practice the equal dignity and rights of all

individuals independently of race, gender, creed, etc. Life conditions may have improved for many humans over time, yet the present global situation remains appalling, notably, with respect to poverty, unequal distribution of health care, and the predominantly non-egalitarian or bellicose relations between individuals or groups. The vast majority of human beings appear reluctant, unable to identify with, or show compassion towards those who are beyond (and sometimes even towards those who are within) *their* sphere. While some societies or individuals may be more prone than others to developing a strong ethnic identity, violence, racism, sexism, social hierarchies, or exclusion, all exhibit some form and measure of xenophobia.

What I have here suggested, however, is that we might make presently unrealistic ideals, such as equality in dignity and rights, somewhat more realistic by selecting them for epigenetic proactivity.

Synaptic epigenetic theories of cultural and social imprinting on our brain architecture open the door to being epigenetically proactive, which means that we may culturally influence our brain organisation with the aim of self-improvement, individually as well as socially, and change our biological predispositions through a better fit of our brain to cultures and social structures.

I suggest that certain areas of research are especially important to pursue with the goal of “epigenetic proaction” in mind. They aim at integrating recent advances in neuroscientific research into normative debates at the level of society. This does not necessarily mean that my level of explanation is “neurocentric” or “neuroreductionist”. My aim is more “encyclopedic” in the sense that I wish to illustrate the benefits that neuroscience can bring to the humanities and social sciences and conversely. I do not see myself as either neuro-“centric” or “reductionist”—which would mean an exclusion of other categories of determinants at the social or historical levels—but I am more modestly willing to unify knowledge between the humanities and the neurosciences, which are too often deliberately omitted from the debate. This can be illustrated by two examples: violence in adoles-

cents in relation to their social environments, and violence in adults associated with interconfessional conflicts.

Violence in adolescents is a common phenomenon in our societies and it is frequently repressed through police and judiciary means, often resulting in incarceration. But this approach to juvenile violence simply omits the scientifically-established fact that adolescence is also a time of “neurodevelopmental crisis”. Evidence from anatomical and functional-imaging studies has highlighted major modifications of cortical circuits during adolescence. These include reductions of gyrification and grey matter, increases in the myelination of cortico-cortical connections, and changes in the architecture of large-scale cortical networks—including precentral, temporal, and frontal areas. (Klein et al. 2014). Uhlhaas et al. (2009) have used MEG synchrony as an indicator of conscious access and cognitive performance (rev. Dehaene & Changeux 2011). Until early adolescence, developmental improvements in cognitive performance are accompanied by increases in neural MEG synchrony. This developmental phase is followed by an unexpected decrease in neural synchrony that occurs during late adolescence and is associated with reduced performance. After this period of destabilization follows a reorganization of synchronization patterns that is accompanied by pronounced increases in gamma-band power and in theta and beta phase synchrony (Uhlhaas et al. 2009). These remarkable changes in neural connectivity and performance in the adolescent are only just being explored and may lead to special unexpected proactive care from society. In turn, this requires active research, including a social educative environment adequate to adolescents’ special needs. This may include adequate physical exercise, cultural games, educational training, and new kinds of therapies yet to be invented.
