Violent interconfessional conflicts have raged throughout human history. They continue to plague our modern societies and are presently an important cause of wars and other forms of violence throughout the world. One should remember that every newborn and child brain incorporates critical features of its biolo-

gical, social, and cultural environment including, in addition to spoken and written language, symbolic systems and religious rituals (which include dietary and vestimentary practices as markers of the faith). These epigenetic traces are almost irreversibly laid down and may persist throughout the whole life of the individual. Yet they might be renewed through epigenetic transmission from adults to newborns. In this context, early proactive epigenetic imprinting through education is of critical importance. The aim of that education should not be to abolish faith or emotional convictions (e.g., moral, political, or religious) but only to control the fervour, intolerance, and fanaticism in their expression. The problem, as I see it, is not a belief itself, but the emotional intensity to which it gives rise and the manner in which it is expressed. Influencing a child brain to reduce its propensity to ideological violence or fanaticism and enhance its tolerance to others’ differences also requires special proactive care from society that per force involves active research—including a social educative environment adequate to this particular goal.

These are only two illustrations of the many that are possible, chosen because they have been problematic throughout the history of humankind and show no signs of disappearing.

At the individual level, the social conditions of an infant, or an adolescent, are of crucial importance in their cerebral development, and adequate conditions can in principle be provided. The factual realism of this application is largely a matter of political will and social agreement. The scientific challenge will be to further develop the knowledge of these conditions and their effects on the developing infant and adolescent brain. Also, the challenge will be to develop our knowledge of how social conditions affect the adult brain, e.g., to prevent neurodegeneration.

On a more general level, when applied on a larger scale to a society, a population, or to the entire human species, the argument follows the same logic and is no less important—but it becomes considerably more complicated to apply, theoretically as well as practically.

If new cultural imprints were epigenetically stored in our brains (say, less violent or less sectarian features), future generations would presumably develop societies that reflect them (i.e., become more peaceful and inclusive). A weakness of this optimistic reasoning is its circularity, since we would already need to be peaceful in order for a peaceful society to be maintained. A crucial question then becomes: how long does it take for a cultural characteristic to leave a cerebral trace? In some measure stable and enduring cultural structures are needed in order to effect stable neurobiological changes and store cultural imprints in the brain that might give evolution a push in the right direction, but the chances of maintaining societies that conflict with the present nature of its inhabitants—say, maintaining a peaceful egalitarian rule in a society of violent xenophobes—are arguably slim.

The challenges involved in trying to be epigenetically proactive by culturally influencing the future actions of human genes and neuronal structures, with the aim of altering higher cognitive functions and their resulting behaviour seem formidable, at least if enlarged sympathy is on the agenda. Still, within the epigenetic neuroscientific framework, at least the theoretical possibility exists, and it is worthy of consideration by many other disciplines beyond neuroscience. Depending on how we choose to develop our culture, one day epigenetic rules that enlarge the presently-narrow realm of human sympathy might perhaps emerge.

5.2 Conclusion: A naturalistic responsibility

The origins of norms and the relationship between facts and values have been much debated in philosophy. Reasoning that weds scientific theory with normative considerations has been accused of committing the logical error of confusing facts and values, which is known as “the naturalistic fallacy”.

The expression “the naturalistic fallacy” was coined by the British moral philosopher G. E. Moore and refers in his work to the identification (or reduction) of goodness with (or to)

another property such as utility, pleasure, or happiness (Moore 1903). That issue is not relevant in the present context. In the interpretation of the naturalistic fallacy that is relevant here, the fallacy consists in deriving an “ought” from an “is”, or a value from a fact, and letting descriptive properties entail normative properties, which confuses the distinction between facts and values in a fallacious manner. This argument is reminiscent of David Hume’s claim that what *is* is entirely different from what *ought to be*, for “the distinction of vice and virtue is not founded on the relations of objects, nor is perceiv’d by reason” but is fundamentally a matter of feelings and as such is neither true nor false (Hume 1739, III, I). I agree that it is fallacious to derive “ought to be” from “is”, and consider this a conceptual mistake that our theory of epigenetic proaction must and indeed does avoid. I do not assert that factual descriptions of the brain’s architecture are tantamount to yielding recommendations or assertions of norms, do not confuse “is” with “ought”, and consequently do not commit the naturalistic fallacy in this formulation.

We should observe that a *value* may be represented on many levels: non-conscious as well as conscious, as a basic biological function or as a feature of advanced moral reasoning. When discussing the naturalistic fallacy, value as a feature of advanced normative reasoning is the relevant sense of the term. The logical distinction between fact and value could collapse if the term is defined differently—say, if it features as a non-normative biological function. The logical error in the naturalistic fallacy concerns the fact/value distinction as it is drawn between normative and descriptive statements, namely between *ought* and *is*; not between facts that are/are not biological values, where that concern would presumably not arise.

However, eagerness to avoid the naturalistic fallacy must not prevent our normative reasoning from being informed by scientific theories. Normative judgments should be informed by facts, even though they cannot be entailed by them. If certain evaluative tendencies are innate in the normal human brain’s architecture, such as self-interest and selective sympathy, this

fact (if it is one) about the human being's neuronal structure would admittedly entail that every healthy, sufficiently mature individual will to some degree feel both self-interest and sympathy towards some other creature. However, this is not the entailment of a norm, but an empirical entailment of another fact. It does not entail that it is good (or bad), or that we ought to conceive it as good (or bad) that we are thus construed. Similarly, if it is true that we are, for example, and as we have argued, self-projective xenophobes, knowledge of this (presumed) fact is not in itself a justification of it. Understanding is not the same as justification: to know, or to understand, is not to approve. On the contrary, knowledge about our neural structures' predispositions should increase our awareness of the need for stable and realistic social structures and agreements to keep us in check.

We should also observe that a belief in the approximate universality of certain values, or preferential tendencies as innate features of the human neurobiological make-up, is logically compatible with a belief in maintaining the description/norm distinction.

My primary focus has been on the important empirical connections between biological facts and norms. Norms are brain constructs elaborated by human societies, biologically as well as culturally embedded in and constrained by the contingent evolution of socio-cultural structures—in particular, by the multiple symbolic philosophical and religious systems that have developed. This fact, and the realisation that normative judgments should be informed by facts even though they cannot be entailed by them suggests that science, philosophy and—not least—neuroethics—have a major responsibility: namely to decipher the network of causal connections between the neurobiological, socio-cultural, and contingent historical perspectives that allow a moral norm to be enunciated at a given moment in human history; and to evaluate their “universal” character as pre-specified in our genome and shared by the human species in distinction from those relative to a given culture or symbolic system. The “fallacy” of the naturalistic approach is thus inverted into a naturalistic responsibility (Evers 2009): the re-

sponsibility to connect facts and values, biology, and socio-cultural structures, and to use that enriched understanding for the benefit of ourselves and our societies.

We may hope that through the rational exchange of arguments between partners with different cultures and moral traditions debating together, a species-specific “human core” could become dominant beyond individual differences and converge on a common structure (Changeux & Ricoeur 2000). At the same time, we must note that the diversity of human individuals and societies is enormous and must be respected while we strive to find this common ground that might allow coexistence.

The idea of proactively selecting those specific dispositions or capacities (such as sympathy) that we all share as human beings which that, if properly developed, may benefit our global co-existence while respecting individual and ideological diversities, is well in line with Darwin. Darwin wrote in *The Descent of Man*:

As man advances in civilization, and small tribes are united into larger communities, the simplest reason would tell each individual that he ought to extend his social instincts and sympathies to all members of the same nation, though personally unknown to him. This point being once reached, there is only an artificial barrier to prevent his sympathies extending to the men of all nations and races.

Lewontin (1993) argues that while traditional Darwinism has portrayed the organism as a passive recipient of environmental influences, a correct understanding should emphasize that humans are active constructors of their own environment—in particular the social and cultural environment. I agree and argue further that, in line with Darwin, we can be active constructors of our own brains through using our environment and culture, in a relationship that is reciprocal.

In this article, my main focus has been on feasibility—that is, on whether we *can* be epigenetically proactive. If we assume an affirmative answer to that question, an important fol-

low-up question arises: whether we *should* be so. My basic position, that I have here tried to express, is that epigenetic proaction could be a very promising, powerful, and long-term way of influencing human nature and of improving our societies. However, in order to pursue this in a responsible and adequate manner, caution is required, along with careful analyses of the relevant social and ethical issues. Science can be, and has throughout history repeatedly been, ideologically hijacked, and the resulting dangers increase with the strength of the science in question. If, say, humans learn to design their own brain more potently than we already do by selecting what we believe to be brain-nourishing food and pursuing neuronally-healthy life-styles, we *could* use that knowledge well—that is, there is certainly room for improvement. On the other hand, the dream of the perfect human being has a sordid past, providing ample cause for concern about such projects. Historic awareness is of the utmost importance for neuroethics when assessing suggested applications in a responsible and adequate manner. Moreover, what we mean by “responsible and adequate” is open to interpretation. The traits we choose to favour epigenetically, and the social structures we choose to develop, depend on who “we” are, and in what society we wish to live.

Arthur Koestler compares evolution to “a labyrinth of blind alleys” and suggests that “there is nothing very strange or improbable in the assumption that man’s native equipment, though superior to that of any other living species, nevertheless contains some built-in error or deficiency which predisposes him to self-destruction” (Koestler 1967, xi). In that light, steering evolution by influencing the cultural imprints to be stored in our brains appears to be an attractive option.

Acknowledgements

I wish to thank Jean-Pierre Changeux for his important scientific contributions to this paper, and for his detailed scrutiny of the arguments expressed. I also wish to thank Yadin Dudai, Sten Grillner, Hugo Lagercrantz, and Arleen Salles for their valuable comments on earlier

versions of this manuscript. The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 604102 (HBP).

Should we be Epigenetically Proactive?

A Commentary on Kathinka Evers

Stephan Schleim

“Can we be epigenetically proactive?”, is the question asked by Evers in her paper in this collection. After describing an original approach to using insights from the epigenesis of neural networks to develop new training and treatment programs, in particular to educate children and adolescents to become less violent and more sympathetic, the author suggests that there is a naturalistic responsibility for using science in this manner. In this commentary, I relate her proposal to the human enhancement debate at large, with a focus on the prevalent concept of human wellbeing. After a discussion of the factors that account for people’s quality of life and the role of research that allows them to decide the priorities for a good life themselves, three caveats against Evers’s approach are presented: (1) that epigenetic intervention carries the risk of psychological side-effects; (2) that people’s autonomy must be respected; and (3) that the world’s situation may not be as bad as suggested by the author when describing the benefits of her proposal. It is therefore concluded that, at least for the time being and until these challenges are met, we should not be epigenetically proactive.

1 Introduction

[Kathinka Evers](#) [this collection](#) discusses the possibility of changing people epigenetically. In particular, she discusses the option of increasing sympathy and decreasing xenophobia and violence. The term “*epigenetics*” is often used to describe processes affecting the activity of genes such as DNA methylation, which might enable the inheritance of acquired properties ([Bird 2007](#)). In contrast to this meaning, Evers uses the term more narrowly, with reference to the epigenesis of neural networks by selective stabilisation of synapses as an essential mechanism of

brain development ([Changeux & Danchin 1976](#)). The idea of affecting people’s development—or *ontogenesis*—through this mechanism, in order to achieve a desired state (e.g., an increase in sympathy) and/or to avoid an undesired state (e.g., a decrease in xenophobia or violence) can then be called *epigenetic proactivism*.

After describing human beings as social individualists and egocentric evaluators predisposed for selective sympathy and xenophobia, Evers explains neuronal epigenesis in detail. By influencing synaptic selection, this process may

critically affect social and cultural evolution. The central brain area for this is, according to the author, the prefrontal cortex, which is involved in planning, decision-making, thought, and socialisation; in particular, lateral prefrontal areas are associated with behaviour control. With respect to a task developed to test prefrontal cortex functioning, namely the Wisconsin Card Sorting Task (Dehaene & Changeux 1991), Evers discusses how neuronal epigenesis could explain rule-learning and top-down control. Finally, she devises two examples—adolescent violence in relation to their social environments and violence in adults associated with interconfessional conflicts—to illustrate what epigenetic proactivism may mean in practice. She eventually invokes a *naturalistic responsibility* to use the respective scientific and philosophical knowledge for the benefit of ourselves and our societies.

In this commentary, I will start out by relating Evers's proposal to the *human enhancement* debate, which has received much attention recently—in particular within neuroethics. After summarising the general assumptions and caveats of this debate, I will elaborate on the definition of people's wellbeing prevalent in the discourse on human enhancement and present an alternative based on social science research.

Finally, I will discuss epigenetic proactivism, Evers's original proposal for changing people, in more detail. Arguing that the actual means—whether neurobiological, psychological, or social—do not matter very much, while issues related to adaptation, autonomy, and instrumentalisation are of essential ethical and philosophical relevance, I will emphasise the role of an individual's *informed decision*. I will discuss in particular the three theses that (1) their proposed epigenetic intervention carries the risk of psychological side-effects; (2) that people's autonomy must be respected; and (3) that the world's situation may not be as bad as suggested by the authors when describing the benefits of their proposal. My conclusion will therefore be that the ethical justifiability of epigenetic proactivism critically depends on whether people can freely choose themselves whether or not to become epigenetically proactive, in a

situation sufficiently free from social coercion and in sufficient awareness of the likely outcomes—effects as well as side-effects—of that intervention.

2 The human enhancement debate

In a paper on the “biopolitics” of cognitive enhancement, Peter Reiner recently referred to Plato's *Phaedros*, where Socrates discusses what we nowadays might call the psychological side-effects of writing, namely the risk that our memory skills will deteriorate when we rely more on written texts (2013). Interestingly, Socrates's concerns—voiced some 2400 years ago—seem to be confirmed by recent experiments indicating that people are less likely to remember information when they expect it to be easily accessible with the aid of computers (Sparrow et al. 2011). It goes without saying that everything we do has some psychological or neural impact, whether transient or permanent. However, writing—and, more recently, digital information processing—can be seen as an enhancement technology, as it enables asynchronous and distant communication with contemporaries as well as saving thoughts and ideas for the future.

We should keep in mind, though, that the very notion of *cognitive enhancement* was introduced only recently into the scholarly debate and its increasing prevalence coincided with the institutionalisation of neuroethics in the early 2000s (Figure 1). In the meantime, some authors criticised the exaggerated promises of the debate, pointing out misperceptions in the assessment of pharmacological enhancement behaviour, the complexity of the brain's neurotransmitter systems, and the insufficient success of the much larger bio-psychiatric paradigm of improving psychological functioning in those looking for treatment (Lucke et al. 2011; Quednow 2010; Schleim 2014a). The latter means that even when the aims of the intervention are clearly circumscribed—e.g., decreasing the severity of the symptoms characteristic of a disorder—and research funds are abundant, bio-psychiatric research has unfortunately not been as successful as expected. This may relativise the hopes for effective bio-

psychological enhancement in the healthy in the near future.

Figure 1: Publications on enhancement. Publication data from the ISI Web of Science show a steep increase in publications covering “cognitive enhancement” (blue) that coincides with the institutionalisation of neuroethics (Farah 2012). “Mood” or “affective enhancement” (orange) and “neuroenhancement” (yellow) are addressed much less frequently, although these topics also are increasingly discussed. (ISI Web of Science Topic Search)

While describing writing as a means of cognitive enhancement may seem plausible at first glance, it also carries the risk of neglecting several distinctions that may be ethically and socially important. Such distinctions are, for example, those between learning the use of an instrument to achieve a certain aim and oneself becoming an instrument for the aims of others; between using an external device and directly interfering in the body; and between defining ends autonomously and being adapted to another’s ends heteronomously. Distinctions in actual cases will not always be clear and often fall into a grey zone, but this does not mean that possible interventions cannot be discussed against these concepts. These may be understood as marking the ends of a spectrum: for example, from full autonomy to full heteronomy. Indeed, while some scholars frame the consumption of stimulus drugs such as amphetamine, methylphenidate, or modafinil by students as individual choices for better cognitive functioning (Greely et al. 2008), that is, in an autonomous fashion, several results suggest that stu-

dents might rather respond to the demands of a competitive academic environment, and thus heteronomously. I will argue later that this opposition between freedom and coercion is the crucible of ethically assessing epigenetic proactivism.

There is already empirical evidence from representative surveys or interviews with students that emphasises the relevance of this distinction. For example, M. Elizabeth Smith & Martha Farah describe in their extensive review on “smart pills” that the largest nationwide study identified admissions criteria (competitiveness) as well as two other social factors as the strongest predictors of stimulant drug consumption (2011). Interviews with non-medical consumers of stimulant drugs at an “elite” college carried out by Scott Vrecko suggest that people use stimulants for emotional and motivational ends rather than for cognitive enhancement, in particular to increase motivation to begin with or to complete boring tasks (2013). Finally, reviewing forty studies on public attitudes toward pharmacological cognitive enhancement, Kimberly J. Schelle and colleagues found that coercion to use drugs is a consistently mentioned concern (Schelle et al. 2014). This evidence associates the availability of enhancements like stimulant drugs with the pressure to adapt people to given standards of performance. Yet in the scientific literature the notion of cognitive enhancement is much more prevalent than the emotional and motivational aspects frequently mentioned in practical contexts (Figure 1).

Scientists and policy-makers in the UK *Foresight Project on Mental Capital and Well-being* note that globalisation increases demands for competitiveness as well as the pressures in our working lives (Beddington et al. 2008; Foresight Project 2008). They conclude that in a rapidly changing world like ours, we must make the most of all our resources in order to keep up with competitors; whole countries have to capitalise on their citizens’ cognitive resources. To achieve this aim, John Beddington and colleagues see vast possibilities in improving a country’s “mental capital” for all members of the population. They identify the possibility to do so at each stage in life, such as the early

identification and treatment of people with learning difficulties or the governmental support of those who want to work longer—though, notably, not shorter. A failure to react in a timely way to the challenges would come at a high cost for society, while early intervention in education could improve productivity at work and avoid costs related to a loss of mental capital (Beddington et al. 2008).

This view on performance enhancement for individual and social welfare reflects the focus of influential papers in neuroethics, emphasising the potential improvement of attention, memory, or wakefulness through the consumption of stimulant drugs or other pharmacological substances and neuroscientific technologies affecting the nervous system (Farah et al. 2004; Greely et al. 2008). Assumptions regarding the possible benefits of such substances are frequently based on trials employing test designs from *clinical psychology*, developed to identify and trace impairment in psycho-behavioural functioning, whether the investigated sample consists of patient populations, healthy people, or both (Bagot & Kaminer 2014; Repantis et al. 2010; Smith & Farah 2011).

Even if such test designs are of high clinical value, it is much less clear what statistically significant, yet often subtle, improvements in such experimental tasks, for example, in planning or memory games, mean for the *living environment* of the healthy. Whether such improvements indeed translate into an increase in individual wellbeing or the mental capital of a nation has yet to be shown. Indeed it is not even clear what a reliable and ecologically valid way of answering this question would look like. While this is still quite challenging after much debate on pharmacological enhancement, it is presently even less clear what such a standard could look like for epigenetic proactivism. In addition to measuring the benefits, neuroscientists frequently address the possibility of a psycho-behavioural trade-off—that is, the risk that an improvement in one domain would come at a loss in others (Brem et al. 2014; Hills & Hertwig 2011; Quednow 2010; Wood 2014). Given these complexities in the empirical research on

enhancement, it will be helpful to introduce an explicit definition for further discussion.

Human Enhancement =_{Df} A change in the biology or psychology of a person which increases the chances of leading a good life in the relevant set of circumstances.

Notice how this definition, proposed by Julian Savulescu and colleagues in the introduction to a recent edited volume on human enhancement (Savulescu et al. 2011), relates the good life of an individual—its biology or psychology—to the context in which that individual lives: human enhancement is something done to or with a particular person in a fixed set of circumstances, namely, a change in her or his biology or psychology. This choice already predisposes the debate and research on enhancement with respect to adapting an individual to her or his environment.

To provide an illustrative and provocative counterexample: under this definition the “treatment” of a homosexual suffering from social exclusion by instigating heterosexual acts and relations, as was routinely performed by clinical psychologists and psychiatrists until the 1970s (Barlow 1973; Hinrichsen & Katahn 1975), would qualify as a form of human enhancement—inasmuch as it succeeds in “helping” the subject to avoid the undesired sexual behaviour that instigates social exclusion and the suffering probably caused by it. With respect to this historical example we already know that leading psychiatrists later acknowledged that there was nothing inherently wrong with homosexuals, but that their suffering indeed originated from social exclusion; this reasoning eventually led to the decision not to consider homosexuality a mental disorder any longer (Friedman et al. 1976). It is instructive to contrast the definition proposed by Savulescu and colleagues with the following inverted alternative.

Human Enhancement-Inverted =_{Df} A change in the relevant set of circumstances that increases the chances of a person to lead a good life according to her or his preferences.

This alternative is not meant to be a logical inversion, but instead switches the levels of intervention, of that which is malleable and that which is considered as given. In an experimental fashion, one could also say that it is about a switch of dependent and independent variables, from the individual to its life context. Yet the aim of the intervention remains unchanged: increasing the chances of leading a good life. It goes without saying that both definitions, when put into practice, are constrained by available means and ethical principles, for example also requiring that we take the likelihood of other people's chances of leading a good life into account. It is not necessary here to argue that the inverted definition is better than the original; my intention is merely to show that we need not focus on bio-psychological changes alone. Instead, we can target the *social context* as well, decreasing the risk of adapting people to a social standard. Please note that this in itself does not imply a normative judgment, but rather widens the perspective for further analysis by taking alternative levels of intervention into consideration. As mentioned before, the balance between freedom and coercion, and autonomy and heteronomy will be essential with respect to epigenetic proactivism.

Here I have described some basic assumptions and criticism of the neuroethics debate on human enhancement, including the association of wellbeing with standards developed in clinical contexts that focus on individuals rather than on their social contexts. In the next section I will introduce research aimed at describing and understanding what people themselves consider to be quality of life, which poses an alternative to the standard adapted from clinical psychology.

3 Who defines wellbeing?

The position paper on cognitive enhancement by Henry Greely and colleagues starts out with the claim that “[s]ociety must respond to the growing demand for cognitive enhancement” (Greely et al. 2008, p. 702). The article by Beddington and colleagues on the mental wealth of nations begins with the conclusion that “[t]o

prosper and flourish in a rapidly changing world, we must make the most of all our resources—both mental and material” (Beddington et al. 2008, p. 1057). Both statements are similar in that they frame recent developments in such a way that they necessitate a reaction: we “must” respond in a particular manner. Greely and colleagues call for a “responsible use of cognitive-enhancing drugs by the healthy” (Greely et al. 2008, p. 702), though the majority of readers responding to their paper understood them as exaggerating the benefits of drug use generally or as being financially influenced by drug companies (Greely 2010). Beddington and colleagues call for the maximisation of our resources. All these authors want to increase benefits and decrease harms. However, who defines what counts as a benefit, as wellbeing, or as a good life? This is an essential and fundamental question that will influence every benefit-risk-analysis on human enhancement (Nagel 2014; Schleim 2014b).

As mentioned in the previous section, several scholars discuss the potential of means for enhancement, particularly psychopharmacological drugs, with respect to studies employing clinical test designs—whether investigating healthy people, those with a mental disorder, or even animals. Such tests measure reaction times or error rates in tasks requiring, for example, attention, memory, or planning. That is, the experimental setting frequently originates from a pragmatic context guided by identifying, treating, and/or predicting the development of a certain mental disorder. The underlying *mental disorder concept*, which is in itself controversial and subject to recurrent modifications, essentially hinges on a subject's clinically significant distress or functional impairment in the domain of cognition, emotion, and behaviour (American Psychiatric Association 2013; Stein et al. 2010). However, benefit, wellbeing, or a good life as discussed in the debate on human enhancement at large are not merely the opposites of clinically significant impairment; a five percent increase, say, in a task where a subject has to memorize as many digits as possible, and that may identify memory problems, does not reflect an increased performance in a real test, not

even a maths exam at school or university. Much less is it a suitable indicator of a benefit for the quality of life, although such a finding may be sufficient for publication in a peer-reviewed pharmacological journal.

However, there are advanced, direct, and representative measures of the quality of life. One example is the United Nations *World Happiness Report*, which compares the situation in 156 countries. The variables GDP per capita, social support, healthy life expectancy at birth, freedom to make life choices, generosity, and perceptions of corruption together explain 75.5% of the international variance of world happiness in 2012 (Helliwell et al. 2013). A more recent development is based on the OECD *Guidelines on Measuring Subjective Well-being* (OECD 2013). These allow people to create their own *Better Life Index*, prioritising eleven pre-defined domains such as education, jobs, housing, or safety.

More than 60,000 citizens from OECD countries have so far submitted their preferences, yielding important regional differences.¹ For example, people from the USA valued housing (on average 7.8 on a scale up to 10 points) and income (10.0) the highest, but work-life balance comparatively low (5.3). By contrast, people from Denmark, which is number one in the World Happiness Report, prioritised work-life balance higher than all others (9.8), and also valued life satisfaction (9.4) and community (10.0) very highly, while considering income less important (4.0). One may raise the question, of course, whether such statements are biased by social stereotypes or social desirability, but what could be a better measure of what people find important for leading a happy life than asking them directly? This is particularly so when they participate in the survey entirely on their own account.

These results emphasise two essential points for the human enhancement debate: first, people differ individually as well as regionally on what they find important for their wellbeing. Second, many of these aspects are not directly based on bio-psychological factors, but on social

factors. Indeed, the OECD construct of subjective wellbeing focuses on income, health status, social contact, employment status, personality type, and culture as determinants of life satisfaction, affect, and eudaimonic wellbeing. Unlike clinical measures of psycho-behavioural performance, they do not primarily rely on functional impairment.

Most importantly, the Better Life Index allows people to indicate themselves what they find important for their subjective wellbeing; and it turns out that many of these aspects, like housing or safety, are actual social factors that can only very indirectly be targeted by bio-psychological intervention. Therefore it becomes clear that a biased or narrowed concept of human enhancement carries the risk of missing the point of what determines or enables a better life. Further systematic analysis beyond the scope of this paper is required to show whether the factors identified are more amenable to individual psychobiological intervention, such as targeted by Savulescu and colleagues (Savulescu et al. 2011), or socio-political initiatives. Yet, while Greely and colleagues or Beddington and colleagues merely assume that increased cognitive performance will increase people's quality of life (Beddington et al. 2008; Greely et al. 2008), an initiative like the OECD Better Life Index allows people to autonomously express their own views on the issue and thus provides robust empirical evidence. This strategy helps to avoid two normative fallacies: first, that a parentalistic decision is possible when it comes to what should be good for others and, second, the idea that just because some intervention leads to a higher test score it is therefore good.

This section has highlighted, again, the tension between individual freedom and social adaptation, between autonomy and heteronomy. While most scholars would emphasise that people should be free to choose for themselves, fundamental definitions as well as the framing of human enhancement can implicitly narrow freedom, for example by introducing a limited standard for quality of life or by constraining the target for intervention. That is, when people apparently have free choice, because they are asked to choose from a number of alternatives

¹ <http://www.oecdbetterlifeindex.org>
accessed July 18, 2014

that choice may actually be quite limited, because the offered options neglect important alternatives.

As described in the previous section, people are well aware of the threat of coercion when discussing the prospects of enhancement. Coercion does not only exist at gunpoint, when acting under duress in a strong legal sense, but it can also come in a much less direct manner: For example, by telling people that they *must* choose from a limited set of options, because otherwise something bad is going to happen. Referring to what, putatively, many people are already doing or what globalisation requires increases the pressure on individuals. There are meaningful and evidence-based alternative views on human enhancement, beyond those focusing on functional impairment, as shown in this section. In the next section, I will focus on the epigenetic proactivism proposed by Kathinka Evers in more detail.

4 Epigenetic proactivism

Evers starts out their description of the naturalistic responsibility to become epigenetically proactive with a reference to the *Universal Declaration of Human Rights*. She criticises that, understood as a description of the present world, it is false to assume that all humans are born free and equal in dignity and rights; and if we understood this as a normative ideal, it would be unrealistic to guarantee these rights for every human being, given our present cerebral structure. In contrast to the human rights ideal, many people suffer from poverty and insufficient health care, and live through serious conflicts. Most people lack the sympathy necessary to respect the rights of others and all humans exhibit some kind of xenophobia. In the end, Evers even refers to the idea that humans might be subject to some built-in error or deficiency, predisposing us to self-destruction. Against this background, she proposes her epigenetic proactivism as follows:

Synaptic epigenetic theories of cultural and social imprinting on our brain architecture open the door to being epigenetically proactive, which means that we may culturally influence our brain organisation

in the aim of self-improvement, individually as well as socially and change our biological predispositions by a better fit of our brain to cultures and social structures. (Evers [this collection](#), p. 12)

She discusses two examples in more detail, namely violence in adolescents and violent interconfessional conflicts. Referring to neurodevelopmental research on children and teenagers' brains, she suggests that different educational measures such as physical exercises, cultural games, and new therapies amount to a kind of proactive epigenetic imprinting that increases control of aggression, emotion regulation, sympathy, and tolerance. It would be largely a matter of political will and social agreement, Evers claims, to develop the research enabling such educational programs and to apply them in practice. If successful, epigenetic proactivism would make societies more peaceful and inclusive, but the author also points to a problematic circularity, namely that we perhaps first need to live in an already peaceful society in order to enact such educational programs to maintain peace.

If we had to choose between epigenetic proactivism and the destruction of humankind, the decision would probably be easy; and the humbler prospect of avoiding adolescent violence and interconfessional conflicts also has some seductive allure. However, for three reasons I hesitate to agree with the conclusion that we have a naturalistic responsibility to improve ourselves epigenetically, assuming that science will develop enough at some point and offer the novel educational measures suggested by Evers: first, decreasing the disposition towards aggressive behaviour and increasing sympathy might have unexpected psychological side-effects; second, the value of human autonomy has to be considered by epigenetic proactivists, too; and third, the human condition might not be as bad as the author describes. I will discuss these three caveats in the following sections.

4.1 Side-effects of epigenetic proactivism

At first glance, who would disagree that a world with less aggression and more sympathy would

be a better world? If we could indeed decrease adolescent and interconfessional violence, why shouldn't we put such an educational program into action? Evers refers to Darwin and evolution several times in her paper. Consequently, this biological framing also raises the question of the possible evolutionary value of aggression and violence (Eibleibesfeldt 1977; Smith & Harper 1988). Darwin's original idea of the survival of the fittest emphasises the very notion of securing access to scarce resources—often at the cost of other living beings, which may even lead to the extinction of a whole species. It may well be that aggression is an essential driver of evolutionary development.

It goes without saying that from the fact that something leads to an increased survival value it does not follow that it is morally good. But it is clear that, even from a social perspective, aggression might have a function, or might be necessary for achieving some desirable ends. In the famous novel *A Clockwork Orange* by Anthony Burgess, we learn about a fictional case where a cruel and ruthless juvenile delinquent—Alex—is successfully treated bio-psychologically to stop being violent. This is carried out in a pharmacologically enhanced operant conditioning program that associates scenes of violence with aversive stimuli, such that the former delinquent feels severe nausea whenever he is confronted with aggression, including assaults against himself. This has the side effect that after the treatment Alex cannot defend himself anymore and he therefore becomes a victim of severe humiliation.

While this example is different from the case of interconfessional violence discussed by Evers, it is directly related to her other example of violence in adolescents. It is a complex bio-psychological question whether negative facets of aggression can be extinguished without also affecting people's capacity for self-defence. The author is aware of the problem of circularity, that a world may first have to become peaceful for epigenetic proactivism to be successful—and the present caveat emphasises this dilemma: if only some people were educated to avoid violence and conflicts, this could easily be abused by others.

How about increasing sympathy, then? Evers is critical about the fact that people are xenophobic and restrict their sympathy to small groups, while they should ideally extend it to human society at large. As disappointing as it may be from an ethical point of view, it could well be that a distinction between one's own or one's group's welfare from that of others is essential for psychological wellbeing. A dysfunctional self-other distinction, drawing a clear line between oneself and others, may play a role in schizophrenia (Decety & Sommerville 2003; Jardri et al. 2011). Furthermore, several investigations reported an association between emotional empathy and depression or decreased life-satisfaction (Gawronski & Privette 1997; Lee et al. 2001; O'Connor et al. 2002).

These links with mental health may be speculative to some extent, yet they illustrate that even a *prima facie* positive capacity may become negative when increased too much. Accordingly, it has become common wisdom within psychopharmacology that there is an optimal level of neurotransmitter concentration in the brain and that both a decrease and an increase may be dysfunctional and/or lead to unexpected side-effects (Wood et al. 2014). Even if ethicists, in line with Evers, presented strong arguments in favour of considering the welfare of those far away from oneself or one's group (Greene 2003; Sidgwick 1907; Singer 2002; Unger 1996), it should be born in mind that an increase of sympathy might lead to a decrease in subjective wellbeing.

4.2 Human autonomy

The vision of a scientifically enhanced world, where people are better at controlling their emotions, particularly aggression and other impulses that might lead to violent behaviour, is a recurrent topic in the history of science. For example, in the 1960s and 1970s, neuroscientists, psychologists, and sociologists all discussed the problem of delinquency and aggression, also with respect to adolescents, and proposed different solutions for coping with it. The pioneer of *brain stimulation*, José Delgado, tested the effects of electrical inhibition or excitation of dif-

ferent brain areas associated with emotion processing, such as the amygdalae, in several animal species as well as in humans (Delgado 1965, 1971; Delgado et al. 1968). His discussion of the social implications of such technology is surprisingly reminiscent of epigenetic proactivism:

Understanding of biology, physics, and other sciences facilitated the process of ecological liberation and domination. Man rebelled from natural determination and used his intelligence and skills to impose a human purpose on the development of the earth. We are now on the verge of a process of mental liberation and self-domination which is a continuation of our evolution. Its experimental approach is based on the investigation of the depth of the brain in behaving subjects. Its practical applications do not rely on direct cerebral manipulations but on the integration of neurophysiological and psychological principles leading to a more intelligent education, starting from the moment of birth and continuing throughout life, with the pre-conceived plan of escaping from the blind forces of chance and of influencing cerebral mechanisms and mental structure in order to create a future man with greater personal freedom and originality, a member of a psychocivilized society, happier, less destructive, and better balanced than present man. (Delgado 1971, p. 223; reference omitted)

He and others (e.g., Mark & Ervin 1970; Valenstein 1973) were convinced that therapeutic need would drive the development of such neurotechnology. The envisioned “psychocivilized” world would be so beneficial for individuals and society at large, Delgado believed, that the advantages overruled any social and ethical caveats (Delgado 1971). At the same time, the psychologist Burrhus Skinner wrote a best-selling book on his vision of a peaceful society realised through *social engineering* and inspired by behaviourism rather than neurotechnology (Skinner 1971). Through rewarding the right

kind of actions, Skinner suggested, the socially desired behaviour would become more likely, and the undesired behaviour more unlikely. To avoid a totalitarian regime, the people subject to this social engineering should in turn control the reward structures, the so-called contingencies of a society. Yet, in spite of the book’s popularity, it was strongly criticised by Noam Chomsky for confusing science and politics and for a misapplication of central notions such as freedom and dignity (1971).

The two utopian proposals by Delgado and Skinner, the part of the human enhancement debate discussed above that describes a need for adaptation as without alternative, and epigenetic proactivism have in common that people should be changed in such a way that they contribute to a (putatively) desired social aim: a macroscopic state with better performance, competitiveness, peacefulness, and/or caring for others. This is in obvious conflict with the notion of autonomy that is so fundamental to Immanuel Kant’s moral philosophy: no human being must be treated only as a means to another end; all humans must also be treated as an ends in themselves (1785/1994). Given the description of epigenetic proactivism by Evers, stating that our brains shall fit better to our cultures and social structures, one may well ask whether those enhanced in this manner would not become mere instruments for the present system, with its social norms and values. Also with respect to John Stuart Mill’s utilitarian liberalism, interventions to improve people seem problematic, as Mill formulated the principle:

[...] that the sole end for which mankind are warranted, individually or collectively, in interfering with the liberty of action of any of their number, is self-protection. That the only purpose for which power can be rightfully exercised over any member of a civilised community, against his will, is to prevent harm to others. His own good, either physical or moral, is not a sufficient warrant. He cannot rightfully be compelled to do or forbear because it will be better for him to do so, because it will

make him happier, because, in the opinions of others, to do so would be wise, or even right. These are good reasons for remonstrating with him, or reasoning with him, or persuading him, or entreating him, but not for compelling him, or visiting him with any evil in case he do otherwise. [...] Over himself, over his own body and mind, the individual is sovereign. (1859/1989, pp. 17–18)

Interestingly, Mill explicitly formulated the exception of self-protection and harm to others, to which Evers refers in her paper as well. However, I doubt that epigenetic proactivists can base their ethical justification on this case, as the harm they want to avoid is very indirectly related to intervention—which will most likely be applied to many people who would not have posed a threat to others without it. Furthermore, it can be doubted how imminent the danger is at all; this last point will be elaborated in the next subsection. Although other and more recent versions of “utilitarianism”, such as preference utilitarianism, place less emphasis on autonomy than Kant or Mill, they also lend the inner core of a person, for example, her or his preferences and values, a status of special protection (Singer 2011). This core is likely to be affected by changing people’s predisposition to aggression and sympathy, as the brief description of psychological side-effects in the previous subsection suggests.

Therefore, the essential question for epigenetic proactivism seems to be whether people can autonomously consent to the intervention. Evers’s title asks whether we *can* be epigenetically proactive; I have reformulated this to ask whether we *should* be epigenetically proactive. Here it is particularly relevant that her two examples, adolescent and interconfessional violence, explicitly address the development of children and teenager’s brains—that is, people whom we do not usually consider to be (fully) autonomous. The question of whether parents can take this decision, aimed at rewiring the nervous system of their children for a social aim, is too complex to be discussed here, but it calls for a solution before we can really think

about putting epigenetic proactivism into practice.

For our present purposes it shall suffice to suggest that it is unlikely that all parents would consent to such a measure. What would then happen to those who declined to participate in epigenetically proactive educational programs? Even today, some families resist education because they see a conflict between their values and teaching on, for example, sex education or evolutionary theory. In particular, those who benefit from the present social order would be unlikely to consent to a measure that might lead to a loss of power for them. As mentioned earlier, this may make those who are made less aggressive and more empathic more likely to be exploited by those who are not. Therefore, it is an essential challenge for epigenetic proactivism to take autonomy, informed consent, and the further complexities of intervening in the core of a person’s personality into account—and to consider that people’s views on these issues will be diverse!

Until these challenges of autonomy and informed consent in particular are met, I draw the tentative conclusion that we should not be epigenetically proactive. It should be noted, though, that while I am discussing the proposal by Evers here, the argument from autonomy is independent of the means actually used to enhance people—whether biological, psychological, or social. Rather, it is essential that people are free from coercion and can decide for themselves whether or not they want to become the kind of human being envisioned by proponents in the human enhancement debate, and that they have sufficient knowledge on the implications of that choice. Evers particularly focusses on children and adolescents when discussing examples of epigenetic proactivism, but it appears to be most difficult to describe what autonomous and informed choice means in precisely this group of human beings.

4.3 The human condition

Evers emphasises that many people live in precarious circumstances, even more than sixty years after the Universal Declaration of Human

Rights; in the end, she even refers to Arthur Koestler's idea that humans might have some built-in deficiency, predisposing us to self-destruction. Obviously, against that prospect, the promises of epigenetic proactivism look seductive. Indeed, we must concede that even some twenty-five years after the Cold War international conflicts have not abated altogether—in some areas they have even multiplied, and terrorism or economic instability are a concern for many. However, from the perspective of cultural evolution, universal human rights are a rather novel development and it may be too early to take a pessimistic stance on their success and effect. Returning to the UN World Happiness Report (Helliwell et al. 2013), one may ask whether the difference between the leading countries—Denmark, Norway, Switzerland, the Netherlands, and Sweden (ranked 1st to 5th)—, those in the middle—Libya, Bahrain, Montenegro, Pakistan, and Nigeria (ranked 78th to 82nd)—, and those at the bottom—Rwanda, Burundi, the Central African Republic, Benin, and Togo (ranked 152nd to 156th)—can be explained or even overcome by means of human enhancement like epigenetic proactivism rather than internationally-aided institutional development.

One shared rhetorical feature of those visions of a better humankind is a claim that all has somehow gone wrong, and even to predict an imminent catastrophe. For example, the various *Humanist Manifestos* of the 20th and early 21st century described serious threats to human survival.² Delgado emphasized an imbalance between our material and mental evolution, putting humanity at risk (1971), and Skinner started out by referring to problems related to population growth, pollution of the environment, and nuclear armament (1971). It probably lies in the eye of the beholder to speculate whether humankind has not yet destroyed itself because or in spite of unprecedented technological powers.

It is a matter of fact that we have not yet done so, and although many things have gone

wrong, others have gone right. Steven Pinker recently gathered evidence that, particularly when viewed in relation to the vast population growth of humanity, our present times are much more peaceful than the past (2011). He describes processes of pacification and civilization as well as a humanitarian and rights revolution that can provide hope that things will change for the better, not only for the worse. Therefore, even if human enhancement in general or epigenetic proactivism in particular may offer genuine improvement of the human condition in several ways, they are probably not necessary for human survival.

5 Conclusion

Kathinka Evers summarises research on the epigenesis of neural networks to describe a vision of epigenetical proactivism, a development of new training and therapeutic programs to improve humans. She asks whether we *can* be epigenetically proactive, pointing out the benefits of decreasing the prevalence of adolescent and interconfessional violence, and in so doing develops her answer: yes, in principle, we can be epigenetically proactive. However, she also describes a naturalistic responsibility to do this, which is the point at which my discussion of her proposal diverged from her view. Particularly with respect to autonomy and free choice I think that, for the time being, we should not be epigenetically proactive; and we should be even more cautious when interventions in children's and teenagers' brains are at issue. Minor caveats are related to the possible psychological side-effects of decreasing our disposition towards aggression and increasing that of sympathy, as well as a more optimistic view of how humankind is developing.

In this paper, I also related epigenetic proactivism to the human enhancement debate more generally, which has become much more comprehensive than can be addressed in such a brief commentary. It was important to examine the definition of wellbeing and the framing of urgency, as well as the primary level of intervention—bio-psychological or social—, issues that are also related to autonomy. This does not

² See the three Manifestos of 1933, 1973, and 2003 of the American Humanist Association on <http://americanhumanist.org/Humanism/> (accessed July 21 2014).

mean that knowledge on epigenetics could not be used in another manner for the purposes of enhancement, in situations where people can make an informed decision for themselves whether and how to engage in a certain kind of training. In this sense, it would be interesting to compare epigenetic proactivism to other non-pharmaceutical means of enhancement, such as nutrition, exercise, sleep, or meditation (Dresler et al. 2013). Generally speaking, the knowledge described by Evers could also be related to debates on improving school education neuroscientifically (Hook & Farah 2013; Posner & Rothbart 2005). Furthermore, when targeting human capacities that are also salient for moral cognition, the debate on *moral enhancement* may be an important reference point with overlapping prospects and concerns (Douglas 2008, 2013; Harris 2011).

Evers warned that science has been hijacked repeatedly throughout history and that in particular the dream of creating perfect human beings has a sordid past. Here I wholeheartedly agree with her and her related call for historic awareness. I hope that I have succeeded in showing why, beyond this awareness, it is also essential to take people's own views and autonomy into account. It may not only be the case that too much focus on enhancing people makes them sad by focusing too much on their deficiencies (Schleim 2014b; Schopenhauer 1874), but in the attempt to create superhuman beings a human catastrophe might also be provoked.

Acknowledgments

I would like to thank the two editors as well as two anonymous reviewers for their extraordinarily helpful and constructive comments on a previous version of this paper.

Understanding Epigenetic Proaction

A Reply to Stephan Schleim

Kathinka Evers

Epigenetic proaction can be described as a way of steering evolution by influencing the cultural imprints stored in our brains. It is not to be confused with “human enhancement”. It is a process on the societal level that need not conflict with the notion of autonomy, nor suggest any “superhuman” ideal. Risks of misuse justify precaution, not abandonment of constructive scientific pursuits. Scientific knowledge can help us improve our life conditions in the long-term. A naturalistic responsibility is born out of science’s strong social relevance.

1 Introduction

Epigenetic proaction can be described as a way of steering evolution by influencing the cultural imprints that are stored in our brains. The question analysed in my target article is what exactly this means and whether it is possible. Can we adapt our societies to constructively interact with the ever-developing neuronal architecture of our brains? The issue of whether such interaction is desirable is also raised but not discussed in depth.

In order to decide whether an action should be pursued it would be wise to first attempt to understand its nature and implications. Regrettably, in his commentary to my article, Stephan Schleim fails to acknowledge the main concern of my paper, namely the sci-

entific issue, moving instead to the normative question via some less relevant detours. The commentary therefore becomes misleading. Rather than engaging with the scientific points I make, Schleim takes as a starting point a flawed understanding of epigenetic proaction and tries to show how undesirable it would be. The arguments have little to do with the article on which he purports to comment.

2 Confusing epigenetic proaction with human enhancement

After making the assertion that “the actual means—whether neurobiological, psychological,

or social—do not matter very much” in his philosophical analysis of epigenetic proaction, [Schleim](#) proceeds to relate my position to the general debate on “human enhancement” ([this collection](#), p. 2). A long discussion follows about this debate that, although quite popular amongst some contemporary philosophers, is here out of context. In the target article, there is no mention of individual cognitive, moral, or performance enhancement, nor any mention of pharmaceutical “smart pills” and so on. The target article does not speak of epigenetic proaction as an individual opt-in/opt-out thing at all, nor does it speak of enhancement. And it certainly does not recommend, as [Schleim](#) suggests at the end of his commentary “the attempt to create superhuman beings” ([this collection](#), p. 15). The statement that my theory proposes methods for parents “aimed at rewiring the nervous system of their children for a social aim” ([Schleim this collection](#), p. 10) is a caricature. Perhaps the author has not read the target paper quite thoroughly enough. This would explain why the author does not specifically address any of the scientific issues raised in the paper.

3 Well-being and exaggerated virtues

In the commentary, the subsequent discussion is about who defines well-being and how. Whilst this in itself is an interesting question that deserves careful consideration from many perspectives, it is not directly relevant to the target article. The article raises the question of whether epigenetic proaction is possible, and presents scientific data and theories to explain what this means. On that basis, I suggest that they can be taken to support the view that it may indeed be possible. The questions of defining well-being or of specifying who should be in charge of defining well-being, whilst interesting, fall out of this scope.

In contrast, the question of “side-effects” can with some effort be considered at least somewhat relevant to the article under debate. Here, [Schleim](#) wonders: is it possible, e.g., to reduce aggression without making a person weak or meek? Can a less aggressive person defend

him- or herself against a more aggressive person? He seems to be doubtful, but my short reply is: obviously, yes. Much education, of children in particular and in human societies in general, includes attempts to check aggression—it does not thereby create either wimps or zombies. Even martial arts focus explicitly on checking aggression, whilst by definition aiming to make students excellent in combat. [Schleim](#) also wonders about the risky side-effects of increasing sympathy. He warns that increasing sympathy too much could perhaps lead to a “dysfunctional self–other distinction” that “may play a role in schizophrenia”. However, even if this were the case, this is not a necessary—or even very common—side-effect of increasing sympathy. Certainly, when we bring our children up to sympathise with others, we may increase their distress at the sight of suffering in others, but I do not believe that we thereby increase their risk of developing schizophrenia. Moreover, as a general principle, that an initially positive value can become negative if exaggerated does not entail that we should stop seeking it altogether. If that were the case, we would have little to strive for.

4 Epigenetic proaction: A process on the societal level

[Schleim](#) compares my theory to the famously misconceived social engineering projects of Skinner and Delgado, for whom, [Schleim](#) says, the goals blessed the means. He argues ([Schleim this collection](#), p. 9) that these “utopian proposals” stand “in obvious conflict with the notion of autonomy”, as understood by Immanuel Kant: no being must be treated only as a means to an end, but as an end in itself. I agree with Kant’s principle and see no conflict between it and the notion of epigenetic proaction. There is nothing in the idea of epigenetic proaction as I develop it in my article that suggests treating people as mere means to a social end, or of allowing them to “become mere instruments for the present system” ([Schleim this collection](#), p. 9). The idea in itself is neutral in this regard: of course the idea can be misused—all science can be misused—but it is no part of the theory to

have this negative consequence. In other words, there is no essential conflict between human autonomy and human epigenetic proaction properly understood.

As for the issue of informed consent that Schleim raises in that context, it does not directly arise through the topics I address in my article, but it would arise in the research that I recommend be pursued. Epigenetic proaction is a process on the societal level. When, for example, educational structures and methods are adopted in a functioning democratic society, people are invited to express their views through political elections, public debates, consensus conferences, etc.; but we do not ask each citizen for an individual informed consent. Nor do we ask for it when laws are passed. For example, in 1979, corporeal punishment of children became illegal in Sweden. The decision was preceded (and followed) by public debate and, as with most rules and regulations, some agreed with the ruling, while others did not—but the question of informed consent does not here arise. In contrast, if research in the natural and social sciences collaborate, e.g., to develop educational structures to assist and protect adolescents during that difficult phase of cerebral development, insofar as such research requires the use of human subjects individual informed consent will be needed. That this is the case is not a specific problem of the theory, but an ethical regulation (amongst many others) that all research must respect.

5 Opposing world-views

Concerning the human condition, surprisingly, Schleim criticises me for being overly concerned about the present states of poverty, war, and the many current violations of human rights around the world. He dismisses these worries as “rhetorical” (again comparing my arguments to those of Skinner and Delgado). Schleim seems to be at relative ease with the present state and future of humanity and, referencing Steven Pinker, draws the conclusion that there is hope that things will change for the better, so there is no need to be epigenetically proactive. Different world-views here confront one another.

Schleim concludes in what seems to me again a spirit of denial that people might be saddened by “focusing too much on their deficiencies” and ends his commentary by saying that “in the attempt to create superhuman beings a human catastrophe might also be provoked” ([Schleim this collection](#), p. 12). True, no doubt—as, notably, Germany’s recent past illustrates. But this is not particularly relevant to my article: there is nothing in the theory of epigenetic proaction to suggest that we either should or could create “superhumans”.

6 Conclusion

Trying to understand and influence human norms in the light of what we today know about the brain is not an easy task. The scientific challenge is increased by the remarkable emotionality with which this whole area of research is permeated and which can apparently make it hard to see clearly what is actually being said. This emotionality is in part understandable: the notion of improving the human condition, including our biology, comes in some very sordid versions, as ideas of “racial purity” or “ethnic supremacy” serve to illustrate, and which remain present in various societies around the world. Historic awareness is indeed essential to safeguard constructive and hope-inspiring scientific ideas from being hijacked by nefarious ideologies (or, indeed, interpretations) and abused for unscientific purposes. However, the risk of misuse justifies precaution, not abandonment of constructive scientific pursuits.

Research collaborations between neuroscience, genetics and social science, notably, today provide rich and multifaceted knowledge about the human being and an increasingly integrated view of us as biological organisms interacting in complex natural and cultural environments in constant evolution. The resulting knowledge could further help us improve our life conditions, e.g., by assisting us in finding remedies for the developmental crises of adolescents, or excessive societal violence. What I call our “naturalistic responsibility” is born out of science’s strong social relevance. Whether or not in the future we shall use this knowledge

soundly remains to be seen. Which traits we decide to favour epigenetically, or what social structures we choose to develop, depends on who “we” are, and on the society in which we wish to live. We may hope that young scientists and philosophers shall rise well to that challenge, and develop the idea of epigenetic proactivity into a dynamic and socially responsible area of research.

The Paradigmatic Body

Embodied Simulation, Intersubjectivity, the Bodily Self, and Language

Vittorio Gallese & Valentina Cuccio

In this paper we propose a way in which cognitive neuroscience could provide new insights on three aspects of social cognition: intersubjectivity, the human self, and language. We emphasize the crucial role of the body, conceived as the constitutive source of pre-reflective consciousness of the self and of the other. We provide a critical view of contemporary social cognitive neuroscience, arguing that the brain level of description is a necessary but not sufficient condition for studying intersubjectivity, the human self, and language; which are only properly visible if coupled with a full appreciation of their intertwined relationship with the body. We introduce mirror mechanisms and embodied simulation and discuss their relevance to a new account of intersubjectivity and the human self. In this context, we focus on a specifically human modality of intersubjectivity: language. Aspects of social cognition related to language are discussed in terms of embodiment, while emphasizing the progress and limitations of this approach. We argue that a key aspect of human language consists in its decoupling from its usual denotative role, hence manifesting its power of abstraction. We discuss these features of human language as instantiations of the Greek notion of *paradeigma*, originally explored by Aristotle to refer to a typical form of rhetorical reasoning and relate it to embodied simulation. Paradigmatic knowledge connects the particular with the particular, moving from the contingent particular situation to an exemplary case. Similarly, embodied simulation is the suspension of the “concrete” application of a process: reuse of motor knowledge in the absence of the movement it realizes is an example of “paradigmatic knowledge.” This new epistemological approach to intersubjectivity generates predictions about the intrinsic functional nature of our social cognitive operations, cutting across, and not subordinated to, a specific ontology of mind.

1 Introduction

The last decades of the twentieth century were marked by great progress in cognitive neuroscience, made possible by recently-developed brain imaging technologies such as functional magnetic resonance imaging (fMRI)—which allowed for the first time non-invasive study of the human brain.

But what is cognitive neuroscience? We think it is fair to say that it is above all a methodological approach whose results are strongly

influenced by which questions are being asked and how. Studying single neurons and/or the brain does not necessarily predetermine the questions to be asked that will help us understand how and how much our human nature depends upon our brains. Even less so the answers. Our purpose here is twofold. On the one hand, we aim to provide a brief overview of current cognitive neuroscience and its methods. We first present the limitations displayed by most

current mainstream cognitive neuroscience, followed by a proposal for an alternative approach, both in terms of the employed methodology and of its main goals. In short, in contrast with what many normally take for granted¹, we assume the brain level of description to be a necessary but not sufficient condition for studying intersubjectivity, language, and the human self, which are only properly visible if coupled with a full appreciation of their intertwined relationship with the body. This overview has been specifically designed to provide a useful tool for researchers working in the humanities. Section 2 is entirely devoted to this goal.

On the other hand, the authors of this essay are a cognitive neuroscientist and a philosopher of language, and as such our second purpose is to propose how cognitive neuroscience could provide new insights on specific aspects of human cognition. In section 3 we introduce mirror mechanisms and embodied simulation and, in the following sections, we discuss their relevance for a new account of intersubjectivity, the human self, and language—which privileges the body as the transcendental foundation of each.

We emphasize the crucial role of the body, conceived as the constitutive source of pre-reflective consciousness of the self and of the other and as the ground upon which linguistic meaning is also based. The body we talk about in this paper manifests itself in two different, complementary, and closely intertwined ways:² it is a *Leib*, a lived body entertaining experiences of self and others, and a *Körper*, the somatic object, of which the brain is a con-

stitutive part. We posit that this dual nature of our experienced body can be fully understood—and its genesis revealed—by investigating its motor neurophysiological underpinnings at the sub-personal level. The naturalization of intersubjectivity, the self, and language implies a first attempt to isolate the constituent components of the concepts we use to refer to these aspects of human social cognition by literally investigating what they are made of at the level of description of the brain–body system. This attempt in relation to the notions of intersubjectivity, the self, and language is intended here to form an identification of their constitutive mechanisms. We believe that this investigation becomes really effective only when it is framed within both comparative and developmental perspectives.³

The comparative perspective not only allows us to frame human social cognition within an evolutionary picture, thus providing access to its phylogenetic antecedents.⁴ It also greatly reduces the risk of the empirical investigation of the human brain being subordinated to a specific human ontology of mind. A further reason for privileging the comparative perspective resides in the fact that it also brings us the most finely grained approach to date for studying the brain, and the possibility of correlating single neurons' activity with behaviour and cognition—as when studying single neurons' activity in non-human primates, like macaque monkeys.

The immanent transcendence⁵ of the body's corporeality can be revealed, we contend, by bringing the analysis back to the level of the brain–body system; that is, to the level of the *Körper*. We show that this particular neurocog-

¹ “Still other accounts of grounded cognition focus on situated action, social interaction, and the environment (e.g., Barsalou 2003, Barsalou et al. 2007a, Glenberg 1997, W. Prinz 1997, Rizzolatti & Craighero 2004, Robbins & Aydede 2007, E. Smith & Semin 2004, Yeh & Barsalou 2006). From this perspective, the cognitive system evolved to support action in specific situations, including social interaction. These accounts stress interactions between perception, action, the body, the environment, and other agents, typically during goal achievement. It is important to note that the phrase ‘embodied cognition’ is often used when referring to this collection of literatures. Problematically, however, ‘embodied cognition’ produces the mistaken assumption that all researchers in this community believe that bodily states are necessary for cognition and that these researchers focus exclusively on bodily states in their investigations. Clearly, however, cognition often proceeds independently of the body, and many researchers address other forms of grounding.” (Barsalou 2008, p. 619)

² We find it useful to employ here the distinction originally proposed by Edmund Husserl in Husserl (1973, p. 119).

³ One of the major contributions to our understanding of human social cognition is provided by developmental psychology. In this paper, for sake of concision we don't focus on developmental aspects, in spite of the crucial importance we attribute to them to thoroughly address the issues we want to address here.

⁴ It is interesting to note that this comparative perspective seems to support the hypothesis of an evolutionary continuity between human and non-human primates in relation to the emergence of language from our sensori-motor abilities. For a discussion of this topic, see Glenberg & Gallese (2012).

⁵ The expression immanent transcendence is meant to signify here the fact that the body, by means of a biological mechanism (immanent), can transcend his usual function (for example, motion) to become expression (a model or paradigma) of this bodily knowledge.

nitive approach is beginning to reveal the tight relationship between a core notion of the bodily self, its potentiality for action, and motor simulation at the level of the cortical motor system. Cognitive neuroscience can enable the analysis of several concepts and notions we normally refer to when describing ourselves and our social cognitive lives. In the present paper we apply this method to the notions of intersubjectivity, the self, and language.

To fully account for the specific quality of human social cognition one cannot undervalue the linguistic dimension. For this reason, we introduce aspects of social cognition related to language and discuss them in terms of embodiment, emphasizing the progress and limitations of this approach. Traditionally, the linguistic and corporeal sensorimotor dimensions of social cognition have been considered entirely unrelated. We posit that embodied simulation, conceived of as a model for important aspects of our relation to the world, might help in overcoming this apparently unsolvable dichotomy. We argue that a key aspect defining the unique specificity of human language consists in its decoupling from its usual denotative role. This means that language allows us to talk about general concepts such as beauty or mankind, without denoting any particular instance of these concepts. In so doing, human language manifests its power for abstraction. We discuss these features of human language as instantiations of the Greek notion of *paradeigma*, originally explored by Aristotle, and relate it to embodied simulation. When a word or syntagm, like the Latin word *Rosa*, is decoupled from its usual denotative role, it can function as a general rule of knowledge, e.g., as a paradigm for the female nominative case of Latin nouns belonging to the first declension. The notion of *paradeigma* does not establish a connection between a universal principle and its contingent aspects, as in deduction, it rather exemplifies a particular case of induction: specifically the transposition of inductive reasoning in the field of studies of persuasive communication, known as rethorics, where contingent particular cases lead to general rules describing them. Paradigmatic knowledge, however, differently

from standard cases of induction, connects the particular with the particular, moving from the contingent particular situation to an exemplary case. We propose that embodied simulation could instantiate such a notion of paradigmatic knowledge, hence enabling its naturalization and helping us overcome the apparent gap between the linguistic and corporeal dimensions.

We conclude by emphasizing how the specific use of cognitive neuroscience here proposed can lead to a new take on social cognition. This new take brings about a demonstration on empirical grounds of the constitutive role played in foundational aspects of social cognition by the human body, when conceived of in terms of its motor potentialities; hence its transcendental quality.⁶ Of course this only covers a partial aspect of social cognition. However, we think this approach has the merit of providing an epistemological model, which is also potentially useful for empirical investigation into the more cognitively sophisticated aspects of human social cognition.

2 The cognitive neuroscience of what?

It is a fact and an undisputable truth that there cannot be any mental life without the brain. More controversial is whether the level of description offered by the brain is also sufficient for providing a thorough and biologically-plausible account of social cognition. We think it isn't. We would like to ground this assertion on two arguments: the first deals with the often overlooked intrinsic limitations of the approach adopting the brain level of description, particularly when the brain is considered in isolation and its intimate relation with the body is neglected; the second deals with social cognitive neuroscience's current prevalent explanatory objectives and contents.

The contemporary emphasis divulged by the popular media, namely the supposedly revolutionary heuristic value of cognitive neuroscience, mostly rests upon the results of brain imaging techniques, and in particular on fMRI.

⁶ The "transcendental quality" attributed to the body is intended to mean that the body is considered as the a priori, non-further reducible condition of the possibility of experience.

fMRI is often presented as the ultimate method of investigation of the human mind. It should be pointed out, though, that fMRI studies do not constitute the whole story in cognitive neuroscience. Cognitive neuroscience can indeed carry out its investigation at a more drastic sub-personal level, such as at the level of single neurons (see below), both in macaque monkeys and, although much more rarely, even in humans. These alternative approaches notwithstanding, the main thrust of cognitive neuroscience in studying human brain function is, as we speak, mostly confined to fMRI.⁷

Unfortunately fMRI only indirectly “sees” the workings of the brain, by measuring neurons’ oxygen consumption. Such a measure is also indirect, as it depends on the local difference between oxygenated and deoxygenated hemoglobin—the iron-rich molecule housed by red blood cells, which carries oxygen to all bodily organs and tissues. Oxygenated and deoxygenated hemoglobin have different paramagnetic behaviours in relation to the strong magnetic field that is created by a big coil, inside which the head is placed. The measure of this functional parameter allows scientists to estimate local neural activity in terms of different MRI (magnetic resonance imaging) signals. The indirect quality of this kind of estimation of brain activity, which is based on local hemodynamic brain responses, inevitably introduces distortions and noise. Indeed, when studying any sensorimotor, perceptual, or cognitive function, in order to maximize the so-called “signal-to-noise ratio”, several repetitions of the same task in many individuals are required.

This means that fMRI allows us to indirectly assess the average brain-activation level induced by any given task across a population of no less than twelve to fifteen different individuals. Within each studied individual brain the spatial resolution of fMRI is within the order of few millimetres. This implies that we are able to measure at best the potentially coherent activation pattern of several hundred thousand neighbouring neurons, possibly also differing

among one another in terms of their excitatory or inhibitory role.

Temporal resolution is even worse, since it is in the order of a few seconds. One should consider that action potentials, or “spikes” as neurophysiologists like to call them—the electric code employed by neurons to “communicate” with each other, and ultimately the true essence of neurons’ activity—last less than one millisecond. fMRI cannot match such temporal resolution because it measures the delayed (of about two seconds) and prolonged (for about five seconds) local hemodynamic response providing neurons with all the oxygen their electric activity requires.

As we have previously argued, fMRI is not the only available experimental methodology for studying the brain. Many different techniques are available nowadays (e.g., PET (positron emission tomography), NIRS (near-infrared spectroscopy), Tdcs (transcranial direct-current stimulation) or TMS (transcranial magnetic stimulation)). Particularly, since the revolutionary introduction in 1927 by the Nobel Prize laureate Edgar Adrian ([Adrian & Matthews 1927a](#), [1927b](#)) of the extracellular microelectrode, which allows the recording of action potentials discharged by single neurons, neurophysiology has made enormous progress in revealing the brain’s physiological mechanisms. Such neurophysiological investigation started with the study of the neural circuits that preside over elementary sensorimotor behaviours, like spinal reflexes, finally moving all the way up to the investigation of action and perception, reward and emotions, spatial mapping and navigation, working memory, decision-making, etc., in behaving animals like macaque monkeys. Unfortunately, such a finely grained level of description—both in terms of spatial and temporal resolution, is most of the time precluded in humans.

We posit that the scientific study of intersubjectivity and the human self requires a comparative approach, and that this is the only one capable of connecting the distinctive traits of human nature to their likely phylogenetic precursors. In so doing, and by making use of the single-neuron recording approach, neuro-

⁷ For an intriguing discussion of the historical antecedents of brain imaging techniques and a passionate criticism of the limitations of current use of brain imaging by cognitive neuroscience, see [Legrenzi & Umiltà \(2011\)](#).

physiological mechanisms and the cortico-cortical networks expressing them can be related with several aspects of primates' social cognitive behaviour and thus be thoroughly investigated. Conceptual notions like intersubjectivity and the self should be analyzed in order to better understand their nature, structure, and properties. Such an analysis, which provides us a deflationary notion of the same concepts, intended as the identification of their minimal component and the detailed study of their origin, will be most successful if driven by a meticulous investigation of the underpinning neurophysiological mechanisms—which most of the time are available only from the study of non human primates' brains, hence the necessity of a comparative perspective.

Human brain imaging, because of the intrinsic limitations we briefly outlined above, can only provide correlations between particular brain patterns of activation and particular behaviours or mental states. This implies that the correlation between a particular brain state and a particular phenomenal mental state of a given individual human being⁸ is most informative when the specificity and uniqueness of such a correlation can be firmly established. Unfortunately, this is not always the case with fMRI studies. Very telling is the supposed mindreading specificity of some cortical circuits comprising the ventral portion of the mesial frontal cortex and the TPJ (temporo-parietal junction; e.g., [Leslie 2005](#); [Saxe 2006](#)). Such specificity is not only so far unproven, but is actually confuted by accumulated evidence (for a lengthier discussion of this point and for arguments and experimental evidence against such specificity see [Ammaniti & Gallese 2014](#); [Gallese 2014](#)).

In spite of all these limitations, this neuroimaging approach turned out to be very productive, enabling us to study for the first time in parallel brains, behaviour and cognition, shedding new light not only on human brain structure, but also on its wiring pattern of con-

nectivity and many of its functions. If we put the newly-acquired knowledge on brain function provided by cognitive neuroscience under scrutiny, we can make very interesting discoveries. For example, we discovered that in many areas of investigation brain imaging replicates and validates *at a different scale* what had been previously discovered at the single neuron level in animals like macaques.⁹

The prominent discoveries, among others, of David Hubel, Torsten Wiesel, and Semir Zeki on the functional organization of primates' cortical visual system, like the orientation-, shape-, motion- and colour-selectivity of visual neurons, were made by correlating the discharge activity of single neurons in macaques' visual cortices with different parameters of the visual stimuli macaques were looking at (for a comprehensive review of this literature, see [Zeki 1993](#)). These results later promoted a similar investigation carried out on the human brain by means of fMRI. Remarkably enough, a similar functional architecture was detected in the human visual brain, in spite of the species difference and, most importantly, the different scale at which these investigations were carried out: a few hundreds recorded neurons at best, in the case of macaques' brains, versus hundreds of thousands if not millions of activated neurons detected by a local increase in blood flow in the case of the human brain.

Face-selective neurons, first described in the early nineteen-seventies by Charles Gross and colleagues in macaques' temporal cortex ([Gross et al. 1972](#)), and immediately ridiculed as “grand-mother cells”, offer another very telling example.¹⁰ Face-selective brain circuits appear to be strikingly similar in macaques and humans (see [Ku et al. 2011](#)). Furthermore, even in human brains single neurons were detected that selectively respond to a single face—such

⁸ For sake of concision and focus we do not discuss here the implicated topic of the apparently absent synchronicity between brain states and phenomenal consciousness (remember that fMRI does not provide a good temporal resolution to firmly match brain states and phenomenal consciousness). We simply want to stress the parallel existence of particular experiences and particular brain states.

⁹ The comparative approach is primarily intended here as a comparison between humans and other animals. As a consequence, it also implies a comparison between different experimental methods.

¹⁰ The notion of the grandmother cell was originally introduced by the neuroscientist Jerry Lettvin to refer to neurons with high integrative power, which are able to map concepts or objects. The term has since then mostly been employed with a negative connotation by supporters of a more distributed population-coding of objects, percepts, and memories. For an historical account of the notion of the grandmother cell, see [Gross \(2002\)](#).

as the so-called Jennifer Aniston's selective neurons (see Quiroga et al. 2005). These neurons respond to multiple representations of a particular individual, regardless of the specific visual features of the picture used. Indeed, these neurons respond similarly to different pictures of the same person and even to his or her written or spoken name. The authors of this study claimed that their evidence supported the notion that single neurons within the human medial temporal lobe cortex instantiate the abstract representation of the identity of a single individual.

Such examples seem to suggest that in spite of the big scale magnification implied when confronting single-neuron data from macaques and fMRI results from humans, some important functional features are nevertheless manifest across these different levels of description (i.e., single neurons vs. brain areas). One can study canonical or mirror neurons (see below) by recording the activity of a few hundred spiking neurons from a behaving macaque monkey during object and action observation, respectively. The same results can be replicated by detecting, by means of fMRI, and during object and action observation, the simultaneous activation of hundreds of thousands of human neurons within analogous cortical areas of the human brain.

This remarkable but often neglected fact cannot be the result of a pure coincidence. This evidence should thus invite us to resist and argue against those who downplay the heuristic power of single-neuron recording. Their thesis is that because of a supposedly incommensurable gap between single neurons and the incredible complexity of the human brain, where information would be exclusively mapped at the level of large populations of poorly selective neurons, it doesn't make any sense to study the brain by recording single neurons. The fact however is that in spite of the almost astronomic figures characterizing the human brain (about 100 billion neurons, each of which connects with thousands of other neurons), its complexity does not parallel such astronomic figures, or at least not in such a way as to deny any heuristic value to the single-neuron recording approach. Let's see why.

As argued by Chittka & Niven (2009), brain size may have less of a relationship with behavioural repertoire and cognitive capacity than generally assumed. According to the same authors, larger brains are, in part at least, a consequence of larger neurons that are necessary in large animals due to basic biophysical constraints. Larger brains also contain greater replication of neuronal circuits, adding precision to sensory processes, detail to perception, more parallel processing, enlarged storage capacity, and greater plasticity. These advantages, maintain Chittka & Niven (2009), are unlikely to produce the qualitative shifts in behaviour that are often assumed to accompany increased brain size, or at least not in a one-to-one manner.

The evidence so far briefly reviewed and that we will present in the next sections suggest that some functional properties of the brain exhibit a sort of "fractal quality", such that they can be appreciated at different scales and levels of investigation. For these reasons fMRI cannot be the sole neurocognitive approach to human social cognition,¹¹ but it must be complemented by other approaches compensating for some of its deficiencies: like TMS, EEG (electroencephalography), and the comparative functional study of non-human primates by means of brain imaging and single-neuron recordings.

After having clarified what we take to be the often-neglected limitations of cognitive neuroscience that may hinder its potential heuristic power (namely, that fMRI offers only an indirect estimation of brain activity, inferred by measuring neurons' oxygen consumption, and this inevitably leads to distortions and noise, and that it does not provide good temporal resolution because it measures the delayed and prolonged hemodynamic responses due to neurons oxygenation), let us now move to the second argument against the sufficiency satisfaction condition of the current approach of cognitive neuroscience to the study of human social cognition. This argument concerns the explanatory goals and contents of contemporary main-

¹¹ Maybe no one explicitly claims this. However, it is very common that researchers neglect many (or all) of the complementary techniques that have been here suggested to be necessary and draw inferences about human social cognition and its neural implementation. As an example, see papers by Ian Apperly.

stream cognitive neuroscience. Vast quarters within cognitive neuroscience are still today strongly influenced by classical cognitivism, on one side, and by evolutionary psychology on the other. Classical cognitive science is the bearer of a solipsistic vision of the mind, according to which focusing on the mind of the single individual is all that is required in order to define what a mind is and how it works. The image of the mind that classical cognitive science gives us is that of a functional system whose processes are described in terms of manipulations of informational symbols in accordance with a series of formal syntactic rules.

According to evolutionary psychology, by contrast, the human mind is a set of cognitive modules, each of which has been selected during evolution for its adaptive value. Major figures of this current, such as John Tooby and Leda Cosmides, have gone as far as maintaining that the brain is a physical system that works like a computer (Cosmides & Tooby 1997). According to Steven Pinker (1994, 1997), our cognitive life can be referred to in terms of the function of a series of modules like the linguistic module, the module for the Theory of the Mind, etc.

Based on this theoretical framework, in the last twenty years cognitive neuroscience when investigating human social cognition has mainly tried to locate—as mentioned above—the cognitive modules in the human brain. Such an approach suffers from ontological reductionism, because it reifies human subjectivity and intersubjectivity within a mass of neurons variously distributed in the brain. This ontological reductionism chooses as a level of description the activation of segregated cerebral areas or, at best, the activation of circuits that connect different areas and regions of the brain. However, if brain imaging is not backed up by a detailed phenomenological analysis of the perceptual, motor, and cognitive processes that it aims to study and—even more importantly—if the results are not interpreted, as previously argued, on the basis of the study of the activity of single neurons in animal models, and the study of clinical patients, then cognitive neuroscience, when exclusively consisting in brain imaging, loses much of its heuristic power. Without the

demonstration of the specific correlation between brain states and mind states and the explanation of such correlation, much of the contemporary brain imaging approach to social cognition looks like a sort of high-tech version of phrenology.

For this reason a “phenomenologization” of cognitive neuroscience is desirable, as Gallese has proposed before (see Gallese 2007, 2009, 2011, 2014). In Gallese’s view, to “phenomenologize” cognitive neuroscience means to start neuroscientific research from the analysis of subjective experience and of the role that the living body plays in the constitution of our experience of material objects and of other living individuals. In this way, the empirical study of the genetic aspects of subjectivity and intersubjectivity can be pursued on new bases—if compared to those thus far adopted by classical cognitivism. Francisco Varela a few years ago realized a similar possibility and set out on a pathway of analysis in this direction (Varela & Shear 1999).

Times change, however. We are insisting on nothing less than a change of paradigm. A new neuroscientific approach to the study of the human mind is gaining momentum. It capitalizes upon the study of the bodily dimension of knowledge: the so-called “embodied cognition” approach. In the next section we introduce mirror neurons and embodied simulation. Our purpose is to show that, starting from a sub-personal neuroscientific description of the pragmatic relationship with the world, a pathway can be traced to define the forms of subjectivity and intersubjectivity that distinguish human nature, rooted in the bodily interacting nature of human beings.

3 Mirroring mechanisms and embodied simulation

The discovery in the early 1990s of mirror neurons in the brain of macaques (Gallese et al. 1996; Rizzolatti et al. 1996), and the subsequent discovery of mirror mechanisms in the human brain (see Gallese et al. 2004; Rizzolatti & Sinigaglia 2010) suggest that there exists a direct modality of access to the meaning of other

people's behaviours—a modality that can be set aside from the explicit attribution of propositional attitudes. Mirror neurons are motor neurons, originally discovered in macaques' ventral premotor cortex area F5, later on also found in the reciprocally-connected posterior parietal areas AIP and PFG. Mirror neurons not only respond to the execution of movements and actions, but also respond to the perception of actions executed by others. Mirror neurons map the action of others on the observers' motor representation of the same action. Further research also demonstrated in the human brain the existence of a mechanism directly mapping action perception and execution, defined as the Mirror Mechanism (MM; for a recent review, see [Ammaniti & Gallese 2014](#); [Gallese 2014](#)). In addition, in humans the motor brain is multimodal. Thus, it doesn't matter whether we see or hear the noise made by someone cracking peanuts, or locking a door. Different—visual and auditory—sensory accounts of the same motor behaviour activate the very motor neurons that normally enable it. The brain circuits showing evidence of the MM, connecting frontal and posterior parietal multimodal motor neurons, most likely analogous to macaques' mirror neurons, map a given motor content like “reach out” or “grasp” not only during their performance, but also when perceiving the same motor behaviour performed by someone else, when imitating it, or when imagining performing it while remaining perfectly still. The relational character of behaviour as mapped by the cortical motor system enables the appreciation of purpose without relying on explicit propositional inference.

Altogether, these findings led to the formulation of the “Motor Cognition” hypothesis as a crucial element in the emergence of social cognition ([Gallese 2009](#)). According to this hypothesis, cognitive abilities like the hierarchical representation of action with respect to a distal goal, the detection of motor goals in others' behaviour, and action anticipation are possible because of the peculiar functional architecture of the motor system, organized in terms of goal-directed motor acts. Traditionally, the relation between actions and their outcomes is assumed

to be largely independent of the motor processes and representations underpinning action execution. Such processes and representations allegedly concern elementary motor features such as joint displacements or muscle contractions only. However, solid empirical evidence challenged this view. Motor processes may involve motor representations of action goals (e.g., to grasp, to place, etc.), and not only kinematic or dynamic components of actions. This suggests that beliefs, desires, and intentions are neither primitive nor the only bearers of intentionality in action. We do not necessarily need to metarepresent in propositional format the intentions of others to understand them. Motor outcomes and motor intentions are part of the “vocabulary” that is spoken by the motor system. On occasion we do not explicitly ascribe intentions to others; we simply detect them. Indeed, we posit that motor representation is enough to ground the directedness of an action to its outcome ([Gallese 2000](#), [2003b](#); [Butterfill & Sinigaglia 2014](#); compare also [Gallagher's 2005](#) notion of direct perception).

One of the consequences of the discovery of mirror neurons was the possibility of deriving subjectivity from intersubjectivity at the subpersonal level of description. The sense of self is precociously developed, beginning from a self that is first of all physical and bodily, and which is constituted precisely by the possibility of interacting and acting with the other. Embodied simulation can provide the neurobiological basis for early forms of intersubjectivity, from which the sense of the self is built. The discovery of mirror neurons and the simulation mechanism would therefore seem to further stress that being a self also implies being with the other. The model of intersubjectivity suggested by mirror mechanisms and embodied simulation correlatively sheds new light on the subjective dimension of existence. Let us see first what type of intersubjectivity mirror neurons seem to suggest.

The discovery of mirror neurons gives us a new empirically-grounded notion of intersubjectivity connoted first and foremost as intercorporeality—the mutual resonance of intentionally meaningful sensorimotor behaviours. The ability

to understand others as intentional agents does not *exclusively* depend on propositional competence, but it is highly dependent on the relational nature of action. According to this hypothesis, it is possible to directly understand the meaning of other people's basic actions thanks to a motor equivalence between what others do and what the observer *can* do. Intercorporeality thus becomes the main source of knowledge that we have of others. The motor simulation instantiated by neurons endowed with "mirror properties" is probably the neural correlate of this human faculty, describable in functional terms such as "embodied simulation" (Gallese 2003a, 2005, 2011; Gallese & Sinigaglia 2011b).

Action constitutes only one dimension of the rich baggage of experiences involved in interpersonal relations. Every interpersonal relation implies the sharing of a multiplicity of states like, for instance, the experience of emotions and sensations. Today we know that the very nervous structures involved in the subjective experience of emotions and sensations are also active when such emotions and sensations are recognized in others. A multiplicity of "mirroring" mechanisms is present in our brain. It was proposed that these mechanisms, thanks to the "intentional attunement" they generate (Gallese 2006), allow us to recognize others as our fellows, likely making intersubjective communication and mutual implicit understanding possible. The functional architecture of embodied simulation seems to constitute a basic characteristic of our brain, making possible our rich and diversified intersubjective experiences, and lying at the basis of our capacity to empathize with others.

4 Body and self

After having delineated a deflationary neurobiologically-grounded account of basic aspects of intersubjectivity, namely an account focused on the minimal core mechanisms of intersubjectivity, let us now address the relationship between body and self. A minimal manifestation of the sense of self can already be identified in our first bodily experiences, and this highlights the potential contribution of bodily experiences to

its constitution. Some aspects of the minimal self proposed by contemporary philosophical and empirical research are the notion of first-person perspective, the "mineness" of the phenomenal field (*Meinigkeit*), embodiment of point of view, and issues of agency and body ownership (Cermolacce et al. 2007).¹² On the philosophical side, phenomenology emphasizes the necessity of embodiment of the self for all the above-cited aspects of self experience. As argued by Cermolacce et al. (2007, p. 704, footnote 3), in phenomenology

the field of experience is not yet considered to be subjective because this predicate already implies that there is a subject. For phenomenology, the very idea of the subject articulates itself in experience. In this sense, the manifestation and appearing of experience are the conditions for the experience of the subject in question.

This philosophical standpoint has important implications for the empirical investigation of the neural correlates of the self.¹³ Rather than empirically addressing the self by starting with a search for the neural correlates of a pre-defined, explicit, and reflective self-consciousness, we believe it to be more productive to investigate what set of constitutive conditions allows an implicit and pre-reflective sense of self to emerge, and how this is effected. The interesting questions to be first answered are: "What enables the basic experience of ourselves as bodily selves? What enables us to implicitly distinguish ourselves, as bodily selves, from other human bodily selves?" In the following we review and discuss recent empirical evidence providing preliminary answers to these questions.

¹² Again, for sake of concision, we do not deal here with the relationship between the notion of a core, minimal self as a bodily self and agency and body ownership. On this topic, see Gallese & Sinigaglia (2010, 2011a). Moreover, it is worth noting that the arguments proposed in this section in relation to the notion of a minimal bodily self could be applied to other non-human animals. The possibility that high-level self-awareness can emerge from a primitive and non-conceptual form of self-awareness, and that it is possible that we share this basic level of the sense of self with other non-human animals, has already been discussed. For a discussion of this and other related topics see Bermúdez (2003).

¹³ See Vokey et al. (2003) and Vokey et al. (2004) for an investigation of the neural correlates of the first-person perspective.

The relationship between the minimal sense of self and the cortical motor system was recently revealed. The motor experience of one's own body, even at a covert level, allows an implicit and pre-reflective bodily self-knowledge to emerge, leading to a self/other distinction. Indeed it was recently shown that in a task in which differently rotated static pictures of right and left human hands were presented, participants who had to determine whether each observed hand was the right or the left one produced faster responses when observing the pictures of their dominant hand with respect to others' hands (Ferri et al. 2011). However, when participants were asked to explicitly discriminate between their hands and the hands of others, the self-advantage disappeared. Implicit and explicit recognition of the bodily self dissociated: only implicit recognition of the bodily self, mapped in motor terms, facilitated implicit bodily self-processing.

A subsequent fMRI study by Ferri et al. (2012), using a similar hand mental rotation task, demonstrated that a bilateral cortical network formed by the supplementary and pre-supplementary motor areas, the anterior insula, and the occipital cortex was activated during processing of participants' own hands. Furthermore, the contralateral ventral premotor cortex was uniquely and specifically activated during mental rotation of the participants' own dominant hands. The ventral premotor cortex might represent one of the essential anatomo-functional bases for the motor aspect of bodily selfhood, also in light of its role in integrating self-related multisensory information. This hypothesis is corroborated by clinical and functional evidence showing its systematic involvement with body awareness (Ehrsson et al. 2004; Berti et al. 2005; Arzy et al. 2006). This evidence demonstrates a tight relationship between the bodily self-related multimodal integration carried out by the cortical motor areas, specifying the motor potentialities of one's body and guiding its motor behaviour, and the implicit awareness one entertains of one's body *as* one's own body and of one's behaviour *as* one's own behaviour. Because the ventral premotor cortex is anatomically connected to visual and somato-

sensory areas in the posterior parietal cortex and to frontal motor areas we hypothesize that premotor cortex activity, by underpinning the detection of congruent multisensory signals from one's own body, could be at the origin of the experience of owning one's own body parts.

This minimal notion of the self, namely the bodily self as power-for-action (see Gallese & Sinigaglia 2010, 2011a), tacitly presupposes ownership of an action-capable agentive entity; hence it primarily rests upon the functionality of the motor system. As we just saw, empirical evidence supports the neural realization of this implicit aspect of selfhood in the brain's motor cortex. Since the minimal bodily self rests neurally on the motor system, it logically follows that characteristics of the latter are defining for the former. This implies that one could attribute to the minimal bodily self known features of the motor system, including its capacities and limitations. The motor aspects of the bodily self provide the means to integrate self-related multimodal sensory information about the body and the world with which it interacts. This is also important from a theoretical point of view, because it opens the possibility of linking the openness of the self to the world to the motor potentialities its bodily nature entails.

One could then posit that the minimal bodily self when conceived in terms of its motor potentialities has a dual function. On the one hand, it constitutes important aspects of the basic sense of self. On the other, it shapes our perception and pre-reflective conception of others as other selves incarnated in a motorly-capable physical body with capacities and experiences similar to ours. Through mirror mechanisms and embodied simulation, others appear to us as second selves, or second persons. We believe that this perspective provides a more vivid experience of intersubjectivity, relative to the detached, propositional deliberation on the experiences of others available in standard mind reading of others.

5 Body and language: Reflexiveness

According to the perspective so far delineated, body, actions, and feelings play a direct role in

our knowledge of others. The question remains open as to whether our propositional representations are totally separate from this bodily dimension. Our hypothesis is that they are not. But it remains a fact that linguistic and bodily cognition afford us diversified modalities of epistemic access to the world, even though often such modalities contaminate one another and are inevitably interwoven.

The mind, from the perspective delineated here, is therefore an embodied mind, though it would be more correct to speak of a corporeal mind. The concept of embodiment can induce one to think that a mind pre-existing the body can subsequently live in it, and use it. The truth is that mind and body are two levels of description of the same reality, which manifests different properties according to the chosen level of description and the language employed to describe it. A thought is neither a muscle nor a neuron. But its contents, the contents of our mental representations, are inconceivable without our corporeity. Likewise it is difficult to imagine how the representational format of a propositional type can have developed without our corporeality. Language somehow allows us, as we will see, to transcend our corporeity; nevertheless, we posit that the bond with the body is always present.

A few years ago, [Gallese \(2000\)](#) proposed that we look at the evolution of human language as an exaptation¹⁴ of functional sensorimotor processes, which put them into the service of human linguistic competence. The hypothesis of exaptation was then developed in subsequent papers and later elaborated in terms of “neural exploitation” ([Gallese & Lakoff 2005](#); [Gallese 2008](#)), or “neural reuse” ([Gallese 2014](#)). “Neural exploitation” consists in the reuse of neural resources, originally evolved to guide our interactions with the world, to serve the more recently evolved linguistic competence. This notion of reuse implies a functional uncoupling of the sensorimotor system from muscular output, to guide the generative-syntactic aspects of language by functionally connecting it to the pre-

frontal and, more generally, non-sensorimotor circuits. According to this view, intentionality, the aboutness of our representations, is—in the first place—an exapted property of the action models instantiated by the cortical motor system ([Gallese 2000](#), p. 34). The sensorimotor system, when uncoupled from muscular output, makes available to us a model, or paradigm, of our motor knowledge. As such, not only it houses causative properties but also content properties. And this relation to a content, or aboutness, is a primitive expression of intentionality, then exploited by other forms of representations. This perspective on reuse is acquiring more and more supporters (see [Dehaene 2005](#); [Anderson 2010](#)).¹⁵

Compelling evidence shows that humans, when processing language, activate the motor system both at the phono-articulatory and at the semantic level. When listening to spoken words or looking at someone speaking to us, our motor system simulates the phono-articulatory gestures employed to produce those very same words. Furthermore, processing action-related linguistic expressions activates regions of the motor system congruent in somatotopic fashion with the processed semantic content. Reading or listening to a sentence describing a hand action activates the motor representation of the same action (for a review, see [Gallese 2008](#); [Glenberg & Gallese 2012](#)). Interestingly, somatotopic motor activation has also been observed during the comprehension of abstract and figurative use of language such as metaphors and idioms (e.g., [Guan et al. 2013](#); [Boulenger 2012](#); see also [Gallese & Lakoff 2005](#) on the bodily foundation of concepts). However, it is important to note that embodied simulation is not always involved in language comprehension, and that there is no contradiction in saying this. There are cases in which language, at least at the content level, is not tied to any form of bodily knowledge. In such cases (e.g., when we talk about the notions such as moral judgement or intelligence) no embodied simulation is likely to be at play.

Nevertheless, the problems that language raises for the embodied perspective on human

¹⁴ Exaptation refers to the shift in the course of evolution of a given trait or mechanism, which is later on reused to serve new purposes and functions (see [Gould & Lewontin 1979](#)).

¹⁵ For a discussion of different views on the notion of reuse, see [Gallese \(2014\)](#).

social cognition are still enormous. As clearly underlined, among others, by the Italian philosopher [Paolo Virno](#) (2003, 2011), the common linguistic space shared by a community of speakers proves to be incommensurably different from the pre-linguistic one. The linguistic dimension is based on a distinction between linguistic utterances and facts about the world, be they referable to physical or psychological events. We can say that “today the sun is shining” and be understood, even if outside the window snow is falling. Or we can maintain that “all Italians want to pay taxes”, again being understood and simultaneously contradicted by the factual truth of the enormous tax evasion in our country.

According to Virno, the gap between meaning and denotation (what he calls the neutrality of meaning, namely the fact that the meaning of a word such as, for example, “man”, can be understood apart from any reference to an instance of man) is referable to linguistic reflexivity, i.e., to the fact that language refers to itself and that with words we can talk about other words. It seems to us that the reflexivity of language is a product of the symbolic nature of linguistic representations. The symbolic nature of such representations is what allows language to break away from the “here and now”; it is what allows the neutrality of meaning.

In order for a sign to be symbolic it necessarily has to be reflexive. What makes a sign a symbol is its being part of a system in which each term is correlatively defined in relation to the other terms within the system and in relation to the renegotiation of this relationship constantly taking place within the system itself. It is the use of a symbol within a given context that each time redefines relationships inside the language system.

Thus, symbolic relationships are by definition characterized by reflexivity. Symbols are defined through other symbols. This level of reflexivity is pre-theoretical; it emerges in the linguistic activity of each speaker and leads to a form of linguistic awareness of a practical character. This practical linguistic awareness has been called the *epilinguistic* quality and thus it

has been distinguished from the theoretical quality that is expressed in the metalanguage of linguistics ([Culioli 1968](#); [Lo Piparo 2003](#)). The concept of epilinguistic quality refers to the natural tendency of speakers to reflect on their own language—a tendency made possible by the distinctive quality of language being able to speak of itself.

The uniqueness of human language is also maintained by classical cognitivism and by cognitive linguistics, but for very different reasons. The otherness of human language in comparison with other systems of communication known in the animal world derives from its linguistic recursive quality. In an often-quoted article written some years ago ([Hauser et al. 2002](#)) defined the faculty of language in a narrow sense (FLN) as being expressed by recursivity. Nevertheless, this perspective, in addition to suffering from the usual cognitivist solipsism, is exposed to comparative verification in the animal world. If the FLN marks human linguistic uniqueness in terms of syntactic recursivity, the latter must be entirely absent in the extra-human animal kingdom.

Actually, the facts tell us exactly the opposite. Recent studies ([Gentner et al. 2006](#); [Abe & Watanabe 2011](#); see also [Margoliash & Nusbaum 2009](#); [Bloomfield et al. 2011](#)) have shown that singing species of birds like starlings or finches demonstrate, both in the production and in the reception of conspecifics’ vocalizations, the ability to produce and to extract recursive syntactic characteristics. The study by Abe and Watanabe also shows that the development of this competence is dependent on social encounters with the vocalizations of other conspecific individuals. Finally, these authors have shown that lesion of the lateral magnocellular nucleus of the anterior nidopallium, a motor structure comparable to the basal ganglia of primates, involved both in the production and the perception of song, prevents finches from discriminating the syntactic-recursive characteristics of the song they hear.

These results show that the best strategy for studying some of the most relevant aspects of human social cognition, even demonstrating the bases of their uniqueness, consists in a pre-

liminary recognition of the mechanisms and faculties that we share with the rest of the animal world. As maintained in the past (Gallese 2003b, 2008), the difference between human and nonhuman nature could originally have been of a quantitative rather than a qualitative nature.¹⁶

6 Body and language: Facts and challenges

One of the key challenges for the embodied approach to human social cognition consists in trying to understand whether and how our bodily nature determines some of our linguistic activities, such as denying, asking, or doubting, that seem to be exclusively human. Are linguistic activities as those ones anchored to bodily mechanisms? The question is open and empirical research must address this challenge in the coming years. In the meantime, at least at a purely speculative level, let us try to delineate a possible point of contact between the anthropogenic power of language and embodied simulation.¹⁷

There is indeed a way to connect the common pre-linguistic sphere to the linguistic one (Gallese 2003b, 2007, 2008; Gallese & Lakoff 2005; Glenberg & Gallese 2012). This consists in showing that language, when it refers to the body in action, brings into play the neural resources normally used to move that very same body. Seeing someone performing an action, like grabbing an object, and listening to or reading the linguistic description of that action lead to a similar motor simulation that activates some of the same regions of our cortical motor system, including those with mirror properties, normally activated when we actually perform that action.

These data on the role of simulation in understanding language (see Pulvermüller 2013 for a review of this topic) broadly confirm a thesis already discussed in the history of philosophy (for instance, by Epicurus, Campanella, Vico,

see Usener 1887 and Firpo 1940 or Condillaco 2001). The thesis in question claims for the bodily, sensory, and motor dimensions a constitutive role in language production and understanding. However, it seems that the relationship between language and body does not move in a single direction. The fact is that language is without doubts constitutive of human nature and, as such, it seems to offer us wholly human modalities of experiencing our corporeity.

In this sense, neuroscientific data on the role of simulation during understanding of language also lend themselves to a mirror and complementary reading with respect to that previously proposed. On the one hand it is plausible that embodied simulation might play a crucial role in understanding language. Indeed, if one reversibly interferes with this process, for instance by means of TMS stimulation, understanding of language is jeopardized. On the other hand, language allows us—and in this we are unique among all living species—to fix and relive specific aspects of our bodily experience. Through language we can crystallize and relive fragments of experiences that are not topical, that is to say are not *my* experiences *now*, but become a paradigm, a model, for understanding ourselves and others.

In the following section we discuss the role of embodied simulation seen as a *paradigm* or model in the light of the Aristotelian notion of *paradeigma*.¹⁸ For the time being it suffices to stress that the possibility of hypostatizing and then segments of our experiences independently of our immediate physical context, or independently of specific physical stimuli, is a possibility that only the possession of language allows us to experience. The faculty of language is therefore, on one side, rooted in corporeality but, in turn, changes and moulds our way of living bodily experiences.

7 Body and language: Embodied simulation as a paradigm?

The relation between body and language was to a great extent underestimated in the last cen-

¹⁶ According to this perspective, linguistic syntax could originate and be modelled upon syntactic motor competence, the latter being adapted and put at the service of the new linguistic competence (see Gallese 2007, 2008).

¹⁷ With the expression “anthropogenic power of language” we mean that the human nature, as we know it, depends on language.

¹⁸ For an earlier formulation of this hypothesis, see Gallese (2013).

tury, thanks, above all, to Chomsky's major influence. In 1966 Chomsky published a book significantly entitled *Cartesian Linguistics*. Descartes is the originator of the idea that language has little to do with the body.¹⁹ The Cartesian thesis on the relationship between language and body implies, on one side, that the body is not a substratum and material of language and, on the other, that language is exclusively a tool that expresses a thought formed independently of language itself. According to Descartes (1642) and the Cartesian tradition in which Chomsky stands, language is a tool through which we manifest an autonomous thought that precedes language—a thought structured by logic but certainly not by language, whose role is circumscribed and downsized to that of being a mere label of thoughts (cf. Hinzen & Sheehan 2013 for a critical discussion of the issue).

The theses informing the Cartesian idea of language are challengeable nowadays. Language makes meaning general, releasing it from the context, that is, from the dimensions of who, what, how, where, and when. Language, in other words, provides us with a unique modality of reference to the world, allowing us at the same time to transcend contingent determinations and to define them at a different level, thanks to the use of concepts like subject, object, time, space, universal, etc. It is perhaps not trivial to notice that such concepts correspond to precise grammatical structures and that, most likely, the use of a grammatically-structured language contributed, by co-evolutionary dynamics, to the structuring of rational thought characterized by such features (Hinzen & Sheehan 2013).

Hence, thanks to language we can speak of humankind without referring in particular to any of the single individuals sharing the property of belonging to the human species. We can speak of a subject aside from the individual embodiments of this attribute, etc. Language, as stressed by Virno, furnishes us with general meanings, that is, meanings valid

for everybody but, at the same time, meanings that do not necessarily denote a particular instantiation.

Interestingly enough, according to Giorgio Agamben (2008) what holds “for everybody and nobody” is referable to the Greek notion of *paradeigma*, originally explored by Aristotle. The *paradeigma* is a typical form of rhetorical reasoning that moves between individual and individual according to a form of bipolar analogical knowledge. Agamben (2008, pp. 23-24), radicalizing Aristotle's theses, maintains that the paradigm can only be conceived of by abandoning the dichotomy between individual and universal: the rule does not exist before the single cases to which it is applied. The rule is nothing but its own exhibition in the single cases themselves, which thus it renders intelligible.

By applying the notion of paradigm to the grammatical “rules” of language, Agamben touches upon a central point: the so-called linguistic rule derives from the suspension of the concrete denotative application:

[t]hat is to say, in order to be able to serve as an example, the syntagm must be suspended from its normal function, and, nevertheless, it is precisely through this non-operation and this suspension that it can show how the syntagm works, can allow the formulation of the rule. (Agamben 2008, p. 26)

To better explain the notions of rule and suspension of a denotative application, Agamben refers to Latin declensions. When we want to learn the first declension we inflect a noun, for example “*rosa*”, “*rosae*”, etc... In so doing, we are suspending the usual denotative application of this noun and, by means of this suspension, we are showing how the declension works. According to Agamben, “[...] in the paradigm, intelligibility does not precede the phenomenon, but is, so to speak, ‘alongside’ it (*parà*)” (2008, p. 29). In other words “[...] in the paradigm there is not an origin or an *arché*: every phenomenon is the origin, every image is archaic” (Agamben 2008, p. 33).

¹⁹ It is worth noting that Descartes also defended the related thesis that animals don't have soul exactly because they do not have language. Cf. Descartes (1637).

On Agamben's reading, the Aristotelian *paradeigma* is a good model for describing the creation of linguistic rules. Starting from Agamben's intuition and seeking to move one step further, the hypothesis that we want to explore here is that the notion of *paradeigma* is a good model not only for the creation of linguistic rules but also for the definition of the embodied simulation mechanism. In this connection, simulation allows us, at a sensorimotor level, to hypostatize and reuse what holds "for everybody and nobody".

To understand to what extent the analogy between embodied simulation and *paradeigma* works it is necessary to go back to Aristotle. What is meant by *paradeigma* in Aristotelian thought and in what context does Aristotle make use of this notion?

The *paradeigma*, as already anticipated, is a typical is a typical argument form used to persuade and devoted to the discussion of "things that can be otherwise." Aristotle discusses this argument form, which does not have any demonstrative aim, both in *Prior Analytics* and in *Rhetoric*. Argumentation based on the *paradeigma*, for example, consists in the presentation by the orator of an exemplary case, based on a historical fact or a figment of the imagination, as in the case of fables. It is the juxtaposition of the present situation and an exemplary one that guides, or should guide, the actions of the person to whom the argumentation is addressed. Thus the *paradeigma*, among rhetorical argumentations, is that which goes from the particular to the particular, from an exemplary case to the present situation. Argumentation based on the *paradeigma* does not make a claim for universality. The orator is not bound to offer an exhaustive number of cases justifying a universally valid conclusion. One case is sufficient, provided that it is particularly suitable, and precisely exemplary, in relation to the context in which the argumentative discourse takes place.

For these reasons, though resembling inductive reasoning (*epagoghé*), which proceeds from the particular to the universal, and indeed considered by Aristotle himself as the transposition of inductive reasoning to the rhetorical

sphere, the *paradeigma* conquers its own autonomous space. To confirm this, one need only to think that in *Prior Analytics* Aristotle (Ross 1978) devotes two separate chapters to paradigm and induction: respectively XXIV and XXI of Book II.

On the one side the *paradeigma*, which proceeds "from the part to the part" (*Prior Analytics* 69a, 15), are peculiar aspects distinguishing it from the *epagoghé*; on the other, it is by all means a form of induction, as Aristotle expressly affirms at the start of Chapter XX of Book II of *Rhetoric*. According to Piazza (2008, p. 117) there are at least two reasons why the *paradeigma* can still be considered a form of *epagoghé*, despite the peculiarities that characterize it. Both these reasons seem interesting, not only for the definition of paradigm that, starting from Aristotle, Agamben discusses in relation to linguistic praxis, but also and above all in the framework of a reflection on the mirror mechanisms enacted in embodied simulation.

Following Piazza's (2008, p. 117) reading of Aristotle, the first of the characteristics of inductive reasoning also found in the *paradeigma* consists in always proceeding from what is "best known and first for us" (Aristotle, *Analytica posteriora* II.19), or from what is for us most immediate and most easily accessible, because being part of our baggage of experiences and knowledge. The second characteristic is, instead, identifying similarities between particular cases.

At another level of analysis, both these features also characterize embodied simulation. One condition for the simulation mechanism's being enacted is sharing a baggage of (motor) experiences and knowledge. Embodied simulation is enacted starting from what for us is "first," i.e., what for us is known and easily accessible in terms of motor potentialities and experiences. Sharing a repertoire of practices, experiences, and sensations is therefore an essential condition, since only by starting from what is well known to us it is possible to identify analogies between our actions and others'. We understand the other starting from our own bodily experience, which is what is "best known and first for us", again using Aristotle's words. On

the basis of this knowledge we identify similar elements in our experiences as well as in those of others.

Embodied simulation, when manifested in the phenomenon of action, emotion, or sensation *mirroring* always involves an original I-thou relationship in which the “thou” is the term with respect to which the self is constituted. On the other hand, the “self” is the basis on which immediate and implicit understanding of the “thou” is possible.

The analogy with the cognitive mechanism subtended by paradigmatic reasoning appears evident. Indeed, in the case of Aristotle’s *paradeigma*, an example, a particular case, is understood because it is close to our feeling, our experiences, and our baggage of knowledge. And nevertheless the process does not stop here. This form of understanding of a particular that is not me will lead me to new conclusions and to a deeper understanding of myself, of *my* particular case, and of *my* situation. Our experiences are therefore the measure from which we understand others and their experiences (i.e., our previous actions, emotions, and so forth). And others’ experiences (i.e., their actions, emotions and so forth) are for us a condition for deeper understanding of ourselves. Thus, the embodied simulation underpinning my present experience is also a *paradeigma* from which I can understand what I observe in others and draw inferences from it for others and for myself.

The embodied simulation mechanism, thus defined, is constitutive of the process of construction of meaning. In this connection, embodied simulation enacted while understanding language is not my present experience but the *paradeigma* in relation to which some of our linguistic expressions acquire a meaning that is rooted in the body. When we read or listen to the description of an action, the process of simulation that takes place in us is not the enactment of the same action; we would be echopractic if we were unable to avoid imitating and reproducing all the actions that we see or whose description we listen to or read. According to our hypothesis, embodied simulation rather makes available to us an exemplary case, a

model, in relation to which understanding of language is also realized. If therefore it is true that the symbolic dimension opens up some possibilities for us and creates worlds for us that only linguistic creatures can enter, it is also true that language strongly exploits mechanisms rooted in our corporeality. Enactment of the simulation process in understanding language seems to suggest that the symbolic dimension and the bodily dimension cohabit in linguistic praxis.

Nevertheless, the nature of this relationship is still not entirely clear, nor is the confine between the bodily dimension and the typically or exclusively symbolic dimension. Can it be hypothesized that corporeal knowledge also plays a role in understanding logical operators such as, for instance, negation or disjunction, or that it plays a role in understanding the interrogative form? The whole symbolic nature of these linguistic structures appears in some respects beyond question. Research on these issues is now open (Kaup et al. 2006, 2007; Tettamanti et al. 2005; Christensen 2009; Tomasino et al. 2010; Liuzza et al. 2011; Kumar et al. 2013) and today many wonder about the possibility of identifying mechanisms that can anchor such structures to our bodily experience. We take this to be the real challenge for the embodied cognition approach to the role played by language in human social cognition.

Let us once more return to the Aristotelian notion of *paradeigma* and appraise other possible hints for substantiating the analogy with the embodied simulation mechanism. The understanding that the rhetor calls for through reasoning based on the *paradeigma* should lead the citizen to choose what is best for him in various circumstances. The goal of such reasoning is to determine understanding of a present situation, by analogy with a historical example or a fable, and, on the basis of this more informed knowledge, to guide the human being’s choices. In other words, the rhetorical example or *paradeigma* is knowledge whose main goal is practical and not theoretical.

A practical aim also characterizes embodied simulation. Embodied simulation is always aimed at “navigating” in the world and, there-

fore, eventually at acting. It was hypothesized that embodied simulation allows us a direct, experiential way of understanding other people's actions and experiences and, on the basis of this understanding, it allows us to regulate our actions and our experiences. These goals are always practical. In some respects, the process of embodied simulation that is enacted, for instance, when reading a novel (see Wojciehowski & Gallese 2011), also has a practical aim. Literature recreates a world of emotions and experiences: the emotions and the experiences of the literary characters inhabit the fictional world of the novel. The simulation mechanism helps us to "navigate" that world, even if it is a fictitious world; it allows us to understand and, in part, to relive the emotions of the protagonists and their vicissitudes. The aim in this case is practical insofar as the simulation mechanism allows us to approach the fictitious other with a second-person epistemic perspective (Gallese 2014).²⁰

Embodied simulation makes implicit knowledge about others immediately available, with the aim of regulating our interactions with them. Our understanding of the literary other is almost always second-person, based on the possibility of perceiving analogies between our own experiences and others' and made possible through a hypostatization of our experiences that is achieved through the simulation mechanism (Wojciehowski & Gallese 2011).

In the end, what is embodied simulation if not a suspension of the application of a process? Let us think of when mirror neurons are activated in observing actions performed by others; or of when canonical neurons are activated while we are looking at the keyboard of a computer thinking about what we want to write; or when cortical motor neurons are activated when we imagine ourselves writing on that keyboard. These responses on the part of motor neurons manifest the activation of implicit knowledge, that is, bodily motor knowledge expressing the motor potentialities of the bodily self mapped by the motor system in terms of their motor outcomes.

Reuse of motor knowledge, in the absence of the movement that realizes it, as exemplified by embodied simulation, is an example of "paradigmatic knowledge." Thus, embodied simulation is a case of implicit paradigmatic knowledge. According to our hypothesis, embodied simulation allows us to naturalize the notion of paradigm, anchoring it at a level of sub-personal description, whose neural correlates we can study.

Our openness to the world is constituted and made possible by a motor system predisposing and allowing us to adapt our daily and contingent pragmatic relationships with the world against the background of a prefigured but highly flexible plan of motor intentionality. Such a plan, intended as the sum of our motor potentialities, provides its coordination to any single contingent modality of relation with the world, that is, to any single action we perform, in which it continues to actualize itself. This aspect seems important to us because it shows how specific aspects of human social cognition are made possible and scaffolded upon processes not necessarily specific to humans, like embodied simulation.

8 Body and soul

It is improper, or at least it seems so to us, to say that the soul, the spirit, or intelligence are embodied. If it were so, we would thus return to a dualistic conception of human nature. Such dualism is always present in the tradition of Western thought, though it is often disguised in forms that, rightly or wrongly, are deemed politically more correct. Today nearly all cognitive scientists declare themselves to be monists and physicalists. Nevertheless, the conception still dominant today about the cognitive structure of humans and their functions draws a clear-cut and apparently unsolvable division between linguistic-cognitive processes and sensory-motor processes. It matters little that everybody admits that both are in some way referable to the biological physicality of the brain. The brain, according to classical cognitivism, is divorced from the body and conceived of as a box of algorithmic wonders.

Classical cognitivism sees the body as an appendix of little or no interest for decoding the supposed algorithms reportedly presiding over

²⁰ A second-person perspective is adopted in social contexts when, implicitly or explicitly, we re-use our own experiences to understand others. On the notion of second-person perspective see Pauen (2012).

our cognitive life. Such is a cognitive life with very little vitality, totally divorced not only from effectual reality, as we try to show here, but also from our daily phenomenal experience. It is not by chance that the language usually used to describe cognitive processes is borrowed from artificial intelligence: algorithms, information processing, etc.

Humans, however, cannot be assimilated to information-processing entities. Even less acceptable is the thesis that the concept of meaning is wholly assimilable to the concept of information. Classical cognitivism has maintained for decades that intelligence depends on the algorithms that substantiate it and not on the material substrata on which the algorithms themselves are believed to be implemented. This is the so-called principle of the multiple realizability of cognitive processes. Embodied Simulation and its relation to language and cognition casts severe doubts on this principle and adds arguments in support of the thesis that human cognition is tightly and necessarily dependent on the kind of body we have. As such, the mechanism of Embodied Simulation and the role it plays in human cognition provide further arguments in support of the idea that the principle of multiple realizability is false. We are who we are because we evolved by adapting to a physical world that obeys a series of physical laws, such as that of gravity.

As the art historian [Heinrich Wölfflin](#) wrote in his 1886 *Prolegomena zu einer Psychologie der Architektur*, if we were exclusively optical creatures, aesthetic judgment of the physical world would be precluded to us. Are the amazement and sense of elevation transmitted to us by the contemplation of a Gothic cathedral conceivable in purely algorithmic terms? Is it conceivable to divorce aesthetic experience from our daily muscular, tactile, and visceromotor experience of reality? Wölfflin (and together with him many others, among them Merleau-Ponty) maintained it was not, and we think that he was right.

We believe that our “natural” propensity to dualism is, on the one side, the product of our being asymmetrically positioned between mind and body, as [Helmuth Plessner](#) (2006) maintained. We are corporeal beings, but at the same time we

maintain that we *have* a body. On the other side, the account of the historical result of the progressive de-centralization of the anthropological dimension leads us to be dualist. We are no longer the living image of God, we are no longer at the centre of the universe, and perhaps in post-modern times we are no longer even subjects or selves. What are we left with but with the claim of the total otherness and discontinuity of our cognitive social life and its underlying processes? Their immaterial nature, or more exactly their total otherness in relation to a corporeity whose animal origin or essence is—evolutionarily speaking—pretty much clear, is perhaps the only way of reaffirming our uniqueness. The dualism between mind and body become, thus, a mechanism of defence. The so-called mental Rubicon that separates us from other non-human living beings is a very powerful anti-depressive argument for a disorientated humanity.

At this point, however, a clarification is required in order to avoid unpleasant misunderstandings. It is beyond doubt that the least intelligent among humans is incommensurably different and *other* in relation to the most intelligent among chimpanzees, despite their almost complete sharing of a genetic endowment. The point is that this quantum leap can be explained, perhaps, by remaining within an evolutionary framework that does not look for discontinuities founded on theories of “cognitive catastrophes,” genetic big bangs (as in the case of the so-called “grammar gene” invoked by Pinker), and so forth. The mysterious uniqueness—and loneliness—of humankind in the universe proves more comprehensible, or at least more easily approachable, if empirically investigated after having set aside the anti-continuist and self-consoling recipes of classic cognitive science. In our continuist approach, humankind is not special, because his evolution follows the same laws that regulate evolution of all other animals and is in continuity with evolutionary paths of other animals. However, our peculiar evolutionary path led us to acquire species-specific characteristics that only human beings share.

[Sigmund Freud](#) realized long before others how much the self is a bodily self (1923). Freud also helped us to understand how little we know

about who we are, particularly when aspiring to ground this knowledge solely on self-questioning rationality. What are the drives of which Freud spoke but a further manifestation of the double status of our flesh? We are *Körper* (objectual and represented body) and *Leib* (lived body), as Edmund Husserl maintained. Today cognitive neuroscience can shed new light on the *Leib* by investigating the *Körper*. The point is not to reduce the *Leib* to the *Körper*, but to understand that the empirical investigation of the *Körper* can tell us new things about the *Leib*.

9 Provisional conclusions

In this paper we addressed and discussed the notions of intersubjectivity and of the self as indissolubly intertwined outcomes of the bodily and symbolic dimensions. We proposed that embodied simulation seems to be able to naturalize the notion of paradigm, thus naturalizing one of the processes that makes language reflexivity possible, and thus contributing to “creating” the human being. Being a subject perhaps means being a body that learns to express itself and to express its world thanks to the paradigm—embodied simulation—that allows one to go beyond the body while remaining anchored to it. A new understanding of intersubjectivity can benefit from a bottom-up study and characterization of the non-declarative and non-metarepresentational aspects of social cognition (see Gallese 2003a, 2007).

One key issue of the new approach to intersubjectivity we proposed here is the investigation of the neural bases of our capacity to be attuned to the intentional relations of others. At a basic level, our interpersonal interactions do not make explicit use of propositional attitudes. This basic level consists of embodied simulation processes that enable the constitution of a shared meaningful interpersonal space. The shared intersubjective space in which we live from birth constitutes a substantial part of our semantic space. Self and other relate to each other because are opposite extensions of the same correlative and reversible we-centric space (Gallese 2003a). Observer and observed are part of a dynamic system governed by reversible

rules. By means of intentional attunement, “the other” is much more than a different representational system; it becomes a bodily self, like us.

This new epistemological approach to intersubjectivity has the merit of generating predictions about the intrinsic functional nature of our social cognitive operations, cutting across, and not being subordinated to a specific ontology of mind, like that purported by the classic cognitivist approach. Open questions that need to be further investigated in the future concern the biological mechanisms underlying our species-specific forms of self-knowledge and intersubjectivity. Language will have a special role in this investigation. To what extent and how are symbolic operations constrained by biological mechanisms? Is this connection between symbolic representations and bodily mechanisms that has been responsible for our specificity? These and other questions will be object of investigation in the next years

Multisensory Spatial Mechanisms of the Bodily Self and Social Cognition

A Commentary on Vittorio Gallese & Valentina Cuccio

Christian Pfeiffer

This commentary aims to find the right description of the pre-reflective brain mechanisms underlying our phenomenal experience of being a subject bound to a physical body (bodily self) and basic cognitive, perceptual, and subjective aspects related to interaction with other individuals (social cognition). I will focus on the proposal by Gallese and Cuccio that embodied simulation, in terms of motor resonance, is the primary brain mechanism underlying the pre-reflective aspects of social cognition and the bodily self. I will argue that this proposal is too narrow to serve a unified theory of the neurobiological mechanisms of both target phenomena. I support this criticism with theoretical considerations and empirical evidence suggesting that multisensory spatial processing, which is distinct from but a pre-requisite of motor resonance, substantially contributes to the bodily self and social cognition.

My commentary is structured in three sections. The first section addresses social cognition and compares embodied simulation to an alternative account, namely the attention schema theory. According to this theory we pre-reflectively empathize with others by predicting their current state of attention which involves predicting the spatial focus of attention. Thereby we derive a representational model of their state of mind. On this account, spatial coding of attention, rather than motor resonance, is the primary mechanism underlying social cognition. I take this as a theoretical alternative complementing motor resonance mechanisms.

The second section focuses on the bodily self. Comparison of the brain networks of the bodily self and social cognition reveals strong overlap, suggesting that both phenomena depend on shared multisensory and sensorimotor mechanisms. I will review recent empirical data about altered states of the bodily self in terms of self-location and the first-person perspective. These spatial aspects of the bodily self are encoded in brain regions distinct from the brain network of embodied simulation. I argue that while motor resonance might contribute to body ownership and agency, it does not account for spatial aspects of the bodily self. Thus, embodied simulation appears to be a necessary but insufficiently “primary” brain mechanism of the bodily self and social cognition.

The third section discusses the contributions of the vestibular system, i.e., the sensory system encoding head motion and gravity, to the bodily self and social cognition. Vestibular cortical processing seems relevant to both processes, because it directly encodes the world-centered direction of gravity and allows us to distinguish between motions of the own body and motions of other individuals and the external world. Furthermore, the vestibular cortical network largely overlaps with those neural networks relevant to the bodily self and social cognition. Thus, the vestibular system may play a crucial role in multisensory spatial coding relating the bodily self to other individuals in the external world.

1 Introduction

The paper by Gallese and Cuccio provides an integrated theoretical framework explaining how the brain and body relate to social cognition, the human self, and language. The authors review empirical evidence from electrophysiological and neuroimaging studies supporting embodied simulation (ES) theory (Gallese & Cuccio [this collection](#), p. 8). According to ES, the brain covertly simulates the bodily actions, perceptions, and emotions observed in other individuals by using parts of our neural architecture involved in acting, sensing, and feeling emotions. Thereby, we infer the goals, intentions, and states of mind of others in a pre-reflective and non-conceptual fashion. But the authors take this a step further and propose that ES is the key mechanism underlying, and hence unifying, both social cognition, the human self, and language. Throughout the paper, the authors emphasize the tight functional coupling between the body and the brain, which when taken into account bears the potential to significantly advance the scientific study of the hard problem of consciousness (Chalmers 1996).

This commentary on Gallese and Cuccio aims to find the right description of the brain mechanisms underlying pre-reflective aspects of both the bodily self and social cognition. Specifically, I will focus on Gallese and Cuccio's central claim that ES, based on motor resonance and neural processing in the motor system, is the primary brain mechanism underlying pre-reflective representations of the bodily self and social cognition (Gallese & Cuccio [this collection](#), pp. 8–14). I ask the following questions: Could there be an alternative theory or empirical evidence countering the claim of a primacy of motor resonance underlying social cognition and the bodily self? Which brain mechanisms in addition to motor resonance might contribute to pre-reflective aspects of social cognition and the bodily self? I will defend the following three theses:

(1) Social cognition and the bodily self depend on multisensory spatial coding, which is distinct from motor resonance.

Thus, motor resonance may be a necessary but insufficiently “primary” brain mechanism of social cognition and the bodily self (cf. section 1, 2).

(2) The brain networks underlying social cognition and the bodily self largely overlap. Specific functional associations exist (a) between motor resonance and body ownership/agency and (b) between multisensory spatial coding and self-location/the first-person perspective (cf. section 2).

(3) The vestibular system, i.e., the sensory system encoding head motion and gravity, might provide unique information used for multisensory spatial coding that relates the bodily self to other individuals and the external world. This is further suggested by the large overlap existing between the human vestibular cortex and the brain networks underlying the bodily self and social cognition (cf. section 3).

My commentary is structured in three sections. In the first section I shall compare ES to an alternative theory of social cognition that assigns priority to spatial coding of attention, rather than to motor resonance. I shall show that both theories bear the potential that their proposed brain mechanisms cooperatively work together in order to support social cognition. The second section addresses the bodily self. I shall review data from neurological patients and full-body illusion experiments, which highlight the importance of two spatial aspects of the bodily self not mentioned by Gallese and Cuccio, i.e., self-location and the first-person perspective. These spatial aspects of the bodily self depend primarily on multisensory integration and on cortical processing outside regions involved in ES. Furthermore, comparisons between the brain networks encoding the bodily self and social cognition show large overlaps, suggesting shared functional mechanisms. In the third section I propose that because multisensory spatial processing appears to be critical for

the bodily self and social cognition, important contributions may come from the vestibular system (Lenggenhager & Lopez [this collection](#)). I shall show that the vestibular cortical network largely overlaps with the brain networks underlying the bodily self and social cognition. I shall discuss potential contributions of vestibular cortical processing to these target phenomena and suggest directions for future research.

2 Is social cognition based on motor resonance or attention tracking?

Social cognition refers to cognitive processes, perceptions, and subjective experiences related to interaction with conspecifics. This section asks: Which are the brain mechanisms underlying pre-reflective aspects of social cognition? Could there be alternative theories and empirical evidence countering the primary role of motor resonance?

Gallese and Cuccio propose that social cognition mainly depends on ES based on motor resonance and processing of mirror neurons (see citations in [Gallese & Cuccio this collection](#)). Mirror neurons were initially discovered in fronto-parietal networks of the macaque monkey brain. They are a specific type of canonical neuron involved in planning and executing hand actions and were found to be activated both when the monkey executed a specific grasping or reaching action and when the monkey passively observed somebody performing similar actions ([Gallese et al. 1996](#); [Rizzolatti et al. 1996](#)). Neuroimaging studies in humans also showed mirror neuron-like activation patterns at the level of populations of neurons in distinct brain regions—mainly the ventral premotor cortex (vPM), the intraparietal sulcus (IPS), but also the insula cortex and the secondary somatosensory cortex ([Rizzolatti & Sinigaglia 2010](#); see also figure 1a gray dots). ES proposes that based on mirror neurons the brain maps observed actions into an action space, into motor potentialities, within our hierarchically-organized motor system, and thereby infers and predicts the action goals of the individual. In this way it penetrates the state of mind of the other, and thus links self and other in a pre-reflective

empathical fashion ([Gallese & Cuccio this collection](#), p. 7).

I would like to point out that motor resonance, i.e., the mapping of observed actions into motor potentialities, necessarily depends on multisensory spatial coding. I argue that this is the case because of five points: First, the brain has access to the physical world only through the different sensory receptors of the body that bombard it with exteroceptive (e.g., vision, audition), proprioceptive (somatosensory, vestibular), and interoceptive (somatosensory, visceral) signals. Second, these multisensory signals must be integrated according to their spatial and temporal parameters ([Stein & Stanford 2008](#)) to inform neural representations of the states of the body and of the world around us—including the agents whose actions are subject to motor resonance. Third, the observed movements of these agents are coded in coordinates distinct from the egocentric spatial frame of reference upon which our motor system operates. Fourth, the brain must necessarily perform spatial transformations of the observed movements by the other agent into the egocentric frame of reference, upon which motor resonance can operate. In sum, multisensory spatial coding is a pre-requisite of motor resonance.

According to Gallese and Cuccio, the outcomes of such multisensory spatial coding are readily available to the brain network of ES through anatomical connections to the vPM that are “anatomically connected to visual and somatosensory areas in the posterior parietal cortex and to frontal motor areas” ([Gallese & Cuccio this collection](#), p. 10). However, it seems that the multisensory spatial coding required for a precise description of complex motor acts might be computationally costly. Might there be a computationally more effective alternative by which multisensory spatial coding is used to decode the intentions of observed agents?

The attention schema (AS) theory of awareness ([Graziano 2013](#); [Graziano & Kastner 2011](#)) proposes that brain mechanisms related to attention and spatial coding, which are distinct from neural processing relevant to ES, primarily underlie pre-reflective aspects of social cognition. Graziano and Kastner define *atten-*

tion as an information-handling mechanism of the brain that serves to give priority to some information (e.g., representational features) out of several equally probable alternatives that are in constant competition for awareness. Furthermore, *awareness* is defined as the process of consciously experiencing something, it is the process of relating the subject (i.e., a phenomenal self, see also Metzinger 2003) to the object/content of experience. Graziano and Kastner summarize AS as follows:

[Awareness is information and] depends on some system in the brain that must have computed [it] [...]; otherwise, the information would be unavailable for report. [...] People routinely compute the state of awareness of other people [and] the awareness we attribute to another person is our reconstruction of that person's attention. [...] The same machinery that computes socially relevant information [...] also computes [...] information about our own awareness. [...] Awareness is [...] a perceptual model [...] a rich informational model that includes, among other computed properties, a spatial structure. [...] Through the use of the social perceptual machinery, we assign the property of awareness to a location within ourselves. (Graziano & Kastner 2011, pp. 98–99)

Related to social cognition, AS proposes that by using a schematic representation of the state of attention of other individuals—including a prediction of the spatial location of their focus of attention—we predict the current state of awareness of the individual, which is informative about their intentions and potential future actions. In short: Awareness of others is an attention schema. As compared to ES, AS is a relatively recent theory that requires extensive empirical studies. Yet the evidence so far shows that indeed the brain has a neural circuitry for monitoring the spatial configuration of one's own attention independent of the sensory modality (Downar et al. 2000), including the direction of gaze (Beck & Kastner 2009; Desimone &

Duncan 1995). These structures are the proposed neural expert system upon which AS is based and consist of the right-hemispheric temporo-parietal junction (TPJ) and superior temporal sulcus (STS) (see figure 1a in black). Notably, this expert system relevant to AS shows little anatomical overlap with the neural structures relevant to ES (figure 1a compare black with gray).

Because the AS relies on coding of the spatial relationship between the location of the observed individual and the likely spatial location of this individual's attention (i.e., independent of a particular sensory modality), the required spatial computations seem simple and straightforward. They require two points, i.e., the individual as a reference point and the potential spatial location of the attention of that individual. According to AS, using such spatial labeling the brain is able to simultaneously track the aware and attending minds of several individuals simultaneously. Thus, spatial coding in the context of AS appears to be less complex and less computationally demanding than spatial transformations underlying ES (see above).

Which of these seemingly distinct brain mechanisms proposed by AS and ES more plausibly underlies social cognition: the neural expert system decoding the state of attention according to AS or the mirror mechanism system decoding observed motor plans according to ES? It has been proposed that AS and ES may in principle work together. Graziano and Kastner propose that the expert system of AS may take a leading role by formulating a hypothesis about the state of awareness of an individual that is likely to drive further behavior and therefore provide a set of predictions based upon which motor resonance could more efficiently perform simulations (Graziano & Kastner 2011). Motor resonance would thus add richer detail to the state-of-attention hypothesis made by the expert system.

This combined mechanism is compatible with the predictive processing principle (Clark this collection; Hohwy 2013, this collection), which has been proposed relevant to the bodily self (Apps & Tsakiris 2013; Limanowski &

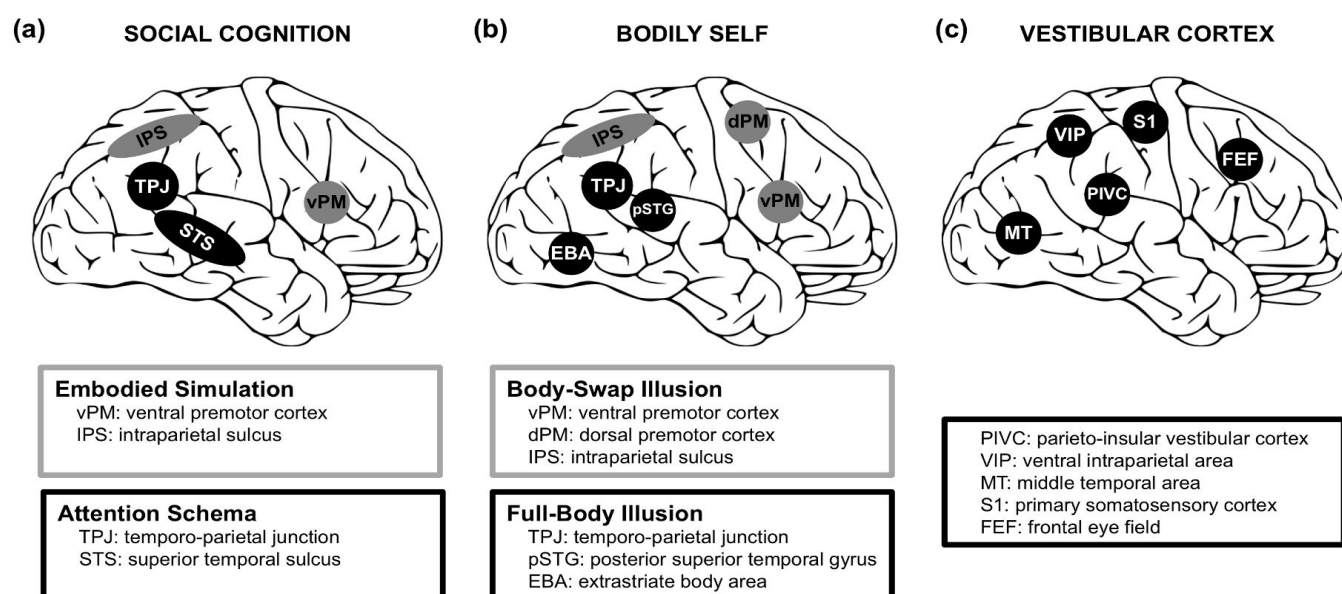

Figure 1: Summary of cortical brain regions involved in social cognition, the bodily self, and vestibular processing. (a) Whereas for social cognition there is little overlap between the brain regions proposed relevant for the attention schema (*in black*) and embodied simulation (*in gray*), both sets of brain regions overlap with (b) the brain network of the bodily self as identified by full-body illusion experiments manipulating self-location and first-person perspective (*in black*) and the body-swap illusion manipulating mainly body ownership (*in gray*). (c) The human vestibular cortical regions (*in black*) are widely distributed and overlap with several regions relevant to both the bodily self and social cognition. (The images are derived from images by NASA, licensed under creative commons.)

Blankenburg 2013; Seth this collection). According to *predictive processing* the brain constantly predicts the potential causes of sensory input by minimizing prediction errors via update of the predicted causes or by action that changes sensory input (Friston 2005). Applying the predictive processing principle to Graziano and Kastner's proposal that AS is a hypothesis-generating tool to which ES adds further detail, one could conceive of both mechanisms as different predictive processing modules aimed at anticipating the state of awareness and of intentional actions observed in others. Although no empirical study so far has addressed this specific hypothesis, a recent functional magnetic resonance imaging study found that predictive processing principles accounted for the blood oxygen-level dependent activity related to the perception of faces, which is an important perceptual function for social cognition in the human species (Apps & Tsakiris 2013).

These common and distinct predictions based on ES, AS, and predictive processing

call for empirical research aimed at providing evidence to further refine, integrate, or reject them.

3 Multisensory and motor mechanisms of the multifaceted bodily self

The *bodily self* refers to the phenomenal experience of being an experiencing subject (i.e., a phenomenal self) bound to a physical body, which gives rise to the dual nature of the body (Husserl 1950; Gallese & Cuccio this collection, p. 2). The unified experience of being a bodily self can be decomposed into different aspects, including the experience that we identify with a particular body (self-identification or *body ownership*), the experience that the self is situated in a specific spatial location (*self-location*), that we take a specific experiential perspective at the world (*first-person perspective*), and that we are the authors of our actions, including having control of attentional focus (*agency*; (Blanke 2012; Ehrsson 2012; Jeannerod 2003; Metzinger 2003).

In their paper, [Gallese & Cuccio](#) highlight the relevance of mirror mechanisms, in particular related to processing in the cortical motor system, to the sense of body ownership and the sense of agency, in particular in the context of action and action observation:

This minimal notion of the self, namely the bodily self as power-for-action [...], tacitly presupposes ownership of an action-capable agentive entity; hence, it primarily rests upon the functionality of the motor system. ([this collection](#), p. 10)

However, recent philosophy of mind and cognitive neuroscience research reveals the crucial role of *spatial aspects of the bodily self*, consisting of a first-person perspective and self-location. In this section I shall compare the brain network contributing to spatial aspects of the bodily self with the brain network underlying body ownership and ask: Do these neuroimaging results support the proposal that motor resonance is a primary mechanism underlying all aspects of the bodily self? What is the relationship between the neural networks of the bodily self and social cognition? Which functional associations can be derived from this?

3.1 Brain mechanisms of spatial aspects of the bodily self

The phenomenal experience of being a subject is associated with a spatial location, which typically is the space of the physical body (see also [Alsmith & Longo 2014](#); [Limanowski & Hecht 2011](#)). However, there are exceptions to these prototypical states of the bodily self in neurological disorders and experimental illusions pointing to a specific set of brain regions involved in spatially linking the phenomenal self to the physical body.

Which brain mechanisms link the phenomenal self to the physical body to give rise to the dual nature of the body as lived body and as physical object? Research in neurological patients who have had out-of-body experiences (OBE) shows that damage or interference with the right TPJ can lead to dissociations between

the bodily self and physical body ([Blanke et al. 2004](#); [Blanke et al. 2002](#); [De Ridder et al. 2007](#); [Ionta et al. 2011](#)). During an OBE, patients typically experience a disembodied self-location in elevation above their physical body, and an altered first-person perspective that originates from an elevated location in the room and is directed downwards at the physical body ([Blanke et al. 2004](#); [Metzinger 2009](#)). These patients do not identify with their physical body but with an illusory double outside of the borders of the physical body. At the phenomenological level, self-location and the first-person perspective are often experienced as having their spatial origin in the same position. However, during OBE there are instances where self-location can be dissociated from the first-person perspective in different sensory modalities ([De Ridder et al. 2007](#)). Further evidence from asomatic OBEs and bodiless dreams suggests that a phenomenal first-person perspective may be reducible to a single point in space ([Windt 2010](#)). In fact, vestibular hallucinations systematically preceded OBEs in patients with sleep paralysis, i.e., a motor paralysis characterised by the transient inability to execute bodily actions when waking up from sleep ([Cheyne & Girard 2009](#)), showing further dissociations of the spatial location of the bodily self and the physical body and links to sensory processing. These studies seem to suggest that the first-person perspective and self-location may depend on different neural mechanisms ([Blanke 2012](#)).

OBE in epileptic patients can be induced by subcortical electrical stimulation of a specific intensity at the TPJ. However, stimulating the same brain region with either lower or higher stimulation intensity induces bodily sensations (including vestibular, visual, somatosensory, kinesthetic sensations) without inducing an OBE ([Blanke et al. 2002](#)). These observations gave rise to the idea that the spatial aspects of the bodily self are based on the accurate integration of multisensory signals (i.e., which was perturbed by electrical stimulation in the patient in [Blanke et al. 2002](#), which are sensory signals from personal space to sensory signals from the external environment [Blanke et al. 2004](#)).

These clinical observations in patients were corroborated by different full-body illusion experiments in healthy subjects, such as the so-called “body-swap illusion” (Petkova & Ehrsson 2008; Petkova et al. 2011; van der Hoort et al. 2011), the “full-body illusion” (Ionta et al. 2011; Lenggenhager et al. 2009; Lenggenhager 2007; Pfeiffer et al. 2013; Pfeiffer, Schmutz & Blanke 2014), and the “out-of-body illusion” (Ehrsson 2007; Guterstam & Ehrsson 2012). In these experiments, healthy subjects receive conflicting signals about the spatial location of their body and of the temporal synchrony of exteroceptive and interoceptive signals, including somatosensory, cardiac, and vestibular signals that at the same time are applied to a virtual or fake body seen by the subject (Aspell et al. 2013; Ionta et al. 2011; Pfeiffer et al. 2013; Pfeiffer et al. 2014). For example, in the *full-body illusion*, synchronous stroking of a virtual or fake body seen from a distance can induce the feeling in participants that they are more closely located to the position of the virtual or fake body, and that they experience and increase of ownership for the seen body. The brain regions involved in these spatial experimental manipulations of the experienced bodily self most consistently involve the right TPJ region, but also draw on somatosensory and visual regions that process the sensory inputs (Blanke 2012; Ionta et al. 2011; figure 1b in black). Recently, several studies have manipulated visual and vestibular signals about the direction of gravity, affecting self-location and perspective and thus showing that those visual spatial cues affect our subjective experience of the first-person perspective (Ionta et al. 2011; Pfeiffer et al. 2013). These authors presented images on virtual-reality goggles showing visual gravitational cues, similar to the visual perspective during an OBE showing a scene from an elevated spatial location and a visual viewpoint directed downwards into the room. At the same time the somatosensory and the vestibular signals received by the participant, who was lying on the back, suggested that the physical body was oriented upwards with respect to veridical gravity. Thus the visual gravity cues (i.e., downwards) and the vestibular gravity cues (i.e., upwards) were in directional

conflict. When the full-body illusion was induced under these conflicting conditions, participants reported subjective changes in their experienced direction of the first-person perspective (upward or downward) in line with experimentally-induced multisensory conflict (Ionta et al. 2011; Pfeiffer et al. 2013).

3.2 Brain mechanisms of body ownership

A different brain network encodes experimental manipulations of another aspect of the bodily self: body ownership. This was shown by the *body-swap illusion* (Petkova & Ehrsson 2008; Petkova et al. 2011), during which the participant views from a first-person visual viewpoint the body of a mannequin or another person. Thus no conflict between the visual spatial coordinates of the participant’s physical body and the visually-perceived location of the mannequin is presented. However, conflicting sensory information about the shape, gender, size, or overall spatial context surrounding the virtual body were presented that typically prevented feeling ownership of the virtual body. If under these conditions visuo-tactile stroking on the abdomen of the participant and the virtual body was synchronously administered, an illusion of ownership for the body emerged, reflected in increased responses to threatening the mannequin. In different variants of the body-swap illusion subjects reported experiencing and adopting different sizes of both the virtual body and the contextual environment (Petkova & Ehrsson 2008; Petkova et al. 2011; van der Hoort et al. 2011). Neuroimaging experiments of the body-swap illusion show activation of the vPM and IPS regions, notably without involving actions made by subjects or performed by the virtual body (Petkova et al. 2011). These brain regions are key nodes of the mirror mechanism network of ES (see Serino et al. 2013). For a recent review see figure 1b.

3.3 A shared brain network of bodily self and social cognition

Although the neuroimaging evidence so far suggests that distinct brain regions encode the spa-

tial aspects of the bodily self and body ownership (Blanke 2012; Serino et al. 2013), the ensemble of those bodily self-encoding regions closely matches the brain regions relevant for social cognition (compare in figure 1a with figure 1b). These empirical data indeed suggest that the bodily self and social cognition are encoded by at least overlapping neural circuits supporting the proposal of ES that neural capacities to control and monitor the own body are used in understanding others.

These neuroimaging data suggest particular functional associations between different aspects of social cognition and the bodily self. In particular, the brain network of ES anatomically overlaps with regions encoding experimentally-induced changes in body ownership during the body-swap illusion (figure 1a–b in gray), which involves spatial congruence of the observational viewpoint and position of the fake body and the participant’s body. A second association can be observed between the brain network of AS and the brain regions encoding spatial aspects of the bodily self, as manipulated during the full-body illusion (figure 1a–b in black). During the latter, the position and observational viewpoints of the virtual body and the participant’s body are in spatial conflict, and thus closely resemble social interaction settings.

Based on these functional and neuroanatomical observations, I propose that ES seems to contribute to the bodily self and social cognition in a way primarily related to the sense of body ownership and agency. However, ES does not account for multisensory spatial representations that relate the physical body to the bodily self in space. These spatial aspects of the bodily self are encoded by brain regions outside of the brain network of ES, and rather resemble those brain regions relevant for coding the spatial configuration of attention (or awareness, according to AS).

Because two crucial aspects of the bodily self, i.e., self-location and the first-person perspective, are encoded in the TPJ region, and full-body illusions show that they can be manipulated without action or motor manipulations, it seems implausible that ES as based on

motor resonance is the primary brain mechanism underlying the bodily self. Instead, the brain networks coding self-location and the first-person perspective, which overlap with brain regions proposed to encode spatial aspects of an attention schema (see figure 1), seem to contribute to at least an equal degree to both the bodily self and social cognition. Thus, ES seems to be a necessary but insufficiently “primary” brain mechanism underlying the bodily self and social cognition.

I do not mean to imply that these are independent processes, because it is possible that they cooperatively work together (Graziano & Kastner 2011). However, I think that Gallese and Cuccio’s claim of a primacy of motor resonance underlying the multifaceted aspects of the bodily self and social cognition is questionable on empirical and theoretical grounds.

4 Vestibular contributions to the bodily self and social cognition

In the previous sections I have provided theoretical considerations and empirical evidence assigning a critical role to multisensory spatial processing in the neural computations underlying representations of the bodily self and social cognition. This section will further examine the multisensory mechanisms relating the space of the bodily self to other individuals and the external world. I propose that important contributions to the brain’s multisensory spatial coding might come from a particular sensory system, i.e., the vestibular system, which has often been neglected in studies of higher brain functions related to subjectivity and intersubjectivity. I will ask: What might be the functional contribution of the vestibular system to pre-reflective representations of the bodily self and social cognition? How does the human vestibular cortex relate to the neural networks of the bodily self and social cognition?

The *vestibular system* consists of sensory organs in the inner ear that sense accelerations of the head in space, including rotational and linear movement of the head and whole body and the constant acceleration of gravity on earth (Day & Fitzpatrick 2005). Vestibular sig-

nals are processed by subcortical and cortical structures (Angelaki & Cullen 2008; Cullen 2012; Lopez & Blanke 2011). Research initially focused on subcortical processing as related to gaze control, postural stabilization, and neural computations of head motion directions (Fernandez & Goldberg 1971; Goldberg & Fernandez 1971). More recently, studies have revealed the contribution of vestibular cortical processing to spatial cognition, body perception, and the bodily self (see Lenggenhager & Lopez this collection; Lopez & Blanke 2011; Pfeiffer et al. 2014 for reviews). These studies show that vestibular cortical processing is based on a neural network of distinct, distributed, and multisensory cortical regions. In distinction from any other sensory modality, there is no primary vestibular cortex that processes purely vestibular signals. Instead, a core vestibular cortical input region, the human parieto-insular vestibular cortex (PIVC; Lopez et al. 2012; zu Eulenburg et al. 2012), processes vestibular, somatosensory, and visual signals and is connected to a number of multisensory brain regions in the parietal, temporal, cingulate, and frontal regions (figure 1c).

The vestibular system contributes to spatial aspects of the bodily self. For instance, OBEs were associated with vestibular sensation, such as floating in elevation (Blanke et al. 2004; Blanke & Mohr 2005; Blanke et al. 2002), and vestibular sensations preceded OBEs in persons with sleep paralysis (Cheyne & Girard 2009). Other studies presented conflicting visual and vestibular signals about earth gravity during the full-body illusion and induced changes in the subjectively-experienced spatial direction of the first-person perspective and self-location (Ionta et al. 2011; Pfeiffer et al. 2013). Thus, it has been argued that vestibular cortical processing does not merely signal the motions of the own body and the external world, but is also constitutive of spatial aspects of the bodily self (Lopez et al. 2008; Pfeiffer et al. 2014).

Previously, Lopez et al. (2013), Deroualle & Lopez (2014), and Lenggenhager & Lopez (this collection) have argued that the vestibular system probably contributes to social cognition. I will briefly summarize their main ar-

guments and complement them with own points:

First, because the human species evolved under the steady influence of the earth's gravitational field, adaptation to gravity also framed and affected action, perception, and social interaction. More recently, research has shown that the brain hosts internal models of gravity, representing the effects of gravity on the motion of objects under the influence of gravity, of self-motion, of bodily actions, and of the direction of the gravitational acceleration. Those internal models of gravity strongly overlap with the vestibular cortex (Indovina et al. 2005; Indovina et al. 2013; McIntyre et al. 2001; Sciutti et al. 2012). More evidence for a vestibular contribution to social perception comes from studies showing the effects of gravitational signals on the perception of emotional faces (Thompson 1980) and the perception of the spatial orientation of bodies (Lopez et al. 2009).

Second, the vestibular system might contribute to social cognition because it detects head motions in space and hence directly enables us, when compared to other sensory signals, to discern movements made by our own body from motions of other individuals and motions of the external environment (Deroualle & Lopez 2014).

Third, mental spatial transformation of the own visual viewpoint to that of another person presents an important underlying cognitive aspect of social cognition (Furlanetto 2013; Hamilton 2009; Newen & Vogeley 2003; also cited by Gallese & Cuccio this collection, pp. 9–11). More direct evidence supporting this hypothesis comes from a recent study that showed that physical whole-body rotations, which stimulate the vestibular sensory organs, affected the ability of participants to perform mental spatial transformations (van Elk & Blanke 2013).

Fourth, I have argued in previous sections of this commentary that multisensory spatial coding is a critical prerequisite that underlies pre-reflective brain mechanisms of the bodily self and social cognition. Because the vestibular cortical processing has been strongly associated with multisensory integration (for review see Lopez & Blanke 2011), it is likely that vestibular

lar signals shape multisensory spatial coding relevant to the bodily self and social cognition (Deroualle & Lopez 2014; Pfeiffer et al. 2014).

Fifth, the distributed multisensory vestibular cortical network clearly overlaps with the neural structures involved in social cognition and the bodily self, which suggests that there is a functional contribution on the part of vestibular processing to these phenomena (compare figure 1c to 1a and 1b; compare also to Deroualle & Lopez 2014).

Together, these five points suggest that the vestibular system may be a promising candidate for future studies of the sensorimotor mechanisms of social cognition, which should motivate research on the intersection of vestibular cortical processing, mirror mechanisms, and intersubjectivity. These studies may, for instance, question how vestibular stimulation affects our ability to reconstruct the process of attention of another person, a function critical in the AS framework. Although the vestibular system is related to reflexive motor control, it is not clear whether it also affects motor resonance (see Deroualle & Lopez 2014 for a related proposal). One might ask whether vestibular processing facilitates or inhibits motor resonance and our understanding of intentional action observed in others. How about vestibular contributions to theory of mind and reasoning? On the other hand, does social interaction modulate vestibular functions, such as self-motion perception, postural stabilization, and gaze control? These questions address the role of vestibular processing in functional mechanisms relevant to the AS and ES frameworks. Furthermore, empirical research addressing the causal relationship between the AS and ES brain mechanisms and the bodily self and social cognition are needed, for instance by brain lesion analysis or direct brain stimulation.

5 Conclusion

At the beginning of this paper I asked which brain mechanisms underlie pre-reflective representations of the bodily self and social cognition. ES, based on motor resonance, substantially contributes to the representation of the bodily

self and social cognition. However, a unified theory of the neural basis of these target phenomena cannot assign a primary role to motor resonance. I have argued that multisensory spatial coding is at least of equal importance and probably more basic than ES in contributing to several key aspects of the bodily self and social cognition.

Specifically, I have argued that:

- (1) Social cognition and the bodily self depend on multisensory spatial coding, which is distinct from motor resonance. Thus, motor resonance may be a necessary but insufficiently “primary” brain mechanism of social cognition and the bodily self (cf. section 1, 2).
- (2) The brain networks underlying social cognition and the bodily self largely overlap. Specific functional associations exist (a) between motor resonance and body ownership/agency and (b) between multisensory spatial coding and self-location/the first-person perspective (cf. section 2).
- (3) The vestibular system, i.e., the sensory system encoding head motion and gravity, might provide unique information used for multisensory spatial coding that relates the bodily self to other individuals and the external world. This is further suggested by the large overlap existing between the human vestibular cortex and the brain networks underlying the bodily self and social cognition (cf. section 3).

A unifying theory of pre-reflective brain mechanisms of the bodily self and social cognition must be able to account for the empirical evidence reviewed here; and it seems that such a theory cannot exclusively depend on motor resonance. Multisensory spatial coding, motor mechanisms, but also representations of the process of attention appear highly relevant to bodily self and social cognition.

I agree with Gallese & Cuccio (this collection, pp. 3–7) that cognitive neuroscience cannot fully explore these exciting topics by limit-

ing itself to a specific neuroimaging method, such as functional magnetic resonance imaging. Instead, we should exploit multi-method approaches in search for correlative and causal evidence relating brain function and anatomy to the phenomenology of the bodily self and social cognition. The body, but also the spatial representation of the world around us, are relevant to understanding brain function, and when taken into account can lead to novel approaches to phenomenal analysis of subjective experience. But we should be careful in assigning priority to a single brain mechanism when aiming to explain the human self and intersubjectivity. Scrutiny and dialogue at the intersection of philosophy of mind and cognitive neuroscience are necessary in order to advance our understanding of the nature of the human mind.

Acknowledgments

I thank Thomas Metzinger, Jennifer Windt, and two anonymous reviewers for constructive comments on an earlier version of this commentary.

Embodied Simulation: A Paradigm for the Constitution of Self and Others

A Reply to Christian Pfeiffer

Vittorio Gallese & Valentina Cuccio

The main criticism Pfeiffer advances in his commentary is that our proposal is too narrow. Embodied simulation (ES), in his view equated to motor resonance, is not a sufficiently primary mechanism on which we can base a unified neurobiological theory of the earliest sense of self and others. According to Pfeiffer, motor resonance needs to be complemented by other more basic and primary mechanisms. Hence, as an alternative to our proposal, he suggests that multisensory spatial processing can play this role, primarily contributing to the earliest foundation of the sense of self and others. In our reply we stress on the one hand that identifying ES only with motor resonance is a partial view that may give rise to fallacious arguments, since ES also deals with emotions and sensations. We also show, on the other hand, that ES and multisensory integration should not be seen as alternative solutions to the problem of the neural bases of the bodily self, because multimodal integration carried out by the cortical motor system *is* an instantiation of ES. We conclude by stressing the role ES might have played in the transition from bodily experience to symbolic expression.

1 An overview of Pfeiffer's criticisms

We would like to thank Christian Pfeiffer for his very well-articulated commentary on our paper “The paradigmatic body: Embodied Simulation, Intersubjectivity, the Bodily Self, and Language” ([Gallese & Cuccio this collection](#)). His comments and criticisms offered us the opportunity to further reflect on some of the ideas

proposed in our piece. The aim of our paper was to discuss the role of the body in the constitution of the earliest and primary sense of self and others and, also, to emphasize the constitutive role of the body in a specifically human modality of intersubjectivity: language. To be more precise, we identified a biological mech-

anism, embodied simulation (ES), as a primary source of intersubjectivity, the sense of self, and language. The mechanism of ES is widely described in the paper and its role in human cognition is explained by also resorting to the Aristotelian notion of *paradeigma*.

The commentary offered by Christian Pfeiffer is focused on a partial aspect of our much wider proposal. In fact, the author only discusses the constitutive role motor resonance has for the sense of self and for social cognition. However, motor resonance is just one dimension of the mechanism of ES. As argued in our paper and elsewhere (see [Gallese & Sinigaglia 2011a](#); [Gallese 2014](#)) the mechanism of simulation is widespread in the brain and it also characterizes the nervous structures involved in the experience of emotions and sensations. All these dimensions of ES should be taken into account. To identify ES only with motor resonance is a partial view that may give rise to fallacious arguments.

The main criticism Pfeiffer advances in his commentary is that our proposal for the constitutive role of motor resonance is too narrow. ES, in his view equated to motor resonance, cannot be the primary neurobiological mechanism at the basis of both the sense of self and others. According to Pfeiffer, motor resonance needs to be complemented by other more basic and primary mechanisms. Hence, as an alternative to our proposal, he suggests that multisensory spatial processing can play this role, primarily contributing to the earliest foundation of the sense of self and others. To support this claim, he provides theoretical arguments and presents empirical data structured in three different sections. Each of these sections supposedly provides evidence of the role of multisensory spatial processing in the foundation of a bodily sense of self and others.

In the first section Pfeiffer addresses the issue of intersubjectivity and presents the Attention schema theory (AS). In his proposal, our ability to understand others is primarily based on a mechanism more primitive than ES-as-motor-resonance: spatial coding of attention. AS predicts that we understand the current state of awareness of our conspecifics by means

of schematic representations of their states of attention ([Pfeiffer this collection](#), p. 4). In other words, according to AS, by using a representation of the spatial relationship between the individual we are observing and the spatial focus of her/his attention we can likely predict his intentions and, as a consequence, his actions. [Pfeiffer \(this collection](#), p. 4) also discusses recent empirical findings on the neural structures underlying the AS. It seems that the neural structures for the spatial coding of attention are based in the right temporo-parietal junction (TPJ) and in the superior temporal sulcus (STS). These neural structures do not overlap with the neural circuits involved in ES.

In the second section Pfeiffer addresses the issue of the bodily foundation of the sense of self. The experience of being a bodily self can be decomposed into four different aspects ([Pfeiffer this collection](#), p. 5): body ownership, self-location, first-person perspective, and agency. According to Pfeiffer, motor resonance can account only for body ownership and agency, directly contributing to these (non-spatial) aspects of the bodily self. However, for the two spatial components of the bodily self we need a different account. In fact, according to Pfeiffer, empirical evidence suggests that these spatial aspects of the bodily self, which imply multisensory spatial representations, are encoded in a brain region, the TPJ, not characterized by motor resonance. Hence, motor resonance, while being still necessary for the bodily foundation of some basic aspects of the self, is not a sufficiently primary mechanism, since different neural structures are also needed for the bodily foundation of the self. In support of this claim, Pfeiffer discusses data from neurological patients with out-of-body experiences and other kinds of altered states.

Finally, in the third section the constitutive role of the vestibular system to the bodily foundation of both the consciousness of self and others is discussed. It is proposed that this system, which encodes gravity and head motion and is associated with multisensory spatial processing, significantly and primarily contributes to our ability to distinguish between motions of our own body and motions of other

people's bodies, in this way contributing to both the foundation of the sense of self and social cognition. Empirical studies are reported to support these claims. In addition, empirical data showing that the vestibular cortical network overlaps with neural structures underlying the bodily foundation of both the sense of self and others, as discussed in the two previous sections, are presented.

In the light of the empirical evidence discussed in his commentary, Christian Pfeiffer concludes that ES-as-motor-resonance is not a sufficiently primary mechanism on which we can base a unified neurobiological theory of the earliest sense of self and others. In the next section we answer these criticisms.

2 Responses

First, we would like to point out that ES is not confined to motor resonance of others' actions, like that instantiated by macaques' mirror neurons, as in humans ES also encompasses the activation of somatosensory areas during the observation of others' tactile experiences, the activation of pain-related areas like the anterior insula and the anterior cingulate cortex during the observation of others' pain, and the activation of the anterior insula and limbic structures like the amygdala during the observation of others' emotions like disgust and fear (see our paper, p. 9 and Gallese & Sinigaglia 2011a). Thus, motor resonance only describes one partial aspect of ES.

Two distinct arguments can be used to explain why we do not think that AS constitutes a valid alternative to ES, as argued by Pfeiffer. We certainly agree with Pfeiffer that shared attention, that is, the capacity to direct the gaze to an object gazed by someone else, is a basic ingredient of social cognition. Indeed, as maintained by Colwyn Trevarthen (1977), shared attention marks in human infants around 9 months of age the transition from primary to secondary intersubjectivity. However, shared attention constitutes only one aspect of intersubjectivity and social cognition, thus AS at best only covers a partial aspect of social cognition and therefore appears to be more limited than

ES in this respect. Furthermore, and most importantly, shared attention can be linked to motor resonance. Shepherd, Klein, Deaner, and Platt (2009) discovered in macaques a class of mirror neurons in the lateral intraparietal (LIP) area involved in oculomotor control, signaling both when the monkey looked at a given direction in space and when it observed another monkey looking in the same direction. These authors suggested that LIP mirror neurons for gaze might contribute to the sharing of observed attention. This evidence shows that shared attention is not divorced from motor resonance, but actually requires it.

A further argument in our opinion demonstrates that ES and AS should not be seen as alternative solutions to the problem of social cognition. Multisensory integration is a pervasive feature of parieto-frontal centers involved in sensory-motor planning and control. Indeed an influential theory about attention, the "Premotor Theory of Attention" (see Rizzolatti et al. 1987; Rizzolatti et al. 1994) states that spatial attention results from the activation of the same "pragmatic" circuits that program oculomotor behavior and other motor activities, even if such activation does not produce any overt motor behavior, thus qualifying as motor simulation.

We would like to emphasize even more strongly than we did in the paper that a crucial role of the cortical motor system is precisely that of integrating multiple sources of body-related sensory signals, like tactile, visual and auditory stimuli (see our paper, pp. 10–11; see also Gallese & Sinigaglia 2010, 2011b; Gallese 2014). The ventral premotor cortex (vPMC) might represent one of the essential anatomofunctional bases for the motor aspect of bodily selfhood, specifically because of its role in integrating self-related multisensory information. This hypothesis is corroborated by clinical and functional evidence showing the systematic involvement of vPMC with body awareness (Ehrsson et al. 2004; Berti et al. 2005; Arzy et al. 2006). This evidence demonstrates a tight relationship between the bodily self-related multimodal integration carried out by the cortical motor areas specifying the motor potentialities of one's body and guiding its motor behavior

and the implicit awareness one entertains of one's body as one's own body and of one's behavior as one's own behavior.

The vPMC is anatomically connected to visual and somatosensory areas in the posterior parietal cortex and to frontal motor areas and for this reason it is plausible to assume that vPMC activity reflects the detection of congruent multisensory signals related to one's own body parts: this mechanism could be responsible for the feeling of body ownership. The motor aspects of the bodily self-enable the integration of self-related multimodal sensory information about the body and about the world with which the body interacts, as epitomized by the properties of macaques' premotor neurons in area F4 (see [Fogassi et al. 1996](#); [Rizzolatti et al. 1997](#)) and the analogous functional properties displayed by the human homologue of area F4 (see [Bremmer et al. 2001](#)). The same neurons controlling the movement in space of the head or of the upper limb also respond to tactile, visual, and auditory stimuli, provided they are applied to the same body part, like tactile stimuli, or they occur in the body-part-centered peri-personal space, like visual and auditory stimuli. Thus, we think that ES and multisensory integration should not be seen as alternative solutions to the problem of the neural bases of the bodily self, because multimodal integration carried out by vPMC *is* an instantiation of ES. We agree with Pfeiffer, however, that other brain areas, like TPJ, might contribute to a coherent sense of one's own body. It must be added that TPJ is part of a network (including the posterior parietal cortex, and the premotor cortex) implicated in multisensory integration during self-related and other-related events and experiences. Indeed, as shown by [Ebisch et al. \(2011\)](#), the observation of others' affective tactile experiences leads to the activation of observers' vPMC and second somatosensory area and to the inactivation of observers' posterior insula. Functional connectivity revealed a significant interaction between the posterior insula, right TPJ, left pre-central gyrus, and right posterior parietal cortex during the observation of other's affective touch. These data suggest that TPJ might be involved in mapping the self-other dif-

ferentiation, by means of lower-level computational mechanisms for generating, testing, and correcting internal predictions about external sensory events.

Last, we agree with Pfeiffer that the vestibular system might contribute to the bodily foundation of both the consciousness of self and others and we thank him for having pointed this out, thus integrating our perspective.

3 Conclusions

It seems that the data discussed in the previous section allow us to come to the conclusion that ES is the primary and earliest mechanism contributing to the foundation of the sense of self and others. That said, in conclusion, we would like to stress again the issue of the cognitive role ES has in relation to language. Though the aspect of the relation between ES and language was not addressed in Pfeiffer's commentary, this was a central point of our proposal. The relation between ES and language is two-sided. On the one hand, empirical evidence has shown the role ES plays in language comprehension. These data (for an overview see [Gallese & Cuccio this collection](#), p. 13) suggest that the bodily, sensory, and motor dimensions play a constitutive role in language, both ontogenetically and phylogenetically. On the other hand, being linguistic creatures, we humans are the only living species able to fix and relive specific aspects of our bodily experiences by means of symbols. Words or other forms of symbolic representations such as art, for example, allow us to activate and relive our bodily experiences. In this way, by means of symbolic representations, we can share our bodily experiences, enacted by ES, even with people far away from us in time and space. As argued in our paper, ES is a model of our own experiences and its defining features are best explained by resorting to the Aristotelian notion of *paradeigma*. ES-as-*paradeigma* (and not just as motor resonance) provides a neurobiologically-based new perspective on human social cognition and ultimately on the very definition of human nature.

All the Self We Need

Philip Gerrans

I use evidence from psychiatric disorders involving the experience of depersonalisation to decompose the causal and cognitive structure of experiences reported as self-awareness. I combine insights from predictive coding theory and the appraisal theory of emotion to explain the association between hypoactivity in the Anterior Insular Cortex and depersonalization. This resolves a puzzle for some theories raised by the fact that reduced affective response in depersonalization is associated with normal interoception and activity in Posterior Insular Cortex. It also elegantly accounts for the role of anxiety in depersonalisation via the role of attention in predictive coding theories.

“Who is the I that knows the bodily me, who has an image of myself and a sense of identity over time, who knows that I have appropriate strivings?” I know all these things, and what is more, I know that I know them. But who is it who has this perspectival grasp? It is much easier to *feel* the self than to *define* the self ([Allport 1961](#), p. 128)

1 Preliminary remarks

I think Allport has it the wrong way round. It is easy to *define* the self, as he in fact does, as the thing that thinks, feels, perceives and has a sense of identity over time. It is hard, however, to find an entity that fits the definition. This is so even though, according to Allport, experiencing being a self is unproblematic (“it is easier to *feel* the

self”). In fact, the experience of being someone is actually very elusive, phenomenologically and conceptually. On some accounts self-awareness is actually the experience of *Being No-One*¹ ([Met-](#)

¹ Strictly speaking, the experience is not of being no one, since there is no one to be. Rather it is an experience we cannot help but take to be of being someone, even though there is no entity causing the experience.

zinger 2003). In this chapter I use disorders of self-awareness to develop an account of the experience which gives rise to the feelings referred to by Allport. In the final sections we shall see whether our experience is of being someone, no-one, or something other than a self. Perhaps a body. Or the process of thinking.

The conclusion is that self-awareness is *almost* a necessary or inevitable illusion when the mind is functioning smoothly. The experience of being a self is produced by mechanisms that compute the relevance of sensory (including, and especially, bodily) information to a variety of organismic goals represented at different levels of explicitness in a cognitive hierarchy. The computations relate information to those goals, *not to selves*. Those computations of goal relevance produce consequent bodily feelings. Those, and only those, feelings give us the phenomenal information we need to plan, remember, and interact with other people and the world as though we are unified selves. Thomas Metzinger argues that integration of information in experience amounts to the construction of a phenomenal avatar, which the brain uses to manoeuvre the organism through the world (Blanke & Metzinger 2009; Metzinger 2011). I agree, and the rest of the chapter can be seen as an attempt to anatomise that avatar. I use evidence from psychiatric disorders involving the experience of depersonalisation to decompose the causal and cognitive structure of experiences reported as self-awareness.

2 Introduction

So many psychiatric disorders are explained in terms of the way the patient experiences herself that, even if intuitive or philosophical theories which posit a self as the object of experience are not correct, there is an interesting phenomenon there to be explained. My idea is that the best integrative explanation of those disorders is *ipso facto* the best philosophical theory of self-awareness because those disorders cannot be explained other than via a model of the way the

experience is generated in normal and abnormal situations.² Once we have explained those disorders we can determine the theoretical utility of overlapping folk, clinical and philosophical conceptions of self-awareness. Thus, the approach I take is consistent with that proposed by Dominic Murphy in his plea for a (cognitive neuro) scientific psychiatry: “we arrive at a comprehensive set of positive facts about how the mind works, and then ask which of its products and breakdowns matter for our various projects” (2006, p. 105).

So until the concluding sections I use the term self-awareness to refer to the experience we report in terms of awareness of being a unified persisting entity: the same person at a time and over time. It may turn out that such experiences are illusions or misinterpretations of some other phenomenon, perhaps because there are no such entities as selves, but I delay that discussion until the evidence is assembled. To anticipate, I think the intuitive folk concept of self-awareness is very like the intuitive concept of episodic memory, which is of “re-experiencing” a previous episode. Cognitive neuroscience tells us that in fact episodic memory experiences are constructed to suit current cognitive context rather than retrieved intact. However it does no harm in everyday life to think of episodic memory as content-preserving retrieval of past experience. Similarly the intuitive conception of self-awareness tracks processes which, when they function harmoniously, produce experiences that provide a plausible basis for the concept of a unified and persisting self. That

2 In other words I take the strong view advocated by Murphy. The ontology of the mind *is* the ontology of cognitive science. The reason is that only with the correct theory of cognitive architecture in place can we understand how neural processes implement the cognitive processes whose operations we experience as personal-level phenomenology. That personal-level phenomenology provides the raw material for intuitive or folk explanations that abstract from cognitive and neural realization. But that abstraction is precisely why, as Halligan and Marshall once memorably said, in the absence of a suitably constrained cognitive model, psychiatry will be consumed by “the expensive and extensive search for non-existent entities” (Halligan & Marshall 1996, p. 6). I take the view that mechanistic (in the sense of neuroscientific) and phenomenological (based on reflection on the nature of experience) explanation are not independent projects. One *could* have a purely personal-level phenomenological ontology of mind. But the fact that such ontologies mislead about the sources of psychiatric disorder is a reason to search for an integrative theory. But the only way neuroscience can explain experience is via a detailed computational, cognitive theory.

There is no substantial Cartesian, or bodily, or neural, entity that sustains the properties ascribed by Allport. Thus part of Metzinger’s project is to explain why we feel as though we are substantial entities.

concept, while not entirely accurate, provides a useful ability to represent and communicate sufficient unity and persistence. If I tell you I will be happy to pick you up at the airport you need to be able to rely on *me* to be at the Arrivals gate. The precise nature of my (dis)unification as a single self is not relevant. If I told you I would send my body but would not be present myself you would phone a psychiatrist. (It would be super to be able to deputise your body to attend departmental meetings, weddings etc. on your behalf, wouldn't it?) Yet something like that phenomenon of alienation occurs in depersonalisation, as a deeply felt and distressing phenomenon. The difference in experience between people with depersonalisation and those without it is an essential *explanandum* both for psychiatry and for philosophers interested in the (possibly illusory) phenomenology of selfhood.

The rest of the chapter proceeds as follows. I first discuss the Cotard delusion, in which people say that they have died, disappeared or do not exist (*déire de négation*). The Cotard delusion raises a set of questions about the relationship between self-awareness, bodily experience, and affective processing. I outline some suggestive intuitive answers to these questions based on the phenomenology of the disorder but argue that they are insufficient as explanations. A deeper explanation is provided by the cognitive neuroscience of depersonalisation. That explanation relies on a theoretical framework that draws on

- I. The appraisal theory of emotion
- II. The simulation model of memory and prospection
- III. The hierarchical predictive coding model of cognitive processing

This framework allows us to explain how:

- affective experiences provide the basis for self-awareness as a distinct form of bodily awareness *moment to moment*
- those moment to moment experiences of self-awareness can be annexed to cognitive processes whose temporal reach is longer than

the present, creating the experience/illusion of a continuing self

- when affective processing is compromised the resultant experience is reported as change, or in extreme cases, loss, of self. Mere absence of bodily or affective response *per se* does not lead to depersonalisation. What leads to depersonalisation is the absence of *predicted* affective responses that normally constitute self-awareness that leads to depersonalisation. This explanation also provides a full explanation of an intriguing phenomenological observation made by Cotard about the role of anxiety in generating depersonalisation.

With this theoretical framework in place I discuss depersonalisation disorder and depersonalisation aspects of the Cotard delusion, resolving some of the questions raised by the initial phenomenological explanation.

Once those questions are answered we can make some comments on the theoretical utility of philosophical theories of self-awareness, which for convenience I classify into four types: Illusory Self, Fat Controller, Embodied Self, Narrative Self. The Illusory Self is a version of the Humean idea that self-awareness is either illusory or a theoretically loaded misdescription of some other experiential phenomenon (perceptual, interoceptive, emotional, somatic). It is quite consistent with the Illusory Self theory that the experience is a “necessary illusion” created by architecture installed by evolution. The Fat Controller theory is that self-awareness is the experience of a genuine *substantial* self, a locus of higher order cognitive integration and top down control (like the aptly-named Will Self's Fat Controller in his *Quantity Theory of Insanity*). Embodied Self theories identify self-awareness with forms of bodily awareness. Finally there are Narrative views of the self, thin and thick. On the thin view the self is a “centre of narrative gravity”, a fictive entity generated by the Joycean machine to organize and communicate. On thicker views the self is not a fiction but a genuine cognitive entity whose essence is to construct and communicate its own autobiography as an essential aspect of higher order cognitive control. The Thin view goes

naturally with the Illusory Self view: it explains the persistence of the Illusion, while the Thick view (naturally enough) fits well with Fat Controller views.

Cognitive neuroscience does not vindicate any of these theories. However this does not mean that we should regard the phenomenon of self-awareness as empirically disconfirmed. It turns out that there are cognitive processes that generate experiences with some of the properties ascribed by different theories under different conditions. So, as with episodic memory, rather than explaining self-awareness away, we can describe and explain the nature of the experiences reported as self-awareness in terms of the structure of the processing which generates it. Self-awareness is a cognitive illusion, based on the nature of affective processing. The relevant experience plays a crucial role in higher levels of cognitive control that organise and communicate experience in narrative form: fragments, episodes, chronicles, histories and epics (Currie & Jureidini 2004; Goldie 2011; Jureidini 2012). This conjunction of processes makes self-awareness an irresistible illusion. The nature and necessity of this illusion is shown by the nature of the disorders that arise when it fails.

3 The phenomenology of the Cotard syndrome

In their study of uncommon psychiatric syndromes Enoch & Trethowan (1991) provided a haunting clinical vignette. They described a patient who said that her body was decomposing and disappearing and that eventually she would be “just a voice”. Another patient suffering from the same condition described himself as a “dead star” orbiting an inert galaxy. The Cotard delusion, from which these patients suffer, was described by Jules Cotard in 1882 as a “*délire de négation*”, a delusion of inexistence (Cotard 1880, 1882, 1884, 1891; Debruyne et al. 2009). It is also described as a paradoxical belief that one is dead. The current cultural fascination with zombies provides the metaphor of “walking corpse” syndrome to describe the condition. However, as with many psychiatric disorders, perhaps the most telling descriptions and ex-

planations of the phenomenon were provided in the nineteenth century, in this case by Cotard himself. He described his patient thus:

Miss X affirms she has no brain, no nerves, no chest, no stomach, no intestines; there’s only skin and bones of a decomposing body. . . . She has no soul, God does not exist, neither the devil. She’s nothing more than a decomposing body, and has no need to eat for living, she cannot die a natural death, she exists eternally if she’s not burned, the fire will be the only solution for her. (Translation from Cotard 1880)

Cotard explained this delusion as a consequence of a particular type of psychotic depression “characterized by anxious melancholia, ideas of damnation or rejection, insensitivity to pain, delusions of nonexistence concerning one’s own body, and delusions of immortality” (Debruyne et al. 2009, p. 67).

More recently (Gerrans 2000, 2001; Debruyne et al. 2009) the delusion of inexistence has been explained as a consequence of the experience of depersonalisation. The delusion is a personal level response to an intractable and impenetrable loss of affective response to the world. Of course to say that an experience is of depersonalization is not an explanation but an intuitive characterization: the concept expresses the phenomenology of feeling disconnected from the world including one’s own body, as though experiences are “not happening to me”. Such feelings plausibly originate in what we might call affective derealisation: the failure of emotionally salient events to trigger affective responses in the patient so that the world feels strange and unreal. Since affective responses are a form of bodily experience it makes sense that the Cotard delusion is often expressed as beliefs about alteration in body state: in particular that the body is vanishing, disappearing or dead. And since there is an intimate connection between felt body state and self-awareness this loss of normal affective response is expressed as the idea that the self no longer exists.

But surely it is equally intuitively plausible that a person suffering from derealisation might express the experience by saying that the world (perhaps including her body) feels strange, emotionally inert or unreal? In other words, why does the patient not report derealisation, the feeling that the world is unreal? One possible answer is contained in the following suggestion:

Cases of the Cotard delusion have been reported . . . in which the subject proceeds beyond reporting her rotting flesh or her death to the stage of describing the world as an inert cosmos whose processes she merely registers without using the first-person pronoun....The patient does not recognize experiences as significant for her because, due to the global suppression of affect [ex hypothesi a consequence of extreme depression], she has no qualitative responses to the acquisition of even the most significant information. These extreme cases of the Cotard delusion are those in which neural systems on which affect depends are suppressed and, as a consequence, it seems to the patient as if her experiences do not belong to her. Thus the patient reports, not changes in herself, but changes in the states of the universe, one component of which is her body, now thought of as another inert physical substance first decomposing and finally disappearing. (Gerrans 2000)

My earlier self suggested that when the patient experiences global affective suppression she experiences her body as simply a body, a physical substance rather than the body which sustains the self or the body *qua* self: Hence the depersonalisation. However this simply begs the question. What is it about affective processing which transforms representations of body states to representations of states of a self?

4 Feelings of self-relevance

Appraisal theory is familiar to theorists of emotion as the theory that emotions are representa-

tions of the significance of events for the organism. Fear, for example, results from the representation of objects as dangerous for the organism. Early appraisal theorists assimilated these appraisals to beliefs about the properties of the objects of emotion (Kenny 1963; Solomon 1976, 1993). Consequently appraisal theory has been criticized as overly intellectualistic and as ignoring the felt aspect of emotion. Fear is a visceral state whose essence is a feeling, not a judgment, runs the objection. Equally an emotional feeling may arise or persist in the absence of, or in opposition to, a judgment.

Recent versions of the theory avoid this objection by recognising that most emotional appraisals are in fact conducted by neural circuits that automatically link perception to the automatic regulation of visceral and bodily responses. Consequently appraisals issue almost instantaneously in feelings that reflect the nature of that appraisal. When we recognize a familiar person and see her smile, for example, the significance of that information for us has been represented and that representation used to initiate our own bodily response within a few hundred milliseconds (Adolphs et al. 2002; Sander et al. 2003; Sander et al. 2005; N'Diaye et al. 2009; Adolphs 2010).

The consequence of these appraisals is autonomically-regulated body states and action tendencies that produce changes in visceral and bodily state. These changes are sensed as affective feelings via specialised circuitry that evolved to monitor organismic state. At any given moment we experience a “core affect” which is the product of multiple appraisals along different dimensions at different time scales.

These affective processes essentially represent the significance of incoming information for the organism along a number of different dimensions—hedonic, prudential, dangerous, noxious, nourishing, interesting, and so on. These representations, however, relate an aspect of organismic functioning to a represented object; they do not represent a self *per se*. The detection of danger alerts the organism to the need for avoidance, for example. The consequent feeling of fear is a way of sensing the bodily consequences of that appraisal. The self as an en-

tity need not be represented in either the initial appraisal or the consequent experience. The self-relevance (as appraisal theorists call it) of dangerous objects is however *implicitly represented* in the bodily experience of fear. The same is true of all affective experiences: they carry important information about the world and the way the organism is faring in it in virtue of the appraisal processes which generate them. But they do so without representing a self in any substantial sense. Rather they relate salient information to organismic goals represented at different levels of explicitness for different purposes (Tomkins 1962, 1991; Scherer 2004).

Cognitive neuroscience has identified circuits that function as “hubs” of distributed circuits that determine the subjective relevance of information. Lower-level hubs, of which the amygdala is a central component, implement rapid online appraisals (Sander et al. 2003; Adolphs 2010) and coordinate visceral and bodily responses. These lower level hubs associate affective experiences with online sensorimotor processing of the type often described as reflexive: that is initiated by, and dependent on, encounters with the environment. It follows that such experiences decay with the representation of the stimulus. They are stimulus dependent. Such reflexive affective processes can of course only sustain a feeling of self-relevance moment to moment.

5 Simulation, affective sampling, and the self

By self-awareness, however, philosophers have in mind the experience of being an entity that exists through time, which is not something that can be produced by reflexive processing. The organism needs to be able to represent itself, not just moment-to-moment but as an entity with a history and a future (“to consider itself the same thing at a time and over time”). It must therefore be able to link affective experience to memory and prospection in the same way as it links it to perception and sensory processing moment to moment. That is to say that it must be able to appraise episodes of memory and foresight for self-relevance.

Because the temporal window of human cognition extends beyond the present we have evolved systems that recapitulate important aspects of reflexive affective processing for those higher level cognitive processes involved in planning, recollection, prospection, and decision-making. These systems *simulate* temporally distant experiences by rehearsing some of the same perceptual and emotional mechanisms activated by the simulated situation. As a result we can recall previous episodes of experience and imagine future episodes of experience and link those simulations to other high-level cognitive processes in order to plan and decide. We remember being sunburnt and imagine getting skin cancer when deciding whether to go to the beach at noon (Gusnard et al. 2001; Buckner et al. 2008; Fair et al. 2008; Broyd et al. 2009).

These simulations are the raw material of autobiographical narratives whose structure and duration can vary depending on cognitive context. They may be as simple as recall of a single event that triggers a flash of affect, but can also be assembled into elaborate histories and imaginative rehearsals depending on the cognitive context. This narrative capacity provides a crucial aspect of cognitive control possibly unique to humans. The most important aspect of these simulations is sometimes overlooked in studies that emphasise their quasi-perceptual content. That is the fact that the simulation of perceptual and sensory experience evokes affective associations. We simulate a scene in order to evoke the affective responses that represent the significance of events and objects for us. When we imagine or recall an episode of experience its affective significance is also represented in experience via the offline rehearsal of affective processing. The ventromedial prefrontal cortex is a structure which “traffics” or makes available the affective information. In effect, the ventromedial prefrontal cortex recapitulates at a higher level the properties of the amygdala. In so doing it associates affective information with explicitly represented information used in reflective decision making and planning (Ochsner et al. 2002; Bechara & Damasio 2005). It thus allows the subject to make explicit reflective appraisals. When I lie on the beach I have pleas-

ant feelings produced by low-level appraisal systems. When I imagine or recall lying on the beach while trying to decide whether to holiday in Thailand or Senegal my ventromedial prefrontal cortex makes available the affective information prompted by that simulation.

This is why “pure” episodic memory studies (such as recall of content of visual scenes) do not activate the ventromedial prefrontal cortex, whereas “activations in the ventromedial PFC [prefrontal cortex] ... are almost invariably found in *autobiographical* memory studies” (Gilboa 2004, p. 1336; my emphasis). Gilboa (2004) suggests that this is because “autobiographical memory relies on a quick intuitive ‘feeling of rightness’ to monitor the veracity and cohesiveness of retrieved memories in relation to an activated self-schema.” This is consistent with studies showing activity in the ventromedial and related subcortical structures when people make intuitive (that is, rapid and semiautomatic) judgments about themselves. When people make judgments about themselves using semantic knowledge and symbolic reasoning, ventromedial structures are less active.

This idea is supported by studies of patients with lesions to the ventromedial prefrontal cortex. These patients oscillate between various forms of reflexive cognition and more abstract forms of thinking using semantic knowledge and procedural reasoning. What they have lost is the ability, provided by ventromedial structures, to simulate affective and motivational response in the absence of the stimulus, while they retain the ability to process information in an abstract way. Consequently, a ventromedial patient may be able to do a utility calculation about her personal future but be unable to act on that knowledge. It appears that semantic knowledge is motivationally inert. Such results are often used to emphasize the necessary role of affect in deliberation, but they also suggest that what those affective responses do is provide the necessary *personal* perspective on information. They make the information *mine*, so to speak. Furthermore, this diminishment is not just *at* a time, but over time. These patients, although not amnesic in the strict sense of the term, have very limited ability for

autobiographical recall or prospection. They have no sense of a persisting self (Damasio 1994; Bechara & Damasio 2005; Gerrans & Kennett 2010).

This suggests that disorders in which people feel a diminished sense of self would be characterized by hypoactivity in the ventromedial prefrontal cortex. In a review of the neuropsychological and imaging literature, Koenigs & Grafman concluded that “one could conceive of the VMPFC patients’ selective reduction in depressive symptoms as a secondary effect of a *primary lack of self-awareness and self-reflection*” (2009, p. 242; my emphasis). In other words, patients with ventromedial damage do not “feel” personally affected when considering even quite distressing events because they cannot access or activate the required affective responses.

It seems that “mine-ness” of experience is a cognitive achievement mediated by the ventromedial prefrontal cortex. As we noted above the ventromedial prefrontal cortex is suited to play this role because it recapitulates at a higher level many of the processing properties of lower-level hubs of emotional processing that represent self-relevance. Rather than reinvent the cognitive wheel for controlled processing, evolution has provided pathways that traffic affective and reward-predictive information processed automatically at lower levels to controlled processing coordinated by the ventromedial prefrontal cortex.

In effect, these studies suggest that in both online reflexive and offline reflective processing affective processes are needed to represent the significance of the information for the subject, and it is the consequent bodily feelings that produce the feeling of self-awareness. My version of this view is in some ways an amalgam of ideas found in Seth (2013) and Proust (2013). All three of us share the view that the mind is hierarchically organized, and that feelings of self-awareness emerge when higher order, metacognitive processes such as planning or deliberation integrate bodily information which signals relevance. On Seth’s and my view the Anterior Insular Cortex (AIC) is in some ways specialized for that function in view of its architecture: it does

not merely relay first order bodily information but is involved in the representation of the significance of that information. Thus it is well placed to be the source of some of the metacognitive feelings identified by Proust (2013) as serving crucial indicator functions.³

Affective processes represent the relevance of information for an organism and initiate suitable action tendencies and autonomic responses. The bodily consequences are sensed and summarised by specialised systems that inform the organism how it is faring in the world: this is affective information (Prinz 2004). This affective information is made available to other cognitive processes, which operate at different time scales, from instantaneous and automatic, to reflective and controlled. We are able to think and behave as continuing entities because the salience of information for different organismic goals is represented by affective processes at different time scales and levels of explicitness. An organism that can *use that affective information in the process* is a *self*.

This suggests that if the ability to access affective information is lost then self-awareness would also be diminished. Thus as we suggested above a key to the experience of depersonalisation in the Cotard delusion is the profound loss of affect associated with extreme depression. This suggestion is almost correct but it ignores another stage in the production of depersonalisation. After all, from what we have said so far affective processes represent the self-relevance of information. If the consequent feelings are unavailable the world should feel not significant for the subject. That is to say the subject might feel detached from the world or as if the world was emotionally inert. But it seems an extra step from a lack of affective experience to the feeling or thought of non-existence. Of course the step might be a small one. This was the

idea of Gerrans in his pioneering work at the dawn of the millennium. He suggested that there was such an intimate connection between affective experience and the self that any profound involuntary change in affect would be felt as a change to the self. However since then interesting work on depersonalisation disorder has provided a deeper understanding of the phenomenon. That work draws on the predictive coding theory of cognitive function.

6 The predictive coding hierarchy

The mind is organized as a hierarchical system that uses representations of the world and its own states to control behavior. According to recently influential Bayesian theories of the mind, all levels of the cognitive hierarchy exploit the same principle: error correction (Friston 2003; Hohwy et al. 2008; Jones & Love 2011; Clark 2012, 2013; Hohwy 2013). Each cognitive system uses models of its domain to *predict* its future informational states, given actions performed by the organism. When those predictions are satisfied, the model is reinforced; when they are not, the model is revised or updated, and new predictions are generated to govern the process of error correction. Discrepancy between actual and predicted information state is called *surprisal* and represented in the form of an error signal. That signal is referred to a higher-level supervisory system, which has access to a larger database of potential solutions, to generate an instruction whose execution will cancel the error and minimize surprisal (Friston 2003; Hohwy et al. 2008). The process iterates until error signals are cancelled by suitable action.

This is a very basic outline of the predictive coding idea dodges a crucial question: the extent to which Bayesian formalisations actually describe neurocomputational processes rather than serving as a predictive calculus for neuroscience (Jones & Love 2011; Hohwy 2013; Clark 2012; Park & Friston 2013; Moutoussis et al. 2014). It also blurs an important distinction which is not salient to formalisations such as Bayesian theory: namely the fact that not all higher level control systems can and do smoothly cancel prediction errors generated at

³ There is an interesting debate to be had here. On the views of e.g., Damasio and Bechara affective feelings are not metacognitive but experiences produced by lower level or first order processes *associated* with metacognitive processes (such as planning and decision making). Proust refers to feelings generated by metacognitive processes. On the view proposed here the AIC metarepresents the *significance* of first order bodily information (e.g., visceral or tonic muscular state) in the context of self-relevant metacognition. It allows the subject to experience not just body state but the relevance of that body state.

lower levels. For example vision and motor control are good examples of predictive coding systems (Hohwy 2013). Often however experiences best explained as carrying information about prediction error are not cancelled by the adoption of a higher-level belief. Consider déjà vu experiences which signal mismatch between an affect of familiarity and perception of a novel scene (O'Connor & Moulin 2010). We know the scene is novel, but it still feels familiar. The point is just that the higher order belief does not always smoothly cancel prediction error. And this should be expected. Coding formats are not uniform across cognitive systems, which is why sensory and higher-level cognitive integration is such a cognitive achievement for the mind.

From our point of view what matters are the key ideas of hierarchical organization, upward referral of surprisal and top-down cancellation of error. Also crucial is the idea that the highest levels of cognitive control involve active, relatively unconstrained, exploration of solution space. This is the level at which attention can be redirected to alternative solutions and their imaginative rehearsal. Phenomena such as delusion represent a high level response to an obstinate signal of prediction error that cannot be simply cancelled from the top down. This way of thinking of the mind weds a version of predictive coding theory to insights from neuro-computational theory that treat executive systems as specialized for the resolution of problems which cannot be solved at lower levels. Thus at low levels in the hierarchy the structure of priors and errors and referral of surprisal is constrained, modularized some might say. At the so-called personal level of belief fixation predictive coding best describes the idea that those experiences which command executive resources are those which signal prediction error which cannot be resolved at lower perceptual and quasi perceptual levels. This is at least one level at which predictive coding involves active sampling of information (active inference) as well as the routine cancelling of surprisal according to a well defined prior model. The latter almost defines perception. The former, according to O'Reilly & Munakata (2000) as well as

predictive coding theorists (Spratling 2008) is definitive of executive control.

Thus most of the detection and correction of error occurs at low levels in the processing hierarchy at temporal thresholds and using coding formats that are opaque to introspection. Keeping one's balance, parsing sentences and recognizing faces are examples. We have no introspective access to the cognitive operations involved and are aware only of the outputs. This is the sense in which our mental life is tacit: automatic, hard to verbalize, and experienced as fleeting sensations that vanish quickly in the flux of experience. This is the "Unbearable Automaticity of Being" (Bargh & Chartrand 1999). However even these relatively automatic processes generate experiences of which we can become aware. The recognition of faces, for example, produces an affective response within a few hundred milliseconds. When that affective response is absent or suppressed due to malfunction a prediction is violated and the discrepancy between familiar face and lack of familiar affect is referred to higher levels of executive control to deal with the problem.

At the higher levels of cognitive control, surprisal is signalled as experience that becomes the target of executive processes. These meta-cognitive processes evolved to enable humans to reflect and deliberate to control their behaviour. The highest levels of cognitive control involve reflection, deliberation, rehearsal and evaluation of alternative courses of action and explicit reasoning. When for example a predicted affect is absent we might find ourselves in the position of a patient described by Brighetti who lost affective responses to her family and her professor. She had "identity recognition of familiar faces, associated with a lack of SCR [SCR is skin conductance response, a measure of electrodermal activity consequent on affective processing]" (Brighetti et al. 2007). In other words her predicted affective response to familiars was absent, which resulted in an experience becoming the target of higher-level control processes. Such patients sometimes produce the Capgras delusion that the familiar person has been replaced by an imposter or double. A truly florid delusion such as is sometimes seen in schizo-

phrenia might elaborate the delusional thought into an epic paranoid narrative.

The aim here is not to enter into the controversy about the explanation of the Capgras delusion but to note the role of the architecture that generates it (Young et al. 1994; Breen et al. 2001; Ellis & Lewis 2001). Higher levels of cognitive control are engaged to deal with error signals referred from lower levels in the hierarchy. Perhaps the most important level in the hierarchy for personal and social life is the level at which subjectively adequate narratives are generated to make experience intelligible and by which we communicate our experiences to others. This is the level at which delusional thoughts originate. By subjectively adequate here I merely mean “fits the experience of the subject”. At even higher levels of cognitive control we can revise and reject those subjectively adequate autobiographical narratives, replacing them with empirical theories that draw on publicly available norms of reasoning and semantic knowledge to produce objectively adequate responses to subjective experience (Gerrans 2014). Delusions are best conceptualized as higher-level responses to prediction error which, however, cannot cancel those errors. In fact as Clark (2013) points out such delusory models in effect “predict” further experiences of that type, which means that the delusion will be strengthened.

A very important point to note for the subsequent explanation of depersonalization and the Cotard delusion is that it is not the absence of affect *per se* which produces the error signal and engages higher-level cognition. Lack of affective response alone does not require a high level response unless that lack of affect is unpredicted. That is why we are not bothered by lack of response to strangers (we don’t predict it at any level in the control hierarchy) but if a new mother has no affective response to her baby the experience can be part of a syndrome of post-natal depression.

The example of post-natal depression allows us to make another important point about the relationship between predicted affect and psychosis. Mothers most vulnerable to post-natal depression are those who had powerful

positive expectations of motherhood and the bond with the infant. When that bond does not materialize for some reason they are confronted with a distressing lack of predicted affective response. Sometimes this will produce a kind of Capgras delusion regarding the baby. The mother might say that the baby has been replaced or is an alien (Brockington & Kumar 1982). Interestingly, and tellingly, if the mother is also extremely anxious the condition can be even more serious. Anxious attention to the experience tends to magnify the problem.

This role for anxiety is nicely elucidated by the predictive coding framework. Formal considerations aside, the concept of predictive coding places a huge emphasis on the signaling of error. This means that incoming information must be compared to a prediction and the difference computed and referred to a control system. At higher levels those error signals take the form of experiences. These experiences are often imprecise and opaque since they are produced by lower level systems that encode information in different formats to those used by explicit metarepresentational capacities. They also compete for metarepresentational resources among the constant flux of experiences that engage attention. Thus they create a problem of working out for any experience how much is signal and how much is noise.

It is very important for high-level cognition to be targeted as precisely as possible for only as long as required. Thus any vagueness in experience needs to be resolved. Attention is the process which solves this problem. Hohwy (2012, p. 1; my emphasis) makes the point for perceptual inference but it applies in general:

conscious perception can be seen as the upshot of prediction error minimization and *attention* as the optimization of precision expectations during such perceptual inference.

Clark (2013, p. 190) makes a similar point:

Attention, if this is correct, is simply one means by which certain error-unit responses are given increased weight, hence

becoming more apt to drive learning and plasticity, and to engage compensatory action.

The point is that attention is directed to error signals in order to make them more precise by increasing the signal to noise ratio. Attention amplifies the signal and maintains it while higher-level systems try and interpret the experience and manage appropriate responses. If the response works the error signal is cancelled and attention can be directed elsewhere.

Within this framework we can make an observation about anxiety that can be overlooked by approaches that concentrate on the arousal, hypervigilance or the associated beliefs concerning threat or danger. These approaches de-emphasise a crucial element. That is uncertainty. Anxiety is an adaptive mechanism that primes the organism cognitively and physiologically to resolve uncertainty. Thus, if a prediction cannot be verified, or an error signal disambiguated, anxiety in this sense will result. Of course what we call pathological anxiety is the dysfunctional activation and maintenance of these mechanisms. The point is that someone who is anxious in this way will continue to misallocate attentional, cognitive and physiological resources to experiences. Another point about anxiety is that, in pathological cases, action does not cancel the signal or the dysfunctional allocation of resources to it. This may be why the role of anxiety in depersonalisation is not straightforward. Some recent studies have not found a strong correlation between anxiety and depersonalisation (e.g., [Medford 2012](#)). However the scales used to measure anxiety give a score that sums scores for self-report of feelings, behaviour and cognition. The suggestion here is that what really matters is the allocation of attention to signals which cannot be resolved, perhaps because they are intrinsically noisy, ambiguous or have insufficient information. It is also important that the patient cannot resolve the uncertainty by revising the predictive model that generates it since that is usually maintained low in the predictive hierarchy by mechanisms that are not accessible. The person with Capgras delusion, for example, automatically

predicts affective response to familiar faces and when it goes missing there is nothing she can do to revise that prediction. Instead she is confronted with an anomalous experience, which automatically captures attention. Similarly with depression. Loss of affective response is not something that can be restored from the top down.

In some cases of post-natal depression all these factors seem to be operative. The mother expected to bond with the infant but in fact perhaps birth was traumatic, the baby did not attach straightaway, and the mother needed more support and reassurance than she received. She was left distressed and unable to cope which made bonding and attachment even more difficult. This would be bad enough but if the mother had a strong prior expectation that motherhood would be straightforwardly rewarding a prediction is violated. If the mother is also anxious she will attend intensively to the resultant experience of absent affect, but she will encounter only further feelings of emptiness and panic. The presence of the baby and the expectations of family and friend only compound the sense that she is not feeling what she should be feeling. What happens next depends on context and support but it is not really surprising, especially given the relationship between massive hormonal fluctuation and emotional regulation, that in some cases new mothers develop psychotic symptoms ([Spinelli 2009](#)).

7 Depersonalisation

Depersonalisation Disorder (DPD) is characterized by “alteration in the perception or experience of the self so that one feels detached from and as if one is an outside observer of one’s own mental processes” ([American Psychiatric Association 2000](#)). Critchley points out that DPD is often accompanied by alexithymia, a condition in which conscious awareness of emotional states is compromised or absent. This is consistent with findings summarized by Medford that “de-affectualisation”, a reduction or absence of affective response, presents as a core feature of clinical cases. Depersonalisation is a separate disorder to derealisation (the feeling that the world is inanimate or unreal) but derealisation

is often an important aspect of depersonalisation. Indeed, as Medford describes their relationship, depersonalisation can sometime be a response to derealisation (Sierra et al. 2002; Hunter et al. 2004).

Seth et al. (2011, p. 9; my emphasis) summarize a range of findings about DPD as follows: “In short, DPD can be summarized as a psychiatric condition marked by the selective diminution of the *subjective reality* of the self and world”. They explain this diminution as the result of the loss of “sense of presence”, the feeling of being engaged in experience. This is what they mean by subjective reality: the condition is not like an hallucination or delusion in which objective reality is misrepresented by faulty perception or belief fixation. In fact the patient correct represents “objective reality” but loses the sense of herself as the subject of experience.

In the attempt to explain the loss of the sense of presence cognitive neuroscience has developed a theoretical picture that considerably augments older theories. On those older theories DPD represented a suppression or inhibition of emotion as a response to trauma or distress. On this view DPD activates mechanisms which might in other circumstances be adaptive. For example, if the subject of violent attack deactivated those mechanisms which produce the experience of distress that would qualify as an adaptive response to trauma. Of course such a response is only adaptive in the short term. Inability to feel distress might also reduce avoidance behavior with disastrous consequences.

It seems that the deactivation is accomplished by inhibitory activity in the Ventrolateral Prefrontal Cortex (VLPFC). The VLPFC is a structure which plays a crucial role in the regulation of affective feeling, especially as part of a process of reappraisal (Füstös et al. 2013). The adaptive aspect here is that it allows the subject to redirect attention and divert cognitive resources to alternative interpretations of self-relevance and response behaviour by inhibiting an experience that would otherwise monopolise cognition. This role has been tested in tasks which involve the top down regulation of negative affect but, as Medford says, “In DPD such suppression is apparently involuntary (and

largely resistant to volitional control), but it is reasonable to suppose that this will nevertheless engage similar inhibitory networks” (2012, p. 142). Thus the patient with DPD experiences the result of *involuntary* deactivation of systems that produce the bodily experience of emotion.

These ideas are consistent with the evidence from cognitive neuroscience about other primary neural correlates of DPD. *Hyperactivity* in VLPFC leads to *hypoactivity* in the Anterior Insular Cortex (AIC). That reduced activity in the AIC produces the loss of a sense of presence. This hypothesis results from findings that it has a primary role in higher order representation of interoceptive (visceral, autonomic, bodily) states. It generates the bodily feelings that signal how we are faring in the world moment to moment consequent on affective processing. Activity in the AIC produces what Damasio called the “core self” and what Critchley calls “the sense of presence”. As Critchley says,

evidence from a variety of sources converges to suggest a representation of autonomic and visceral responses within anterior insula cortex, where, particularly on the right side, this information is accessible to conscious awareness, influencing emotional feelings (2005, p. 162).

When Damasio made his contributions to the neurophilosophy of emotions and self-representation the computational theory in the field was less developed so that we can now make some additional observations about the role of the AIC.

To do so we first reiterate the distinction between being able to sense body state, which is the phenomenon baptized by Damasio *interoception*, (to distinguish it from *exteroception* [perception of the external world]), and sensing states of a self. The distinction is a subtle one of course but we can approach it intuitively by noting that there is a crucial difference between being able to sense heart rate, blood pressure or temperature as part of an illness and as part of an emotional episode. We observed earlier that the second kind of awareness is the one we describe as self-awareness in virtue of the fact that

it reflects affective processing rather than pure bodily regulation. There is a difference in feeling state caused by raises in blood pressure generated by walking up stairs and by heated argument. This is so even though heart rate is heart rate, however caused. But the point of affective processing, as we saw, is to assess the self-relevance of unpredicted changes in things like heart rate and to indicate to the subject how and why they might matter in the cognitive context.

The experiential differences between heart rate *per se* and heart rate consequent on affective processing can be explained in terms of the principle of hierarchical computational organization, reflected in cortical organization (Craig 2009, 2010; Dunn et al. 2010). The insular cortex is hierarchically organized to map body state at different levels of abstraction and integration. Posterior sections map body state directly and integrate those representations to coordinate *reflexive* regulatory functions. Thus the Posterior Insular Cortex (PIC), for example, represents things like blood pressure and departures from homeostasis and integrates that information to enable reflexive regulatory processing. More anterior regions re-represent and integrate this information in formats available for higher levels of cognitive control. If we sense raised blood pressure the PIC is primary in the representation of that information. When, however, we are deciding how to respond, we need to integrate that information with current and long term goals, representations of contextual information, memory, planning and inference. We may have to inhibit or reprogram automatic behavioral tendencies (not punch the boss) and perhaps reappraise the situation. Thus we need a way, not just to feel raised blood pressure, but to *feel its significance* in order to program a suitable response. This is the role of the AIC.

This explains a recent finding which seems paradoxical on the “somatic” James-Lange view of emotions revived by Damasio. On that view emotions are representations of body state *simpliciter*. The feeling of fear is the feeling of being primed to take avoidance action, for example. Michal and collaborators compared the “interoceptive accuracy”, that is ability of patients to judge body state (using heart rate as a

proxy), of patients with DPD to normal patients. Strikingly they found that “[there] was no correlation of the severity of ‘anomalous body experiences’ and depersonalization with measures of interoceptive accuracy.” They explained this finding as follows: “[The] findings highlight a striking discrepancy of normal interoception with overwhelming experiences of disembodiment in DPD. *This may reflect difficulties of DPD patients to integrate their visceral and bodily perceptions into a sense of their selves*” (Michal & Reuchlein 2014, p. 1; my emphasis).

The AIC can only integrate currently available bodily feeling. As Craig says, it “represents the sentient self at one moment of time [and] provides the basis for the continuity of subjective emotional awareness in a finite present” (2009, p. 67). However we can extend the temporal range of information represented by those feelings by integrating them with representation of past and future episodes of experience and/or semantic knowledge. Simulations involved in planning and episodic memory are associated with activation of the AIC to provide sense of extended self. In other words it is the integration of the metarepresentations of body state produced by the AIC with representations of episodes of a temporally extended autobiography that produces the feeling that we are a self with a past and future, rather than a series of disconnected selves, moment to moment.

Nothing in what I have said refutes skepticism about the self, or episodic theories of first person experience (Strawson 2004). It is in fact consistent with the idea that experience is a series of episodes. Whether we feel those episodes are ours depends on how they are integrated. There is no suggestion that everyone integrates them the same way or that integration evokes an equally strong sense of presence in each person. All I have suggested is that there are mechanisms which can create self-awareness moment to moment and mechanisms which integrate those moments of self-awareness with higher level forms of cognitive control that represent past and future actions and outcomes in order for the organism to assess the self-relevance of actual and potential actions. The ex-

planation of awareness of self-relevance in different contexts is a sufficient explanation of the phenomenon of self-awareness that was our initial quarry.

Craig adds a subtle but important qualification to this account. He (and others) remind us that if the predictive coding account of the mind is correct then we are never directly aware of objects, including the body (Craig 2009, 2010; Seth et al. 2011; Garfinkel & Critchley 2013). Rather representations of objects are computed on the basis of discrepancy between their predicted informational effects on us and actual incoming information. It is fluctuations and discrepancies measured against expectations computed at different levels in the control hierarchy that determine the information that becomes consciously available. “An *expected* event does not need to be explicitly represented or communicated to higher cortical areas which have processed all of its relevant features prior to its occurrence” (Bubic et al. 2010, p. 10; Clark 2013, p. 199; my emphasis.)

The same should be true of neural activation in the AIC, and hence of moments of self-awareness. We are aware of what is relevant to us via unpredicted changes in bodily feeling consequent on affective processing.

This latter feature is the key to understanding the link between “de-affectualisation”, as Medford called it, and depersonalization (Medford 2012). It is not the fact that affect is suppressed that matters, but that affect which was predicted to occur does not in virtue of the *involuntary* inhibition of the AIC by the VLPFC. When people engage in voluntary or effortful inhibition of affect they do not feel depersonalized. We noted earlier the role of expectation in post-natal depression, but there the expectation is of affective response to a specific object, a baby. In depersonalization it seems that almost all expected affective feelings are absent because of hyperactivity in the VLPFC.

The predictive coding framework also allows us to finesse explanations of the role of anxiety in the experience of derealisation. We noted that Cotard described anxiety as part of

the aetiology of the depersonalization experience in Cotard delusion. Medford, in an early discussion of DPD, also postulated a role for anxiety in order to explain an apparent paradox of DPD: the distress experienced by the patient at the absence of affective response. It is not merely that the patient has no emotions, but, as a patient of Medford’s said, “I don’t have any emotions—it makes me so unhappy.” Medford (2012) pointed out that this is only slightly paradoxical: the distress is at the lack of *internal* affect, the inability to feel rather than at the derealisation of the external world. Medford related this specifically to the anxiety component of the syndrome. The patient expects that the world will induce positive affect but when it does not an expectation is violated and the patient anxiously attends to that absence of affect. On this view highly anxious patients are hyperattentive to their experience and encounter, not the normal bodily experience, which represents how they are faring in the world, but a strange absence of such experience, in combination with intact exteroception which tells them that the world is unchanged (Paulus & Stein 2010; Garfinkel & Critchley 2013; Seth 2013; Terasawa et al. 2013). Their problem is that they no longer feel the relevance of changes in their own bodies and the world to themselves and this inability to feel the world increases their anxiety. Medford quotes an earlier theorist (Ackner 1954) who noted “increased responsiveness for anxiety of internal origin, whereas that of external origin [is] reduced” (Medford 2012, p. 141).

This perhaps explains the differences in casual aetiology between depersonalisation arising in the Cotard syndrome and in DPD. In the Cotard syndrome something is amiss with the mechanisms that appraise perceptual and interoceptive information for self-relevance. The AIC is not getting any information from affective systems to integrate and relay to higher order cognition. Thus felt significance disappears. When the depressive patient then focuses on her experience she feels alienated from the world and depersonalised. In the case of DPD it appears that the AIC is

hypoactive for another reason: its activity is inhibited by the VLPFC.

In both cases the patient attends to her experience and tries to interpret it in order to respond. This is consistent with the role postulated by predictive coding theories for attention: the attempt to interpret and sharpen the informational content of a signal by improving the signal to noise ratio. Unfortunately an increase in attention does not provide any increase in precision, it only makes the absence of predicted response more salient. Since those predictions are, in effect, representations of expected self-relevance that normally provide the experience of self-awareness, the patient concludes that the self does not exist. After all, the information necessary to generate self-awareness is still in place. The body, the world and first order representations of their interaction are all represented in experience. What is lost is a sense of the significance of those interactions for the body that mediates them.

The explanation has become complicated so at this point it is useful to situate it in terms of the conceptual architecture (points (i)-(iii) below) outlined in the introduction. On this view DPD arises in the following way as a personal level response to the absence of predicted affective experience.

- i. Appraisal systems normally represent the significance of information for the organism. The primary way of experiencing the result of those appraisals is via activation in the AIC. This is because the AIC is specialised for informing the subject, via bodily experience, of the affective significance of its encounters with the world. These experiences are not the same as experience of body state *per se* but the emotional significance of that body state.
- ii. Those experiences can be rehearsed offline in planning and deliberation to extend the temporal horizon of affective experience. We feel like temporally integrated selves because memory and prospection have affective significance.
- iii. Predictive coding architecture has the effect of making discrepancy between anticipated and actual affective feeling highly salient.
- iv. In DPD activity in the AIC is inhibited most likely as a result of the involuntary activity of the VLPFC.
- v. Consequently the patient has normal perceptual and sensory responses to the world but those responses are not integrated into a bodily representation which informs her of their significance. The world feels derealised or as Medford puts it de-affectualised
- vi. However, given the way predictive coding works, the patient actually has a model of the world that predicts activity in the AIC as a result of her perceptual encounters. Thus absence of AIC-produced experience is a prediction error that drives metacognitive responses.
- vii. Those responses include increased attention (driven by sub personal mechanisms of resource allocation) to the experience itself as the patient tries to extract further information from it. However, being produced by subpersonal mechanisms the experience is both intractable and inscrutable.
- viii. Highly anxious people cannot divert attention from the experience, since anxiety is driven by the need to resolve uncertainty. But the experience is inexplicable and irresolvable.
- ix. The patient's personal level interpretation of the experience is of depersonalisation "it feels like it is not happening to me". The interpretation is not a direct report of the experience, which I have argued is more like a total deaffectualisation. It amplifies it.
- x. However the form that amplification takes, depersonalisation, is explained by the role such experiences have in creating the normal sense of being a self. We feel we are selves precisely because the significance of the world for our organismic goals is normally computed by appraisal systems and represented in characteristic forms of bodily experience.

8 Anatomy of an avatar

Thomas Metzinger has argued that the persisting self is neither an illusion (in the sense of a perceptual experience whose content is incorrect) nor a genuine entity in the sense of an object existing outside the mind like a body or a neural state. Instead the self is a creature of experience itself, a phenomenal representation constructed by the brain to control the body. This representation is in effect an avatar that unifies experiences of ownership (the sense of the integrity of bodily boundaries), perspective on experience (which I have not talked about in this essay), and selfhood (“a single coherent and temporally stable phenomenal subject”). An especially attractive aspect of Metzinger’s view is that he treats the nature of the avatar as an empirical matter so that our understanding of its properties can be refined in the face of further discoveries.

Metzinger’s view nicely captures what is right and wrong in the illusory view of the self. The illusory view is correct that the self is not an object to be experienced in the same way as we experience perceptual or somatic objects. The self is a way of experiencing the interaction of the body and the world. It is a creature of experience, constructed by the brain to navigate the organism through the world. The self exists as a virtual phenomenal entity in virtue of the integrative processes that create and sustain it.

The Fat Controller view of the self also has some of the picture correct. Self-awareness is needed for higher order cognitive control to integrate and organise experience moment to moment and to assimilate those experiences to an ongoing autobiography for longer-term cognitive control. However there is no single cognitive process with an identifiable neural substrate that represents an organiser/narrator. Also, and this is where Metzinger is correct, there is a genuine experience of being a person in control, but this experience is the experience of integration itself, which suggests that it is a process which can disintegrate and degrade in different ways and to different degrees. It also suggests, although I have not discussed it here, that experience of the self is a prefrontal achievement

since prefrontal structures are specialised for “large world” integrative processing (the orchestration of synchronised activity across widely distributed brain areas).

The Embodied Self view is of course very close to the one I have discussed here. I have argued that a particular type of bodily feeling is what goes awry in depersonalisation and hence that those feelings produce the experience of the self. While this is correct, we need to recall that Damasio distinguished between the “core self”, which is very close to the phenomenon I have described, and the autobiographical self. Sometimes he treats the autobiographical self as a more abstract or narrative construct. I have tried to show that the integration of the core self with the autobiographical self comes, as it were, for free, given the automatic links between affective processing and the processes which construct the autobiographical self. It is impossible to rehearse episodes of one’s autobiography without a sense of presence—unless, of course, one has DPD or the Cotard delusion. But those cases demonstrate the component structure of the avatar.

Finally, the narrative view captures the crucial role of temporal integration in the experience of the self. But the self is not *just* a fictional protagonist in the brain’s stories (though it is that). The specialised simulation mechanisms that generate the actual and potential autobiographies automatically integrate each episode with affective feeling. That feeling allows us to experience in the process of recollection, imagination or narration the significance of each episode to our unique organismic trajectory. That, and the ability to incorporate and act on those feelings, is all the selfhood anyone needs.

Memory for Prediction Error Minimization: From Depersonalization to the Delusion of Non-Existence

A Commentary on Philip Gerrans

Ying-Tung Lin

Depersonalization is an essential step in the development of the Cotard delusion. Based on [Philip Gerrans'](#) account ([this collection](#)), which is an integration of the appraisal theory, the simulation theory, and the predictive coding framework, this commentary aims to argue that the role of memory systems is to update the knowledge of prior probability required for successful predictions. This view of memory systems under the predictive coding framework provides an explanation of how experience is related to the construction of mental autobiographies, how anomalous experience can lead to delusions, and thus how the Cotard delusion arises from depersonalization.

1 Introduction

In [Le Délire de Négation](#) (1897), Jules Séglas considers depersonalization to be an essential step in the development of the Cotard delusion¹

¹ According to [Berrios & Luque \(1995\)](#), the English translation of “le délire des négations”—a term first introduced by the French neurologist, Jules Cotard (1840–1889)—only conveys a part of what it means: “Délire is not a state of delirium or organic confusion (in French, *délire aigu* and *confusion mentale*) or a delusion (in French, *idée* or *thème délirante*)—it is more like a syndrome that may in-

(CD; as cited in [Debruyne 2009](#); [Gerrans 2002](#)), and *prima facie* the two states share a number of characteristics: Patients suffering from the former feel *as if* they are dead or do not exist,

clude symptoms from the intellectual, emotional, or volitional spheres” (p. 219). The original French concept of “délire” fits better with Gerrans’ account of the Cotard delusion, in which the Cotard delusion does not merely concern beliefs of denial, but also anomalous affective processing.

whereas those who suffer from the latter sincerely believe and experience this state. However, the central characteristics of these disorders are distinct. Patients describe the experience of depersonalization as follows:

It's really weird. It's sort of like I'm here, but I'm really not here and that I kind of stepped out of myself, like a ghost... I feel really light, you know. I feel kind of empty and light, like I'm going to float away... Sometimes I really look at myself that way... It's kind of a cold eerie feeling. I'm just totally numbed by it. (Cited in [Steinberg 1995](#))

The emotional part of my brain is dead. My feelings are peculiar, I feel dead. Whereas things worried me nothing does now. My husband is there but he is part of the furniture. I don't feel I can worry. All my emotions are blunted. ([Shorvon 1946](#), p. 783)

As illustrated in these subjective descriptions, depersonalization is characterized by a loss of the sense of presence ([Critchley 2005](#)) or an increased “sense of detachment”—the “[e]xperience of unreality, detachment, or being an outside observer with respect to one's thoughts, feelings, sensations, body, or actions” ([American Psychiatric Association 2013](#), p. 302). On the other hand, in the Cotard delusion (CD), mental autobiographies are acutely distorted—in such a way that patients are convinced that they are dead or that they do not exist:

An 88-year-old man with mild cognitive impairment was admitted to our hospital for treatment of a severe depressive episode. He was convinced that he was dead and felt very anxious because he was not yet buried. This delusion caused extreme suffering and made outpatient treatment impossible. ([Debruyne et al. 2009](#), p. 197)

Researchers in the field of delusion studies have debated the way in which anomalous experience leads to false belief. In this commentary I am

interested in the following questions: What cognitive architecture could, in principle, explain CD in terms of its development from depersonalization, and what exactly are the underlying differences between patients suffering from the Cotard delusion and those suffering from depersonalization disorder (DPD) but free from the Cotard delusion?

In his target paper, [Gerrans](#) explores the cognitive structure of self-awareness—the “awareness of being a unified persisting entity” ([this collection](#), p. 2). To explain the emergence of self-awareness and its loss in DPD and CD, he provides an account that integrates the appraisal theory of emotion, the simulation model of memory and prospection, and the hierarchical predictive coding model. First, based on the appraisal theory, Gerrans shows that the activation of the anterior insular cortex (AIC) allows an organism to experience the emotional significance of a relevant state by experiencing appraisal. According to [Gerrans](#), these reflexive processes are what sustain the self from moment to moment: “An organism that can use that affective information in the process is a self” ([this collection](#), p. 8). Second, the integration of affective processing and simulated episodes allows the organism to experience itself as a persisting entity overtime (see more below). Last, he endorses the predictive coding framework, according to which the human mind can be accounted for by the principle of predictive error minimization. Perception, for instance, is realized by the operation of both top-down prediction and bottom-up predictive error. If the general theoretical model is correct, it will not only apply to perception, but also to affective processing (*ibid.*, p. 9). [Gerrans](#) ([this collection](#)) applies this framework to explain the phenomenon of depersonalization and CD: Depersonalization occurs due to a failure to attribute emotional relevance to bodily states, which results from hypoactivity of the AIC. The prediction error from the mismatch between the predicted and the actual activation level of the AIC would lead to allocation of attention, the function of which, according to the predictive coding framework, is to disambiguate signals. If the prediction error cannot be cancelled and attention

cannot be diverted, increased attention brings about anxiety in DPD and CD, which is “an adaptive mechanism that primes the organism cognitively and physiologically to solve uncertainty” (*ibid.*, p. 11). This is reflected in the patients’ subjective reports concerning the loss of awareness of their bodies. This integrated theory provides an explanation of depersonalization as well as of how self-awareness is constructed through the interaction of different forms of cognitive processing.

In Gerrans’ account, the simulation system allows the organism “to *simulate* temporally distant experiences by rehearsing some of the same perceptual and emotional mechanisms activated by the simulated situation” (*ibid.*, p. 6), such that the affective associations result in integrated episodes of experience that lead to the feeling of persisting over time. I argue (1) that the simulation model should not be thought of as independent from other memory systems: without memory systems at lower levels—semantic and procedural memory systems—the simulated episodes cannot be constructed (section 2); and (2), that by considering the role of memory under the predictive coding framework, the simulation model not only plays a role in simulating temporally-distant episodes but also contributes to the knowledge required for the creation of predictive models in the present (section 3). On such a view of the simulation model, delusion can be explained and I will suggest (3) two factors contributing to the development of CD from depersonalization: the compromised decontextualized supervision system and the expectation of high precision from interoceptive signals (section 4); that is, only if these two factors are present in a depersonalized subject may CD develop.

2 The simulation model and the mental autobiography

[W]e are all virtuoso novelists, who find ourselves engaged in all sorts of behavior, more or less unified, but sometimes disunified, and we always put the best ‘faces’ on it we can. We try to make all of our material cohere into a single good story. And

that story is our autobiography. (Dennett 1992, p. 114)

As persons, our beliefs and desires are structured in a more or less coherent fashion, such that a mental autobiography—an autobiographical framework (Gerrans 2013) or narrative (Schechtman 1996)—can be attributed, which can explain our cognitive structure. Many people have proposed theoretical entities such as the “autobiographical self” (Damasio 1999, 2010), the “conceptual self” (Conway 2005; Conway et al. 2004), and the “narrative self” (Feinberg 2009), etc. to account for how one comprehends and navigates through the world and over time—that is, how one is able to make sense of external or internal signals, to have preferences, to have goals and to values, to know who oneself is, to be a diachronically persisting agent, to recall the past, and to imagine the future. In general, these different versions of the “extended self” (Gallagher 2000) are characterized by the following phenomenal and epistemic properties.

First, phenomenally, we experience ourselves as thinkers of thoughts (e.g., “I think...” or “I believe...”) and as beings who recollect the past and plan for the future; while at the same time we have a sense of ownership of relevant beliefs (e.g., “this thought is mine”). Second, subjectively, events and objects are presented in a way that manifests their relevance to the subject. In addition, epistemically, we tend to treat the self-told story as if it were highly reliable: The content is treated as objectively real, and its truthfulness is seldom questioned. This is the way we consciously comprehend the world and our place within it, and it is thought to be reliable. Accompanied by a certain degree of the “feeling of familiarity” and the “sense of pastness” (Russell 2009, p. 208), there is a degree of certainty about the veridicality of a mental autobiography. When inconsistency or non-veridicality is detected and such certainty is lost (e.g., due to introspection or contradiction to external information), the mental autobiography will be modified to re-create a new subjective reality—a new story about ourselves with more or less difference (e.g., self-deception).

Delusional patients have anomalous forms of mental autobiography: Their mental autobiographies are radically distorted, for different reasons. For instance, RZ, a 40-year-old female patient with reverse intermetamorphosis, believed that she was her father (and sometimes believed that she was her grandfather) during her assessment by Breen et al. (2000). When asked to sign her name and answer questions about her life, she signed her father's name and provided her father's personal history. She acted according to her delusional beliefs. Here we see that her mental autobiography constructs her subjective reality. Semantic dementia patients who suffer from an incapability of constructing personal futures (Irish & Piguet 2013) provide examples of the loss of partial subjective reality.² It is speculated that this form of futureless mental autobiography accounts for the higher suicide rate in semantic dementia (Hsiao et al. 2013). As we will see, patients suffering from CD also maintain a mental autobiography.³ They believe that they are dead or no longer exist: They may refuse to eat or visit the graveyard—the place in which they believe they belong. But how are mental autobiographies constructed? The rest of this section considers how memory systems and simulation models lead to the construction of a mental autobiography.

Studies on misrepresentations in memory have suggested that—against the traditional and folk-psychological idea of a “store-house” (Locke 2008), in which memory as a copy of past experience is stored for future use—memory is constructive in nature. It represents different facets of experience, which are distributed across different regions of the brain, where retrieval is realized in a process of pattern completion, which allows a subset of features to comprise a past experience (Schacter et al. 1998). The prevalence of misremembering (episodic memory in particular) and the view of con-

structive memory have led to the debate over the function of memory: If the proper function of memory is to veridically represent past experiences or events, is our memory system fundamentally defective? Or, does it serve other functions? If there is any adaptive advantage of memory systems, they must serve a function that concerns the *current and/or future* states of the organism (Westbury & Dennett 2000). New findings regarding a default-mode network suggest a “constructive episodic simulation hypothesis” (Schacter & Addis 2007a, 2007b), according to which the constructive nature of episodic memory is partially attributable to its proposed role in mentally simulating our personal futures (e.g., planning a future event). This hypothesis is supported by fMRI evidence showing that remembering the past as well as imagining the possible past and future share correlates with the activities of the default mode network (Addis et al. 2007; De Brigard et al. 2013; Szpunar et al. 2007). Therefore, it is suggested that episodic memory is adaptive in that it allows us to employ past experiences in such a way as to enable simulations of possible future episodes.

However, simulation is not realized by episodic memory alone. Though memory systems (i.e., procedural, semantic, and episodic memory) can be conceptually distinguished, they are considered parts of a “monohierarchical multimemory systems model” (Tulving 1985): Semantic memory is a specialized subsystem of procedural memory that lies at the lowest level of the hierarchy, and semantic memory in turn contains episodic memory as its specialized subsystem. The subsystems at higher levels are dependent on and supported by those at lower levels. That is, our everyday autobiographical memory is realized by multiple memory systems. For instance, a recent study has shown the importance of semantic memory in the construction of autobiographical memory: While episodic memory provides episodic details, semantic memory acts as a schema for integrating them (Irish & Piguet 2013). That is, our mental autobiographies are constructed by the interplay of multiple memory systems (e.g., Tulving's SPI model, see Tulving 1995).

² If the predictive coding framework and the role of memory for which I argued in section 3 is correct, one should expect to find an anomalous phenomenon in semantic dementia—not only with respect to one's narrative consciousness, but also with respect to one's perception.

³ It might be a contradiction in terms to claim that patients suffering from the Cotard delusion have mental autobiographies, since “auto” means “self, one's own” and “bio” means “life”. Here, it can merely be understood as a personal-level response to the system's condition.

This applies to prospection as well. Different categorizations of prospection are proposed (e.g., [Atance & O'Neill 2001](#); [Szpunar et al. 2014](#)). In this commentary, I adopt a distinction offered by [Suddendorf & Corballis \(2007\)](#), who distinguish procedural, semantic, and episodic prospection (p. 301, Figure 1). [Suddendorf & Corballis \(2007\)](#) suggest that the function of the memory and anticipatory systems is to provide behavioral flexibility; and they also examine the phylogenetic development of different memory systems. According to their model, the flexibility of anticipatory behavior supported by different memory systems can offer varies in degree. From the primitive form, procedural memory enables stimulus-driven predictions of regularities and allows behavior to be modulated by experience, such that the resulting behavior is stimulus-bound. Declarative memory provides more flexibility because it can not only be retrieved involuntarily, but can also be voluntarily triggered top-down from the frontal lobe, which enables decoupled representations that are not directly tied to the perceptual system. That is, even though we are still tied to the present in that we recall and imagine the future at the present moment, the content of representation can extend beyond the current immediate environment. Specifically, semantic memory is considered more primitive than episodic memory as it has less scope for flexibility ([Suddendorf & Corballis 2007](#)).⁴ The former, in allowing learning in one context to be voluntarily transferred to another, provides the basis for reasoning. However, this is about regularities and not particularities. Episodic memory supplements this weakness: A scenario can be simulated and pre-experienced. Through mental reconstruction or memory construction, episodic memory not only recreates past events, it also allows the learned

elements to be incorporated and arranged in a particular way in order to simulate possible futures. It thereby provides greater flexibility in novel situations and provides for the possibility of making long-term plans, extending even beyond the life-span of the individual.

To sum up, our mental autobiography is constructed through the interaction of multiple memory systems at different levels. The simulation model should not only be associated with the episodic memory system; rather, it should be understood as a hierarchical model of multiple memory systems—i.e., procedural, semantic, and episodic memory as well as procedural, semantic, and episodic prospection. In the next section I will consider the role of memory systems within the predictive coding framework.

3 Memory under the predictive coding framework

Recent development of the predictive coding framework ([Clark 2013b](#), [this collection](#); [Friston 2003](#); [Hohwy this collection](#)) provides an integrated conceptual framework for perception and action. According to the framework, the brain constantly attempts to minimize the discrepancy between sensory inputs (including exteroceptive and interoceptive signals) and the internal models of the causes of those inputs via reciprocal interactions between hierarchical levels. Each cortical level employs a generative model to predict representations of the subordinate level, to which the prediction is sent via top-down projections—the bottom-up signal is the prediction error. Prediction error minimization can be achieved in a number of ways ([Clark this collection](#); [Hohwy this collection](#)); but in general, errors can be minimized either by updating generative models to fit the input or by carrying out actions to change the world to fit the model. In the target paper, [Gerrans](#) integrates appraisal processing into the predictive coding framework; however, he treats only the simulation model as a mechanism for simulating temporally distant experiences ([this collection](#), pp. 6–8). In this section, I propose that under the predictive coding framework, the simulation model serves the function of updating

⁴ [Tulving \(2005\)](#) and [Suddendorf & Corballis \(2007\)](#) argue that episodic memory emerges later in the course of evolution and belongs uniquely to human beings. Even if there is evidence suggesting the existence of episodic-like memory—memory encoding “what”, “where”, and “when” information—in non-human creatures (e.g., Western scrub jays; [Clayton 2003](#); [Clayton & Dickinson 1998](#)), [Tulving \(2005\)](#) argues that these phenomena can be explained merely by semantic memory. In a recent paper, [Corballis \(2013\)](#) changes the claim he makes in the earlier article ([Suddendorf & Corballis 2007](#)) and argues that mental time travel also exists in rats, and that the difference between this and human mental time travel is simply the degree of complexity.

the knowledge required for successful prediction, which constitutes perception and affective experience.

How can we understand the role of memory or the simulation system under the predictive coding framework?⁵ Here I examine how memory systems can be incorporated into the framework. According to the predictive coding framework, perceiving is distinct from the traditional model of perception; instead, it is:

to use whatever stored knowledge is available to guide a set of guesses about [...external causes], and then to compare those guesses to the incoming signal, using residual errors to decide between competing guesses and (where necessary) to reject one set of guesses and replace it with another. (Clark 2013a, p. 743)

That is, perception is knowledge-driven and top-down, rather than stimulus-driven and bottom-up. “Stored knowledge” refers to a repertoire of prior beliefs or knowledge—the belief of the likelihood of a hypothesis or guess irrespective of sensory input. It is acquired or shaped by learning from past experience—or, in other words, it is a modification of parameters in order to minimize prediction error.⁶

Moshe Bar (2009) suggests that “our perception of the environment relies on memory as much as it does on incoming information” (p. 1235). Since we seldom encounter completely novel objects or events, our systems rely on representations stored in memory systems to generate predictions. According to Bar’s “analogy-association-prediction” framework (Bar & Neta 2008), once there is a sensory input, the brain actively generates top-down guesses in order to figure out what that input looks like (analogy); the match triggers activation of associated rep-

resentations (association), which allows predictions of what is likely to happen in the relevant context and environment (prediction). Thus, instead of aiming to answer the question “what is this?”, perception studies should answer the question “what is this *like*?” or “what does this resemble?”: Brains proactively compare incoming signals with existing information gained in the past (see Bar 2009, Figure 1 & Figure 2). Bar (2009) suggests that predictions also influence memory encoding. Memory systems primarily encode that which differs from memory-based prediction, and if sensory information meets the prediction, the information is less likely to encode (Bar 2009, p. 1240).

This account provides a new view of the concepts of encoding, retrieval, and reconsolidation. The older view describes encoding as the process by which incoming information is stored for later retrieval, and retrieval as a process involved in utilizing encoded information in reviving past events. Nevertheless, under the predictive coding framework, when discrepancy between prediction and perceptual information occurs, encoding is the process of minimizing prediction error—the adaptation of the model to reduce discrepancy based on the forward-feeding, bottom-up input from its subordinate level. Retrieval is then regarded as the process of utilizing this knowledge for predictive model construction.

Accordingly, I suggest that the role of memory systems is to update the knowledge required for successful predictions of the organism’s current (and future) informational state. That is, under the predictive coding framework, our perception is knowledge-driven, and knowledge is experience-based. The mechanisms of our memory systems allow the knowledge required for the construction of predictive models to be updated based on experience. Prediction error can trigger encoding that modifies our knowledge, which then optimizes the predictive model to achieve prediction error minimization. In addition, as we will see later in this section, the development of episodic memory and mind-wandering allows us to generate new knowledge.

This knowledge-driven perception is realized by a multi-layer hierarchical structure in

⁵ Felipe De Brigard (2012) considers how the predictive coding framework can predict remembering. He modifies Anderson’s Adaptive Control of Thought-Rational model (Anderson & Schooler 2000); here the probability of a memory retrieval can be calculated based on how well memory retrieval will minimize prediction error given the cost of the retrieval and the current context. Here, however, I shall not consider the retrieval of individual memories; instead I focus on the role of the memory systems within the framework.

⁶ See Clark (2013a) for the problem of the acquisition of the very first prior knowledge.

which “each layer is trying to build knowledge structures that will enable it to generate the patterns of activity occurring at the level below” (Clark 2013a, p. 483). The information encoded at each level is distinct: At higher hierarchical levels, the representations become more abstract and involve a larger spatial and temporal dimension: The predictive models generated not only represent the immediate state of the system or environment but also the system in relation to the spatially and temporally-extended environment. Moreover, the higher-level knowledge also supports predicting how sensory signals will change and evolve over time. It allows one to predict the future and execute long-term plans involving multiple steps. The hierarchical structure is crucial to our capacity to comprehend the world, which is highly structured, with regularity and patterns at multiple spatial and temporal scales and interacting and complexly-nested causes (Clark 2013a).

I suggest that each level of knowledge has an updating mechanism, which is consistent with Tulving’s (1985) monohierarchical multimemory systems model and Suddendorf & Corballis’ (2007) model of memory and prospection. Procedural memory at the lowest level is involved in the sensori-motor predictive function: It updates the procedural knowledge required for predicting the states in which given actions are executed. Whereas implicit memory is mainly involved in immediate responses to current stimuli, declarative or explicit memory (episodic memory in particular) contributes to the construction of a model of the system itself and its environment with spatial and temporal dimensions. It supplements higher-level knowledge structures for the construction of a generative model, which explains actual states and predicts possible changes and actions for reaching desired states. Under the predictive coding framework, the semantic memory system, which allows learning in one context to be transferred to another, supports semantic knowledge, which in turn provides regularities in the construction of predictive models (e.g., during reading). And episodic memory, together with semantic memory, supports the knowledge required to construct a model of one’s autobiography—a

model of one’s own relevant past and potential future. However, it is worth noting that our mental autobiography is not realized by knowledge at a single hierarchical level; instead, it is constructed through the interplay of the mechanisms at multiple levels.

In addition to its contribution to an autobiographical-scale model, episodic memory, along with other memory systems, also generates new knowledge by simulation. Bar (2007) proposes that:

[the] primary role [of mental time travel] is to create new ‘memories’. We simulate, plan and combine past and future in our thoughts, and the result might be ‘written’ in memory for future use. These simulated memories are different from real memories in that they have not happened in reality, but both real and simulated memories could be helpful later in the future by providing approximated scripts for thought and action. (p. 286)

This is supported by the evidence that mind-wandering—that is, having thoughts that are unrelated to the current demands of the external environment (Schooler et al. 2011)—is beneficial to autobiographical planning and creative problem solving (Mooneyham & Schooler 2013).⁷

The role of memory systems under the hierarchical predictive coding framework is consistent with the function of memory and the concept of a memory system proposed by De Brigard (2013). Following Carl F. Craver’s idea of a mechanistic role function (2001), De Brigard argues for a larger cognitive system of “episodic hypothetical thinking”, which includes

⁷ This is related to the philosophical debate on whether one can gain new knowledge from imagination or a purely mental activity, as was famously denied by Sartre (1972) and Wittgenstein (1980) (for a general discussion, see Stock 2007). It is worth noting that if the predictive coding framework is correct, the concept of “knowledge” may be revised: Knowledge may depart from veridicality; instead, it is close to information that can provide successful predictions. Thus, under the predictive coding framework, the only kind of knowledge Sartre recognizes (as cited in Stock 2007, p. 176)—observational knowledge—is not substantially different from other kinds of knowledge, because the knowledge gained through perception cannot be conceptually distinguished from those that are not: Gaining knowledge at each level is all about optimizing the predictions of lower levels.

future simulation and past counterfactual simulations: To determine the mechanistic function of memory we require an investigation into the way that its components contribute to the system, and then of how memory contributes to the functioning of the organism, helping it to reach goals at higher levels. It is worth noting that these concepts of memory function and malfunction are different to traditional ones: The distinction between memory function and malfunction is not equivalent to the distinction between remembering and misremembering or veridical representation and misrepresentation. Under the predictive coding framework, memory function can be regarded as updating knowledge for predictive model construction. Likewise, memory function and malfunction are independent from the generation of a predictive model that succeeds or fails in representing the world. That is, certain misrepresentations can lead to error minimization; furthermore, it is possible for misrepresentation rather than veridical representation to lead to a generative model.

4 From depersonalization to Cotard delusion

If the predictive coding framework is correct, it provides a new view not only on memory function but also on how we think about memory systems and the relation between memory and other cognitive systems. This framework provides a theory about the role of simulation models in the relationship between reflexive forms of self-consciousness and the narrative self (Hohwy 2007). It provides a theoretical explanation of the finding that memory systems are also involved in perception⁸ and interoception. This implies that we not only simulate offline (e.g., mental time travel, mind-wandering), but also simulate online. The simulated model provides us with a subjective reality through which we see the external world and ourselves. It is transparent and immediate: We experience it as objectively real and we directly interact with what is represented.

⁸ This is consistent with the evidence that memory influences perception (e.g., Summerfield et al. 2011).

However, this characteristic is absent in patients suffering from depersonalization. Depersonalization is an example of how one can become detached from one's simulated model of oneself: One's mental autobiography is no longer direct, and one experiences a sense of distance from the model.⁹ Gerrans (this collection) suggests that the loss of sense of presence in depersonalized patients results from a failure to minimize prediction error from the hypoactivity of the AIC—the activation of which informs us of the significance of external or internal information. Gerrans' theory is based on Seth et al.'s idea of interoceptive inference (or interoceptive predictive coding; see also Seth this collection), according to which predictive coding not only applies to exteroception but also to interoception, and emotional states, including the sense of presence, arise from interoceptive prediction successfully matched to actual interoceptive signals (Seth 2013; Seth et al. 2011). As it is suggested that the AIC is suggested to be the correlate of the integration of exteroceptive and interoceptive signals and that it plays a role in maintaining a salience network for the relevant states, the hypoactivity of the AIC leads to the failure to associate affective significance with bodily states. As Gerrans suggests, “not all higher level control systems can and do smoothly cancel prediction errors generated at lower levels” (this collection, p. 9). Because the coding formats at each level are distinct, the coding format of low-level processing is opaque to introspection (p. 9). The problems faced by depersonalized patients can be accounted for by the prediction error based on persisting, unexpected hypoactivity. Attention is then directed towards resolving the prediction error. Gerrans' proposal is that an inability to explain away the surprisal and this increased attention causes anxiety in DPD. Here, CD can be seen as a strategy for some systems to react to anxiety in order to minimize the prediction error.

As Gerrans suggests, “[d]elusions are best conceptualized as higher-level responses to pre-

⁹ In contrast to depersonalization, derealization refers to the “[e]xperiences of unreality of detachment with respect to surroundings” (American Psychiatric Association 2013, p. 302)—patients suffer from detachment from the simulated model of the environment.

diction error which, however, cannot cancel those errors” ([this collection](#), p. 10). That is, even though not all prediction error can be successfully cancelled, the brain—the organ that constantly minimizes prediction error, according to predictive coding framework—still tries to modify its model in order to decrease surprisal, though unsuccessfully. If what I have suggested in the last section is correct, the function of memory systems is to update knowledge contributing to the construction of predictive models in order to minimize prediction error. The anomalous model of CD is thus one constructed by the hierarchical simulation model to match the hypoactivity of the AIC—the loss of appraisal that represents the significance of self-related information. To construct a model in which oneself is dead or does not exist cannot successfully explain away the prediction error—since one still has the experience of a bodily state—it may nevertheless be the best solution the given system can come up with in order to cope with the increased anxiety resulting from increased attention.

However, this still leaves us with the question of why some depersonalized patients develop CD, whereas most of them do not develop this delusion. [Gerrans \(2014\)](#) suggests that the difference between delusional and non-delusional minds lies in differences in the default mode network, which include information that triggers activity, hyperactivity, and hyperconnectivity, interaction with the salience system, and absent or impaired “decontextualized supervision” (pp. 73–74). Decontextualized supervision allows one to “reason about *oneself* using impersonal, objective rules of inference” (p. 76).¹⁰ The activity of its circuit is anti-correlated with the activity of the default mode network (pp. 83–84) because of the limited cognitive resources for high-level metacognitive processes. Gerrans suggests that delusional thoughts arise from the system’s failure to balance this allocation; thus they slip through the supervision system.

Nevertheless, the existence of decontextualized supervision explains how anomalous forms of predictive models—which would be suppressed in non-delusional subjects—could emerge, but it does not account for the model’s relation to anomalous experience or to the way in which the content of delusion is constructed (e.g., Cotard delusion). I therefore propose that a delusional mind does not only result from a compromised decontextualized supervision; it also results from an aberrant precision expectation¹¹ of exteroceptive or interoceptive signals. [Jakob Hohwy \(2013\)](#) proposes the notion of uncertainty expectations: We predict the causal structure of the world (and of one’s own bodily state), as well as the level of uncertainty in the environment, which allows us to respond to the external environment under various levels of uncertainty. The strength of prediction error is proportional to the expected certainty: When the uncertainty level is expected to be higher (due to external or internal noise), the prior model is weighted higher, whereas expected low uncertainty gives more weight to bottom-up prediction error. According to [Hohwy \(2013\)](#), delusion arises when precision expectation is either too high or too low, and those in between would report only the anomalous experience, without forming a delusion. In the case of Cotard delusion developed from depersonalization, when one has the expectation of high precision, the system tends to be driven by the bottom-up predictive error of unexpected hypoactivity of the AIC, rather than the prior model. One is, therefore, more likely to revise the model in order to explain away the surprisal resulting from the mismatch between the actual and predicted activation level of the AIC; that is, the systems of patients suffering from CD are driven by an urge to modify their top-down predictive models in order to conform to the loss of AIC activity. The construction of the model in CD is considered an attempt to minimize prediction error.

Finally, explaining delusion under the predictive coding framework provides new understanding to the debate between one- and two-

¹⁰ The system of decontextualized supervision is distinct from the semantic memory system discussed in the last section: The latter provides objective elements for the construction of a contextualized autobiographical episode, while the former supervises autobiographical episodes by utilizing decontextualized reasoning.

¹¹ “Precision” is also used to refer to the precision of inferences about hidden causal structures (e.g., in [Friston et al. 2013](#)). Here and in [Hohwy \(2013\)](#) it indicates the precision of incoming signals.

stage models of delusion. The one-stage model holds that anomalous experience only suffices to explain the occurrence of delusion (Gerrans 2002; Maher 1974, 1988); according to two-stage model, however, other cognitive disruption is required to explain the content of the delusion in particular (Young & De Pauw 2002). However, if the predictive coding framework is correct, the clear distinction between experience and rationalization assumed in the traditional discussion does not exist: Perception, cognition, and action are now considered continuous and highly integrated (Clark 2013b; Hohwy & Rajan 2012). Experience and rationalization are different layers of abstraction within the very same process of prediction error minimization under the predictive coding framework.

5 Conclusion

In his target paper, Philip Gerrans proposes a theory of self-awareness that integrates the predictive coding framework, the appraisal theory, and the simulation model. It accounts for the loss of self-awareness in DPD and CD, and provides a new understanding of patients' anxiety. In this commentary, I have proposed (1) that the simulation model should be considered a hierarchical model involving multiple memory systems—namely, it is constituted by procedural, semantic, and episodic memory and prospective (section 2); and (2) that the function of memory systems or simulation models, under the predictive coding framework, is to update the knowledge required for successful prediction (section 3). This implies that memory function and malfunction are independent from the generation of a predictive model that succeeds or fails in representing the world, since it is possible that misrepresentation rather than veridical representation leads to a generative model that minimizes prediction error. Based on such view of the simulation model, CD can be regarded as the modification of top-down prediction in an attempt to explain away the prediction error resulting from unexpected hypoactivity of the AIC. I also suggested (3) that a combination of two factors is necessary for the occurrence of CD from depersonalization: the

compromised decontextualized supervision system and the expectation of high precision of interoceptive signals (section 4).

If both the general framework and my suggestions are correct, there are a number of issues worthy of further investigation: First, if the model that explains the symptoms of CD is created by the system in order to minimize prediction error from hypoactivity of the AIC, with the aim of affording relief from anxiety, it is expected that the change of prediction may be accompanied by minimized prediction error or/and prediction error from other unpredicted activities. In the case of Cotard delusion, the new model—the model of the organism's death or non-existence—would encounter new kinds of prediction error due to information about bodily states, instead of a lack of emotional significance. This may as well be the kind of prediction error that cannot be cancelled top-down and which can be expected to lead to anxiety based on Gerrans' theory. Therefore, the anxiety characteristic of the Cotard delusion is speculated to be the result of different prediction errors from patients suffering from Cotard syndrome. Studies on the difference between the anxiety present in DPD and that in CD can support or refutation of the framework proposed. Furthermore, it is worth noting that not all patients with the CD suffer from anxiety. For example, in Berrios & Luque's (1995) analysis of 100 cases, anxiety is reported in only 65% of subjects, and patients were categorized: Cotard type I patients showed no affective component, whereas type II patients showed depression and anxiety. Can the proposed framework account for both types of patients?

Another interesting question for future research is whether we can better understand the relation between the simulation model and affective processing within the predictive coding framework, and whether an explanation of this would be consistent with the existing evidence relating to emotional memory (e.g., LaBar & Cabeza 2006). Affective processing can influence encoding and retrieval of memories, whereas simulating possible episodes is thought to help rehearse affective responses. One possible avenue might be the investigation of the influence

of different forms of simulation on affective processing (e.g., memory retrieval from a field or an observer perspective; Berntsen & Rubin 2006), and further on one's awareness of one's future and past (Wilson & Ross 2003): How can this be accounted for by the principle of prediction error minimization? Does the simulation of potential affective responses optimize prediction and reduce potential error in the future? The simulation and integration of future potential changes into the model of one's autobiography is thought to potentially contribute to the prevention of dramatic changes in one's model at higher levels, and to maintain mental autobiographies that are more consistent across time.

Acknowledgments

I am grateful to Thomas Metzinger and Jennifer M. Windt, as well as two reviewers, for their critical and constructive comments.

Metamisery and Bodily Inexistence

A Reply to Ying-Tung Lin

Philip Gerrans

The difference between the Cotard Depersonalisation and Depersonalisation Disorder may consist, not only in the fact that the Cotard delusion is a response to prediction error affective/bodily information, but the level in the predictive processing hierarchy at which predictions about bodily information are violated.

1 Prediction error and veridicality

My explanation of Depersonalisation Disorder (DPD) argued that the characteristic experience is shared by people who suffer from the Cotard Delusion (CD). The difference between the two conditions is that the person with DPD does not develop a delusional response to her experience of de-affectualisation. She simply reports as it is: “I *feel as if* my experiences do not belong to me”. The person with Cotard, however develops an explanation of that feeling and identifies with it “I no longer exist”. In commenting on this proposal Ying-Tung Lin opens up a range of new possibilities for cognitive the-

orizing. The first is that the predictive coding approach provides a new framework for cognitive theorizing which improves on “second factor” approaches to delusion. The second is that attention to the predictive nature of the processes which generate experience might suggest an important difference between the two conditions: namely the role of the Anterior Insular Cortex (AIC).

One way to approach the phenomenon would be to ask why the person with DPD seems to be able to understand that her experience is not veridical while the person with CD

does not (*modulo* all the *caveats* about the epistemic status of delusional attitudes). The CD patient for example does not say “It feels as if I don’t exist” she says “I don’t exist”. This way of approaching the problem fits with a now standard approach to delusion, that argues that there are (at least) two stages of cognitive processing involved in delusion formation. The first generates an anomalous experience and the second generates a delusional response to that experience.

Ying-Tung Lin however, following Hohwy and Clark, explains delusion in terms of the attempt by higher order control systems to account for surprisal in a predictive coding hierarchy. The radical aspect of these ideas is that neither the precipitating experience nor the delusional response need be conceived of as the result of cognitive malfunction. Because there is no intrinsic connection between error minimization and malfunction “certain misrepresentations can lead to error minimization; furthermore, it is possible for misrepresentation rather than veridical representation to lead to a generative model” (Lin this collection, p. 8).

Ying-Tung Lin’s commentary applies these ideas to the Cotard delusion, arguing that it is a model that minimises the prediction error represented by depersonalisation experience. Her target is to describe a

cognitive architecture [that] could, in principle, explain CD in terms of its development from depersonalization, and what exactly are the underlying differences between patients suffering from the Cotard delusion and those suffering from depersonalization disorder (DPD) but free from the Cotard delusion? (Lin this collection, p. 2)

2 The sense of presence

Before I make some comments, I want to highlight the original aspects of her account and show how it can explain how experience acquires a quality of “mineness” or “sense of presence”, that is of belonging to a self. We can then use the predictive coding framework to ex-

plain how the sense of presence can go missing. Loss of the sense of presence signals a prediction error which then requires a higher-level system to build a predictive model that fits that error.

The first point to note is that on the most radical interpretation of predictive coding ideas the veridicality of representation is a corollary of cognition not its primary goal. The primary goal of a cognitive system is to predict its own informational states consequent on its actions (broadly construed to include internal regulatory actions). The point is not just that the objects of experience are constructed and hence may be illusory or misrepresented. Rather veridicality of experience is secondary to the accuracy with which cognitive process predicts the flow of information in sensory systems. As she says in the case of perception this means that “instead of aiming to answer the question ‘what is this?’ perception studies should answer the question ‘... what does this resemble?’” (Lin this collection, p. 6). This formulation captures the idea that the visual system, for example, is not passively registering retinal information and constructing a representation of the external world, but using a model which predicts the flow of information coming from the retina.

The first step is to apply the same idea to interoception. We see that the mind is not passively registering changes in body state and constructing a model of the body accordingly but predicting the flow of bodily information in cognitive context. Those contexts range from maintenance of homeostasis to the use of affective experience to inform decision-making and reflective cognition. Thus when I think about the past or future these episodes of retrospection or prospection are infused with affective significance.

The radical import for the understanding of pathologies of self-representation is very elegantly brought out by her discussion. Ying-Tung Lin in effect argues that the experience of the self in autobiographical episodes is no more direct than experience of the world in perception or of past events in memory. In each case no object is directly represented or experienced. Rather the relevant object in each case (object

of perception, remembered event, or self in the case of first person awareness) is *inferred* as a part of a process of optimizing predictive accuracy in specific cognitive contexts.

As many have argued the role of the Anterior Insular Cortex (AIC) is to integrate and represent affective information: i.e., those bodily states, which tell the organism how it is faring in the world, actual, imagine or remembered. The point to recall from Ying-Tung Lin's account is that the AIC is not representing a self but constructing and optimizing a model that predicts the flow of affectively-charged bodily information.

This is why when AIC is hypoactive the subject feels a loss of subjective presence, reported as depersonalization. In particular the patient has a loss of subjective presence for her own body: she registers changes in body state but they do not feel affectively significant for her. Because that lack of feeling is not predicted she then reports it in the vocabulary of DPD.

Why does the DPD patient not proceed to something like the Cotard delusion? According to Ying-Tung Lin whether a delusion is formed depends on the degree of precision assigned to the information produced by hypoactivity in the AIC.

In the case of Cotard delusion developed from depersonalization, when one has the expectation of high precision, the system tends to be driven by the bottom-up predictive error of unexpected hypoactivity of the AIC, rather than the prior model. One is, therefore, more likely to revise the model in order to explain away the surprisal resulting from the mismatch between the actual and predicted activation level of the AIC; that is, the systems of patients suffering from CD are driven by an urge to modify their top-down predictive models in order to conform to the loss of AIC activity. The construction of the model in CD is considered an attempt to minimize prediction error.

3 Conclusion

Reading over this account I wonder if there is an alternative interpretation available consistent with the predictive coding account. It is consist-

ent with the view that patterns of activity in the AIC are abnormal in CD, but unlike DPD those patterns are not the result of VLPFC-induced hypoactivity.

Ex hypothesi the CD patient is extremely depressed. Evidence suggests that circuitry centred on the amygdala is affected, which means that online affective responses are flattened.

The role of the AIC is to monitor for changes driven by affective processing. It thus predicts for example that a typically positive event would be processed as positive. Thus, when that event is processed as negative or neutral, the AIC detects an error, signaled in the form of an anomalous experience. The patient is in the position being able to detect and signal changes in her affective responses, which take the form of unpredicted absences in bodily response. Thus *her lack of felt bodily response is processed as affectively significant* in the Cotard delusion with the result that she experiences it. Thus she does not feel neutral she feels miserable. Or as we might put it *she feels metamisery* because the role the AIC is to enable the person to feel the affective significance of bodily changes *including the absence of predicted changes*. In Cotard delusion the patient feels the affective significance the unpredicted absence of positive changes.

In DPD, by contrast, the patient does not feel the significance of bodily information because her AIC is inhibited and hypoactive.

Thus the difference between the two conditions may consist, not only in the fact that the Cotard delusion is a response to lower level prediction error, but the level in the predictive processing hierarchy at which predictions about bodily information are violated.

Visual Adaptation to a Remapped Spectrum

Lessons for Enactive Theories of Color Perception and Constancy, the Effect of Color on Aesthetic Judgments, and the Memory Color Effect

Rick Grush, Liberty Jaswal, Justin Knoepfler & Amanda Brovold

Many forms of visual adaptation have been studied, including spatial displacements (Heuer & Hegele 2008), spatial inversions and rotations (Heuer & Rapp 2011), removing or enhancing various colors in the visual spectrum (Belmore & Shevell 2011; Kohler 1963), and even luminance inversion (Anstis 1992). But there have been no studies that have assessed adaptation to an inverted spectrum, or more generally color rotation. We present the results of an adaptation protocol on two subjects who wore LCD goggles that were driven by a video camera, but such that the visual scene presented to subjects was color-rotated by 120°, so that blue objects appeared green, green objects appeared red, and red objects appeared blue (with non-primary colors being analogously remapped). One subject wore the apparatus intermittently for several hours per day for a week. The second subject wore the apparatus continually for six days, meaning that all his visual input for those six days was color rotated. Several experiments were run to assess the kinds and degrees of adaptation, including Stroop (1935), the memory color effect (Hansen et al. 2006), and aesthetic judgments of food and people. Several additional phenomena were assessed and noticed, especially with respect to color constancy and phenomenal adaptation. The results were that color constancy initially was not present when colors were rotated, but both subjects adapted so that color constancy returned. However, there was no evidence of phenomenal color adaptation. Tomatoes continued to look blue, subjects did not adapt so that they started to look red again. We found no reliable Stroop result. But there was an adaptation to the memory color effect. Also, interesting differences were revealed in the way color affects aesthetic judgments of food versus people, and differences in adaptation to those effects.

1 Introduction

The idea of a subject whose visual experience is color inverted has been a philosophical mainstay at least since [Locke \(1975\)](#), and has fuelled a great deal of philosophical work on the nature of perception up to the present day. In psychology, testing the extent to which subjects' visual systems can adapt to alterations in visual input has likewise been a fruitful mainstay for over a century (for current research and references see [Heuer & Hegele 2008](#); [Heuer & Rapp 2011](#); [Belmore & Shevell 2011](#)). Despite these two facts, adaptation to an inverted spectrum has never been studied. Given that there is adaptation to a wide range of distortions to visual input, including spatial manipulations and spectral filtering, we speculated that it was conceivable that there might be adaptation, in some form or other, to color rotation. That is, if visual input was reworked such that tomatoes appeared blue, would subjects over time adapt so that tomatoes regained their normal (red) phenomenal appearance? And even if such a shocking result did not occur, might there nevertheless be adaptation to other color-relevant phenomena, such as color constancy, aesthetic judgments, or the memory-color effect?

Figure 1: An inverted spectrum. The familiar red-to-violet spectrum laid out from left to right (top) compared to an inverted violet-to-red spectrum from left to right (bottom). Note that the central colors map to themselves or very similar colors.

We tested this as follows. First, rather than an inverted spectrum, we employed a *rotated spectrum*. An inverted spectrum is one in which one takes the usual red-to-violet spectrum and just reverses it to get a mapping from colors to colors. Red would map to violet, orange to blue, violet to red, and so on (see [figure 1](#)).

For two reasons we chose to systematically alter color input not with an inverted spectrum,

but with color rotation (see [figure 2](#)). In a 120° degree rotation, greens become reds, reds become blues, and blues become greens (see [figure 3](#)).

One reason to employ a rotation rather than an inversion is that in a rotation, all colors map to different colors, whereas in a spectral inversion, the middle of the spectrum maps to itself, and so not all colors differ. Also, with a 120° rotation, primary colors map to primary colors, and this was convenient for testing purposes. For instance, we wanted to test semantic adaptation via a Stroop task, and Stroop is difficult to test if one is dealing with non-canonical colors (since subjects pause to think of what seems to be the best name for the color: “... um, periwinkle?”). It was important that the text was colored in a primary color during baseline testing (before subjects' vision was color-altered), and that it continued to be presented in a primary color during testing while colors were altered.

Figure 2: Color rotation. If colors on the left disk are mapped to colors that are 1/3 of a clockwise rotation (120°), then green (lower left) maps on to red (slightly left of the top); red maps to blue (middle right); and so forth. The disk on the right is a 120° color-rotated version of the disk on the left.

The rotation was implemented in the following way. A small video camera was mounted on a bike helmet, as were a pair of LCD goggles (see [figure 4](#)). The sides of the goggles were sealed against the wearer's face so that there was no peripheral visual input; subjects could only see what was displayed on the LCDs. The video camera output was run to a laptop computer, which ran software that color-rotated the

video feed and pushed the result to the LCD goggles. The subject would wear the bike helmet and carry a bag that held the laptop and battery packs for the laptop, camera, and goggles. In what follows we will refer to this as the *rotation gear*, or simply the *gear*. Moreover, we will use the expression *under rotation* to refer to the condition of having one's visual input color-rotated by the gear. In addition to rotating the spectrum (the intentional effect), the gear also eliminated binocular disparity since there was only one camera (which projected the same image to both eyes), and also impaired peripheral vision, since the camera's field of view was less than normal vision. As a result, while most normal activities were possible (if cumbersome), some, such as driving a motor vehicle, were not possible.

Figure 3: A typical outdoor scene color-rotated by 120°.
(<http://www.open-mind.net/videomaterials/grush-color-video>)

There were only two subjects, and both were investigators in this project (and authors of this paper). This was for practical reasons. First, we anticipated that UCSD Internal Review Board would be reluctant to grant human subjects approval, based both on the length and significant inconvenience of the protocol and also because this particular protocol had never been attempted before, and so, for example, there was no precedent concerning whether such a regimen might cause long-term damage to participants' color vision. And even if approval were obtained, we anticipated that finding volunteers for such a protocol would be difficult, and, even if we did find them, the small grant we were operating with did not give us the resources to appropriately compensate them. Employing two of the investigators as subjects solved these problems. Because investigators

were aware of the protocol and risks, and were intimately familiar with the relevant equipment and potential problems and so in a position to more accurately assess conditions under which the protocol should be aborted, some of the concerns were eased, and approval was eventually granted. Moreover, investigators were willing to put themselves through the arduous protocol.

Subject 1 (RG) wore the gear intermittently, in several multi-hour sessions per day for a week. Two reasons for an initial intermittent protocol were, first, that it would allow us to trouble-shoot the equipment—if it had to be shut down for a few hours for tinkering this would not interfere with the protocol, and we wanted to ensure that everything was functioning smoothly before subject JK's continuous protocol began. And, second, we wanted to compare the results of a subject who wore the gear intermittently with the results of one who wore it continually. Subject JK wore the gear continually for six straight days, meaning that he had no unrotated visual input for that entire period. He slept with a blindfold and showered with closed eyes in the dark, but otherwise wore the gear at all times.

Figure 4: The camera and goggles used.

Our high-level goals were to assess phenomenal and semantic adaptation. Phenomenal adaptation would manifest as a return to normalcy such that under rotation tomatoes would start to look red again, the sky would appear blue, and so forth (this is discussed in more detail later on). It might also manifest as a gaining of color constancy under rotation. These would be parallel to adaptation to spatial inversion in which, after adaptation objects begin to

look right-side-up again. We assessed this in several ways. One was the memory-color effect. A second was aesthetic judgments. A final method was subjective report: subject JK kept a hard-copy journal in which he wrote observations, and RG had a digital voice recorder that he used for similar purposes. There were also audio recordings made during the testing periods, as well as when JK finally removed the rotation-gear.

Figure 5: Images of people and food, in normal color, and with a 120° color rotation, for purposes of illustration only—none of these was in the stimuli set used in the experiment. The food items are French toast with maple syrup and strawberry confit (middle row), and chicken salad with guacamole (bottom).

Semantic adaptation would manifest as a remapping of color terms to their “correct” referents. So, for example, when first putting on the

gear, if a subject were asked to pick up the “blue block,” they would pick up a block that was in fact red. Would subjects semantically adapt such that the word “red” was immediately semantically connected to the red block, despite the fact that the block was presented as blue through the rotation gear? This was assessed via subjective report and Stroop. In the following sections we discuss each investigated phenomenon, the results we found, and their implications.

For all experiments there were four times at which trials were run: i) *pre-rotation*, in which trials were run after the subject initially put on the gear but the colors were not yet rotated; ii) *early rotation*, wearing the gear and first color-rotating visual input; iii) *late rotation*, at the end of the time during which the subject was wearing the gear and had time to adapt; and iv) *post-rotation*, while the subject was still wearing the gear, but colors were not rotated. The reason for running trials (i) and (iv) while wearing the gear without rotating the colors, rather than just through normal vision without the gear, was to control for effects possibly due only to the fact that visual input was going through a camera and LCD goggles. For some experiments there were additional times at which the trials were run, as will be explained below.

A final note on methodology. A number of factors distinguish the current study from an appropriately run and controlled psychological experiment. The small n and the fact that both subjects were also investigators in the study are perhaps the two most significant differences. These limitations were forced by a variety of factors, including the unusual degree of hardship faced by subjects, our relatively small budget, and the fact that this protocol had never been tried before. Because of these limitations, the experiments and results we report here are intended to be taken only as *preliminary* results—as something like a pilot study. Even so, the results, we believe, are quite interesting and suggestive.

2 Color, color constancy, and enactive vision

According to proponents of enactive perception, perceptual experience amounts to relevant beha-

vioral skills (O'Regan & Noë 2001; Noë 2004, [this collection](#)).

To be a perceiver is to understand, implicitly, the effects of movement on sensory stimulation [...]. An object looms larger in the visual field as we approach it, and its profile deforms as we move about it. A sound grows louder as we move nearer to its source. Movements of the hand over the surface of an object give rise to shifting sensations. As perceivers we are masters of the sort of sensory dependence [...]. We spontaneously crane our necks, peer, squint, reach for our glasses, or draw near to get a better look (or better handle, sniff, lick, or listen to what interests us). The central claim of what I call the enactive approach is that our ability to perceive not only depends on, but is constituted by, our possession of this sort of sensorimotor knowledge. (Noë 2004, pp. 1–2)

The enactive approach correctly predicts that there will be adaptation to certain kinds of spatial distortion to visual input (Noë 2004). The idea is that if perception is a matter of learning sensorimotor contingencies, then though these contingencies can be disrupted via altering the spatial features of the input, the new contingencies can be learned (they are just a different set of contingencies, after all) and when this happens, perceptual input will seem normal again.

Noë (2004) boldly claims that not just spatial features, but even color phenomenology might be explained on enactive principles.

Our ability to perceive [a] wall's color depends on our implicit understanding of the ways its apparent color varies as color-critical conditions vary. At ground, our grasp of these dependencies is a kind of sensorimotor knowledge. We can distinguish two different kinds of sensorimotor dependencies [...]. Crucially, the perceptual experience of color depends on the perceiver's knowledge of both kinds of sensorimotor patterns.

Movement-dependent sensorimotor contingencies are patterns of dependence between sensory stimulation, on the one hand, and movements of the body, on the other [...].

[O]bject-dependent [...] sensorimotor contingencies [...] are patterns of dependence between sensory stimulation and the object's movement, or the object's changing relation to its environment. (Noë 2004, pp. 129–130)

Accordingly, our protocol speaks as directly to the enactive account of color as inverting prisms speak to an enactive account of vision's spatiality. Notice that the technological apparatus of color rotation comes into play *after* both sorts of patterns have manifested (with the exception of eye movements, which happen after the rotation is effected, though this fact does not change any of the contingency patterns). What this means is this: suppose that there is a particular way that a red surface changes its reflectance properties both as we move around it (movement-dependent), and also as it changes relevantly with respect to the environment (object-dependent). Call this pattern of changes Pattern R. And suppose that the same is true for a blue surface, meaning that it has a different, but characteristic pattern of changes we can call Pattern B. To get a specific example, let's suppose that the red surface gets brighter when it gets angled upwards, but the blue surface does not (the details of these patterns don't matter for purposes of illustration, all that matters is that there are such patterns, and that they differ for different colors). Whatever the patterns R and B are, they occur whether anyone is wearing rotation gear or not. But after the rotation gear is involved the surface that is behaving according to Pattern R will be presented to the subject with stimulation from the blue part of the spectrum, and the surface that is behaving according to Pattern B will be presented with stimulation from the green part of the spectrum. For instance, the subject will see the *apparently blue* surface getting brighter as it is angled upwards, which

is Pattern R, because the apparently blue surface is actually red, and hence behaves according to Pattern R.

So the question is: after experience with red surfaces, which behave according to objective patterns appropriate to red surfaces (Pattern R), but are presented through the goggles with blue parts of the spectrum, will these surfaces start to look red again? This is clearly the prediction that is made by the enactive theory of color, since to appear red just is to behave according to Pattern R on this theory, and the surfaces that are being presented with light from the blue parts of the spectrum are behaving according to Pattern R. The enactive theory makes this prediction for both color constancy and color phenomenology. We will discuss color constancy first.

We did not test color constancy in any controlled way, but the subjective reports are quite unmistakable. Subject RG noticed that upon first wearing the rotation gear color constancy went “out the window.” To take one example, in normal conditions RG’s office during the day is brightly lit enough that turning on the fluorescent light makes no noticeable difference to the appearance of anything in the office. But when he turned the lights on after first donning the gear, everything had an immediate significant change of hue (though not brightness). He spent several minutes flipping the light on and off in amazement. Another example is that he also noticed that when holding a colored wooden block, the surfaces changed their apparent color quite noticeably as he moved it and rotated it, as if the surfaces were actively altering their color like a chameleon. This was also a source of prolonged amusement. However, after a few days the effect disappeared. Turning the office light on had little noticeable effect on the color of anything in his office, and the surfaces of objects resumed their usual boring constancy as illumination conditions or angles altered.

Subject JK reported the same thing: an initial period in which the apparent colors of objects shifted widely with changes in illumination conditions or viewing angles, followed after a day or two with the restoration of color con-

stancy such that those same changes had no effect on apparent color.

There was one difference, though, between RG and JK. While RG’s perceptual system gained the capacity for color constancy under rotation, he never lost color constancy in normal conditions. After the first few days of intermittently wearing the gear, objects had stable apparent colors whether he wore the gear or not. Though of course the colors that were stable were different in the two conditions. JK (who wore the gear continuously for six days) also gained color constancy under rotation, but lost it for normal conditions, as was apparent at the end of his trial when he removed the gear. Indeed, almost immediately after he removed the gear and was seeing things without rotation for the first time in six days, he spent several minutes flipping a light switch on and off and marvelling as the apparent color of everything in the room changed at his command (while no one else in the room noticed anything). So while RG’s visual system became, so to speak, bi-constant, because he switched back and forth between rotated and non-rotated visual input, JK’s visual system, because it was exclusively rotated for six days, gained color constancy under rotation, but temporarily lost normal color constancy. Normal constancy returned for JK within a few hours after he stopped wearing the gear.

These results are precisely what the enactive theory of color constancy would predict. Initially the kinds of patterns of color-relevant change exhibited by objects in the environment was different from what the visual system had come to expect, both in terms of changes in environmental conditions generally (e.g., switching on a fluorescent light), and movement specific changes (e.g., walking around them or rotating them in hand). The sensorimotor contingencies changed, and as a result color constancy was disrupted. But after a period of time during which these new dependencies were, presumably, learned, color constancy was restored.

A more convincing protocol would be one in which there were control subjects whose visual input was rotated, but who were not active in their color environment. Such a protocol

would be difficult to implement. Wearing rotating equipment for six days is quite difficult. If you were then to disconnect visual input from overt behavior on top of that, this would become extremely burdensome for test subjects. This could be done either by having the video camera not moving at all, or moving randomly; or by recording the video from a rotated subject as they are actively exploring their environment, and simply play that video back to control subjects, so that their visual input would not change at all as a consequence of their own actions. But even though there was no control of this sort in our protocol, it is safe to say that the proponent of an enactive theory of color constancy should be encouraged by this result.

But what about color adaptation? Did red surfaces start to look red again? The results here are less encouraging for the enactive theorist. With one interesting and suggestive observation to be discussed shortly, we found nothing that suggested color adaptation. As assessed by subjective report, stop signs continued to appear blue, the sky green, and broccoli red throughout for both subjects.

Though this is not the result that the enactive theorist would hope for, it isn't entirely conclusive. First, it may have been the case that a protocol of longer than six days would have resulted in phenomenal adaptation. Six days may simply not have been long enough to learn the new relevant sensorimotor contingencies. This is certainly possible. But it should be noted that all other sorts of visual adaptation (to spatial inversions, spectral filtering etc.), including our own result with adaptation to color constancy, occurred in less than six days.

Second, the gear does in fact introduce a lot of artefacts besides just the change in presented colors. Artefacts are introduced by the digitization of the image and its presentation through LCD goggles. So proponents of the enactive theory of color needn't jump off a building just yet. They may maintain that because of these artefacts, the process of relearning the needed sensorimotor contingencies was somehow short-circuited.

But there are a couple of considerations that suggest that the result is not so easily dis-

missed. First, whatever artefacts the gear did introduce were not such as to make any difference to normal color vision. If one wears the gear without color-rotation, things appear to be in their normal colors. This seems to suggest that whatever patterns of change account for our ability to see normal things in their normal colors, they are not significantly compromised by whatever artefacts the gear introduced. This would seem to remove some of the motivation from the suggestion that adaptation did not occur because of artefacts introduced by the gear. Second, the gear clearly maintained enough information about patterns of color change that adaptation to color constancy occurred fairly quickly. Again, this suggests that much or all of whatever is important in patterns of change relevant to color perception is preserved by the gear. If it was not, adaptation to color constancy should not have occurred. The one thing not preserved by the rotation gear was the sensorimotor-*independent* feature of which retinal cells were stimulated when various surfaces were in view. And that one feature seems to be the best candidate for the determinant of apparent color, given that everything else changed but apparent color did not.

We mentioned above that there was an interesting pair of events that, while not quite amounting to phenomenal adaptation, are at least very suggestive. On two occasions late into his six-day period of wearing the gear, JK went into a sudden panic because he thought that the rotation equipment was malfunctioning and no longer rotating his visual input. Both times, as he reports it, he suddenly had the impression that everything was looking normal. This caused panic because if there was a glitch causing the equipment to no longer rotate his visual input, then the experimental protocol would be compromised, and the value of his days of sacrifice in the name of science and philosophy would have been significantly diminished.

However, the equipment was not malfunctioning on either occasion, a fact of which JK quickly convinced himself both times by explicitly reflecting on the colors that objects, specifically his hands, appeared to have: "OK, my hand looks purplish, and purple is what it

should like under rotation, so the equipment is still working correctly.”

Prima facie there seems to be a clear difference between i) a tomato looking “normal” because it now appears phenomenally to be red; and ii) a tomato looking “normal” because though it appears blue, one is now used to tomatoes appearing blue, that is, blue no longer appears unusual. JK’s situation was a case of (ii), but the lack of a sense of novelty of strangeness made him briefly fear that he was in a (i) situation. He described it as a cessation of a “this is weird” signal.

Even though (i) and (ii) seem to be quite different, the phenomenon is suggestive. It indicates that there is definitely a stage in which the subject requires explicit reflection to discern (i) from (ii). This might lead one to speculate that this stage might signal an early stage of genuine color adaptation (we will discuss this further in the final section).

But it could also be an initial stage of a very different possibility, one discussed by Noë himself:

[...] the strongest [inverted spectrum] arguments ask us to consider the possibility in the first person. At stage 1 I am inverted. At stage 2, I get used to the inversion. I realize things now look color-inverted compared to the way they used to look, and I use this knowledge to guide my correct use of words. I get really good at acting normal. At stage 3, I suffer amnesia and forget that things ever looked different. The point of this thought experiment is that it suggests a reason to believe that things are now different with me with respect to my color experience, even though I am now unable to report those differences. (2004, p. 94)

While JK never suffered from amnesia, his two episodes suggest that it is possible to at least go some distance down precisely this path.

3 The memory-color effect

If subjects are given control over the hue of an image and asked to adjust it until it appears

grey scale there is an interesting effect. If the image is of an object with a salient prototypical color (such as bananas, which are saliently and prototypically yellow), subjects will judge that it is grey scale when in fact the hue is slightly in the direction opposite to that of the standard color. So, for example, an image of a banana will be judged to be grey scale when it is in fact just slightly periwinkle. This is the memory-color effect (Hansen et al. 2006). One possible explanation of this effect is that when the image actually is grey scale, subjects’ top-down expectations about the usual color make it appear (in some way or another) to be slightly tinted in that hue. So when the image of the banana is actually completely grey scale subjects judge it to be slightly yellow. The actual color of the image must be slightly in the direction opposite yellow (periwinkle) in order to cancel this top-down effect and make the image appear grey. This is the memory-color effect.

We expected that after a period of wearing the gear this effect would diminish or even reverse. The reasoning was that if the rotated experience either just disrupted the association of the objects with their prototypical color, or even established a different prototypical color, the effect would be compromised.

Stimuli used in our trials were images of a banana, tomatoes, broccoli, a fire engine, a school bus, a stop sign, and a Starbucks logo. We wanted examples of natural objects as well as artefacts with strong color associations. We also used squares and circles, which have no obvious prototypical color, as controls. The hue of the initial image presentation was random, and subjects were to adjust the hue until the image appeared completely grey scale.

There were technical issues with RG that prevented his data from being usable. But subject JK’s results were in fact what we expected. Pre-rotation, JK’s results were normal. He judged the stimuli to be grey when in fact they were, on average, 3.5% saturated in the direction of the opponent color. JK was quite consistent with this except for one stimulus condition, broccoli, which he actually exhibited the opposite of the expected pattern. He judged it to be grey when it was about 1% saturated in

its normal color. The effect was robust, and we have no idea why. We suspect that it was some sort of artefact connected to that stimulus being presented through the rotation gear, but we don't know for sure.

Post-adaptation JK's assessments were, on average, about 0.5% saturation, again in the direction of the opponent color. Meaning that he still exhibited the effect, but its magnitude was lessened. This could mean one of two things: i) the rotation protocol disrupted the usual associations of colors and objects, and so all stimuli ended up being treated by his perceptual system just as controls, that is, as objects with no salient associated color; and ii) JK partially adapted to objects' new prototypical colors. Unfortunately the result we got, in which assessments were on average very close to grey, is consistent with both. The alteration was consistent with both a movement towards grey and a movement towards the canonical color, since both are in the same direction from a spot opposite the canonical color. But one consideration that speaks in favor of (ii) is that the broccoli stimuli, post-adaptation, did not move towards grey, but in fact were judged to be grey when they were even more green than in the pre-rotation trial. That is, the broccoli stimuli judgments moved not in the direction of grey, but in the direction of canonical color, and by about the same amount as the other stimuli moved in that direction: 2.5%.

Our result in the memory-color effect and the two occasions in which JK panicked are consistent. Both effects would seem to result from a re-aligning of the salient prototypical color of objects that have a salient prototypical color. The adaptation of the memory-color effect suggests that the experience of being color-rotated lessened the extent to which top-down effects associated certain objects with their actual prototypical colors, and perhaps even started associating them with new, different prototypical colors. And the lack of the "this is weird" signal when viewing his purple hand also suggests that the old prototypical look of his hand was being supplanted with a new prototypical look. And it also suggests not just that the old prototypical color association was being

lessened, but that a new one was emerging. What failed to look weird was his *purple* hand—not just a hand in any non-flesh color, but in *purple*. We did not test this, but it seems quite unlikely that had his hand suddenly looked bright red he would have similarly experienced a loss of the "this is weird" signal. This is speculative, but it at least suggests, consistently with the broccoli effect discussed above, that the result we saw with the memory-color effect was not just a loosening of the old associations, but the emergence of new ones.

Moreover, the adaptation of the memory-color effect appears to have been *general*. The items we used for testing in the memory color effect fell into two groups: first, there were those items, such as Starbucks logos and bananas, which were such that items of that type were observed at least sometimes during the period of rotation; and second there were others, such as fire trucks and baby chicks, which were not observed by the subject under rotation. If what was being altered by rotated experience was just the specific associations of colors with experienced objects, then we should have found different results for these two groups of objects. Bananas and Starbucks logos would be subject to adaptation with respect to the memory-color effect, and fire trucks and baby chicks would not. But this is not what we found. We found the memory-color effect was impacted for *all* tested objects, even those that had not been seen during rotation.

This suggests that the effect was general, meaning that the adaptation was manifested not as an alteration in some part of the perceptual system concerning its expectations about what bananas or other specific objects look like. Rather, the alteration appears to have concerned expectation about what *yellow things* generally look like. To put it in dangerously loose and anthropomorphic terms, some part of the system started cranking up the periwinkle knob when objects known to be yellow, like baby chicks, were seen. If this is indeed a *memory* effect (psychologist do, for some reason, call it the *memory-color* effect), then it suggests that some part of the system knew that baby chicks were supposed to be yellow, but was beginning to misremember what yellow was like.

Table 1: Assessments of food appeal. The graphs show the average scores for both subjects. For each subject, before testing each subject scored all images on a scale of 1–10, 10 being the most appealing. These scores were used to establish a normalization for each subject so that all scores could be re-expressed in terms of σ . They were also used to divide the dishes into high-rated and low-rated groups for each subject. Each subject then re-assessed each dish at four times during the experiment: pre-rotation, early-rotation, late-rotation, and post-rotation (see text for explanation). As can be seen, upon color rotation all dishes plummeted in their perceived appeal to a level below the score the unappealing dishes had before rotation. But after adaptation (late rotation) the low-rated dishes regained all of their appeal, and the high-rated ones regained a moderate amount.

Recall where we left off in the last section. There was a suggestion to the effect that for a subject who underwent an inverted spectrum procedure, a cessation of the “this is weird” signal, together with a loss of memory of how things used to look might result in that subject’s inability to report differences between their current inverted experience and their prior non-inverted experience. Such a subject would of course verbally report that their phenomenology had adapted (or, if they were more reflective, they might also admit the possibility that their phenomenology was still inverted, but that

their memory was failing to make this fact apparent to them). To indulge in some wild speculation, the general nature of the adaptation to the memory-color experiment suggests that something along these lines might possibly happen if there was a longer adaptation period. We will return to this in the final section.

4 Aesthetic judgments

Color plays a large role in a variety of aesthetic judgments. Red broccoli doesn’t look terribly appealing as a food item, and Hollywood main-

Table 2: Assessments of physical attractiveness of people. The graphs show the average scores for both subjects. For each subject, before testing each subject scored all images on a scale of 1–10, 10 being the most attractive. These scores were used to establish a normalization for each subject so that all scores could be re-expressed in terms of σ . They were also used to divide the images into high-rated and low-rated groups for each subject. Each subject then re-assessed each image at four times during the experiment: pre-rotation, early-rotation, late-rotation, and post-rotation (see text for explanation). As can be seen, color rotation had much less effect on ratings of physical attractiveness of people than it did on the appeal of food. The low-rated group was essentially unchanged throughout the protocol. The high-rated group experienced a relatively small drop during early-rotation, but regained nearly all of it by late rotation.

tains that gentlemen prefer blondes. But to what extent are these judgments malleable with experience? Might the red broccoli start to look more appetizing if one has enough experience eating it? To assess these questions we ran two aesthetic judgment experiments. In one, we measured how appealing different dishes looked, and in another we measured judgments of physical attractiveness of people (figure 5). For the first we used images from a large cook-book with a wide variety of dishes. For the second, since both subjects were heterosexual males, we used pictures of adult women taken from the in-

ternet. In both cases we separated the stimuli into high-rated and low-rated groups so that we could assess whether color rotation had a differential effect. And in both cases we ran four trials: an unrotated baseline trial of judgments before beginning the rotation period; an early-rotation trial immediately upon wearing the rotation gear; a late-rotation trial at the end of the adaptation period; and finally a post-rotation trial normal color vision was restored. Subjects scored all stimuli with a 1–10 numerical rating. We used the normal vision early-rotation ratings of each subject both to sort stimuli into

subject-specific high-rated and low-rated groups, and to establish a normalization (average and standard deviation) so that we could translate all ratings provided by each subject in terms of σ , meaning that 0 was average, 1 was one standard deviation above average, -1 was one standard deviation below average, and so forth.

The results can be summarized quickly (see table 1). For dishes in the appealing group, their appeal ratings immediately dropped significantly from pre-rotation to early-rotation. The drop was, on average, 3σ , from an average of 1.06σ to an average of -2.06σ ! Some notes from JK's diary speak to the effect of color rotation on food appeal:

Spinach looks a glossy, poisonous red (it's the texture and the color that look really nasty together, I think).

I genuinely lost my appetite at the sight of four enormous bowls of glossy red salad, pale pink cheese, blue kidney beans, deep blue beets, bright red peas, etc. [...]

I've noticed that I don't anticipate food at all the way I normally do. Normally during the day I think about food, think about making food, think about eating food, and when I get a full plate of tasty looking food in front of me, I'm a very happy person. Now there's a real disconnect between the way food tastes and the way it looks, and I don't honestly find myself craving anything during the day. I get hungry, yes, but a full plate of food in front of me looks intensely neutral on the desirability scale.

At the end of the adaptation period, those high-rated dishes had regained half of their appeal, being judged on average about -0.41σ . Both RG and JK followed this pattern. Interestingly though, in the post-rotation rating, RG's ratings returned to within $.35\sigma$ of baseline for the appealing dishes (to $.71\sigma$ compared to an initial average rating of 1.06σ), while JK's ratings were lower, returning only to within 0.61σ of

baseline, from 1.09σ to 0.48σ . But this is still a very significant absolute gain. On average, both ratings returned to 0.60σ post-rotation. Again, from JK's diary after his return to normal vision and going to a salad bar:

The various greens were really intensely "green," the carrots looked like they were going to leap out of the buffet line. The onions (red onions) were the only vegetable that didn't surprise me with its vividness. I was horribly hungry; eating was immensely pleasurable. You have no idea how nice it is for food to look and taste right.

For the less-appealing group of dishes the ratings also dropped immediately from pre-rotation to early-rotation, on average by $.89\sigma$, from -1.23σ to -2.12σ . This group of dishes recovered to -1.06σ in late-rotation, just slightly above their pre-rotation ratings. In post-rotation this group of dishes rose to above their baseline ratings, to -0.31σ , nearly a full standard deviation above their pre-rotation baseline!

Interestingly, the overall pattern was that while the high-rated dishes started at 2σ , and low-rated dishes started at -1σ , they all dropped to the same -2σ immediately upon early-rotation. The color rotation just made everything, dishes that normally looked appealing as well as those that did not, look very unappealing. After adaptation at late-rotation, the lower-rated dishes recovered all of their perceived appeal (low though it was), and the higher-rated dishes recovered half. But it is worth remarking that the appealing dishes had a larger absolute gain after adaptation, suggesting that experience with appealing and unappealing food did have an effect on how each subject judged the appeal of foods based on color. Unappealing dishes returned to their normal level of unappeal, and the appealing dishes made significant gains towards looking as appealing as they had before.

As for the physical attractiveness assessments, the effect of color rotation was much less pronounced than it was in the case of food. We dubbed this the Star Trek effect (in honor of

Captain Kirk’s romantic liaisons with green alien women): attractive people are still pretty attractive whether their skin is blue, or green, or any other color.

The results are summarized in table 2. As in the case of food, we did an initial norming trial, and then separated stimuli into high-scoring and low-scoring groups. And we tested at the same four times: pre-rotation, early-rotation, late-rotation, and post-rotation. For the low-scoring stimuli, there was almost no difference across the four trials. The average rating in this group started at -1.49σ pre-rotation, and then actually (slightly) improved during early-rotation to -1.30σ . Late-rotation ratings fell to -1.44 , and then post-rotation ratings were at -1.50 . Basically, color rotation had no pronounced effect on this group, either before or after the adaptation period.

For the high-scoring stimuli the pattern was more interesting. Pre-rotation average was 1.07σ , which dropped to 0.23σ immediately at early-rotation. While this is indeed a drop, it is a *much* smaller drop than the corresponding condition with food, in which high-rated dishes dropped 3.00σ . High-rated people ratings dropped only about $\frac{1}{4}$ as much as high-rated food ratings upon rotation. Late-rotation the high-scoring people had nearly completely rebounded to 0.92σ , only 0.15σ less than their pre-rotation scores. Post-rotation the ratings dropped slightly to 0.77σ , meaning that the people were actually judged to be less attractive in their normal color, than they were when color-rotated, though the degree of drop was small.

The difference we found between food and people is consistent with studies involving less extreme color manipulation. It is well known that color has a very large effect on the appeal of food (Delwiche 2004; Zampini et al. 2007; Shankar et al. 2010). Existing studies of food-color effects typically involve less extreme color manipulations than we studied here, but the results are similar. With people, though skin color does have an effect on perceived attractiveness, structural features (e.g., facial bone structure, symmetry, body proportions) seem to be more significant (Barber 1995; Dixon et al. 2007).

5 Semantic adaptation

We were keen to investigate the extent to which there would be semantic adaptation. When a normal fluent English speaker hears “red” as part of a sentence, a host of cognitive and behavioral states and processes are invoked that are keyed to a certain phenomenal appearance. If I ask you to “hand me the red block” you can immediately and without overt reflection grasp the correct block, even if it is surrounded by other, differently colored blocks. To what extent would color-rotated subjects show semantic adaptation? Would a point be reached at which the sentence “hand me the red block” just as fluently resulted in the grasp of the block that was in fact red, but presented as blue?

To help facilitate semantic adaptation both subjects spent a good deal of time each day performing tasks requiring engagement with color vocabulary. The most relevant of which was the building game, in which subjects were given written or verbal descriptions for building constructions from colored blocks. The constructions required blocks of specific colors to be placed in specific locations and orientations. Instructions were given in terms of the blocks’ actual color. Success required that subjects select the correct blocks even though the color terms used mismatched their visual input.

Our main method of testing adaptation in a detailed way was Stroop (1935). For technical reasons we have data only for JK (RG’s trail exposed a problem with the interaction between the goggles and the computer display presenting the stimuli, which rendered those data unusable but did allow us to fix the issue so that we could collect valid data from JK). In one standard Stroop set-up, subjects are shown color words presented in colored text, the text either spelling out a color name, or being a neutral series of asterisks, such as ****. For example, subjects might see the word RED in blue text. The task is to name, as quickly as possible, the color of the text while ignoring the color named by the word. When presented with the word RED in blue text, the subject is to say “blue” as quickly as possible.

The standard result is that there is significant interference. Subjects are fastest and most accurate when the color of the text and the color word match, as in the word BLUE in blue text. When there is a mismatch, they are slower and commit more errors, especially errors in which the subject replies with the color word named by the text, and not the color of the text. Our hypothesis was this: with colors rotated by 120° but before a period of adaptation, subjects would show the same pattern as normal subjects in that they would have interference when the color named by the text mismatched the rotated color of the text. So for example the word RED in red text (which would be presented as blue through the goggles) would result in interference, but the word RED in green text (which would be presented as red) would not. But after wearing the gear for a period of time there would be some degree of semantic adaptation. This would manifest in two ways. First, there should be facilitation, or at least diminished interference, when the color named is the same as the actual color of the text, even though it is presented in a different color. And second, there should now be interference, or less facilitation, when the color named is the same as the color in which the word is presented, because that color would be different to the color the word actually is.

The results were that we found no significant effect in either direction. This was disappointing, but it is consistent with the subjective reports of both RG and JK. They both remarked that it quickly became easy to do the appropriate translation and, for instance, grab the green block when one was instructed to “grab the green block” despite its being presented as red through the goggles. But even near the end of their adaptation periods, it still felt like it was an active (though fast and easy) translation, and not a pre-reflective semantic connection between “green” and the actually green objects.

6 Discussion

All of the experimental results reported here should be treated as pilot study results. Our n

was very small, either 1 or 2 depending on the experiment, and investigators were themselves experimental subjects. Both of these are significant limitations. Nevertheless we’re confident that any follow-up studies, with larger n , with more subjects who are not investigators, and perhaps with better equipment than we had available (for example, a camera with higher resolution), will yield results consistent with ours. We hope that any group that chooses to follow up will have an easier time than we did. To that end, we can report that post experiment both subjects’ vision returned to normal, including color discrimination (which we assessed a few days post gear), and so perhaps with verification in hand that the protocol is safe, it will be a little easier for others to get approval for use of human subjects.

The experiment as we have described it was designed to assess, among other things, phenomenal adaptation. We’ve acted so far as though what this means is obvious. But we’re now in a position to see that it isn’t obvious at all. For anyone who believes in qualia (and [Dennett 1988](#) is right when he says that most people do, philosophers or scientists, whether they realize it or admit it or not), then the idea would be straightforward. Phenomenal adaptation would occur when, for instance, tomatoes start causing red qualia again, even if the subject is wearing the rotation gear. There are alternatives to the qualia theory. The enactive approach offers one: the idea would be that phenomenal adaptation is nothing but *enactive adaptation*, that is, learning new sets of sensorimotor (and related) contingencies. Our results, especially the lack of any straight-forward phenomenal adaptation, though far from decisive put at least a little pressure on the enactive view, however. Another approach (e.g., [Dennett 1988](#)) would be to first cash phenomenology out in terms of inner discriminatory states that are tied to various reactive potentials. Described in this broad way, the enactive approach would be a very special case. The reactive potentials would include behavioural dispositions and possibilities, and even predictive possibilities, but also aesthetic reactions, emotional reactions, cognitive reactions, and so forth. As [Dennett](#)

puts it, the mistake made by the believer in qualia is the mistaken belief that

[...] we can isolate the qualia from everything else that is going on—at least in principle or for the sake of argument. What counts as the way the juice tastes to *x* can be distinguished, one supposes, from what is a mere accompaniment, contributory cause, or byproduct of this “central” way. One dimly imagines taking such cases and stripping them down gradually to the essentials, leaving their common residuum, the way things look, sound, feel, taste, smell to various individuals at various times, independently of how those individuals are stimulated or non-perceptually affected, and independently of how they are subsequently disposed to behave or believe. (1988)

On this view, JK (and to a lesser extent RG) may have been part way down the path to the only thing that would legitimately count as phenomenal adaptation, namely, changes in the way that some inner discriminatory ability is evoked and what its various consequences are. As we found, aesthetic judgments had started to adapt, and even the memory-color effect had begun to adapt in a way that speculatively may have been a reflection of alterations in what canonical colors were supposed to look like. Moreover, JK was losing his “this is weird” signals. And though we did not find evidence of semantic adaptation, it would be quite surprising, given humans’ ability to learn new languages and dialects, if after a more extended period of time semantic adaptation did not occur.

Whatever the details, for purposes of this experiment, we don’t feel compelled to take a detailed stand on any of this. We would have been satisfied with subjective report of phenomenal adaptation, and then left it to further philosophical and even psychological investigation to unpack what this could mean. Nevertheless, the adaptation to color constancy and the memory-color effect, as well as the loss of the “this is weird” signal, are all suggestive results

that we hope will help move debate in the relevant fields forward.

Acknowledgements

We would like to thank Paul Churchland for assistance in constructing the physical equipment. His job mounting the video camera and LCD goggles on the bike helmet was fantastic. We would also like to thank Eileen Cardillo and Tanya Kraljic for assistance with the Stroop experiments. We also received excellent feedback and advice from many people, including Stuart Anstis, Vilayanur Ramachandran, Pat Churchland, Paul Churchland, two referees, and many others. This work was supported by a grant from the UCSD Academic Senate. It is dedicated to the memory of Liberty Jaswal, one of the investigators who was originally intended to be the second subject, who died tragically just before we were about to begin data collection.

What Can Sensorimotor Enactivism Learn from Studies on Phenomenal Adaptation in Atypical Perceptual Conditions?

A Commentary on Rick Grush and Colleagues

Aleksandra Mroczko-Wąsowicz

Grush et al. present a pilot study on visual adaptation to a remapped color spectrum. Their preliminary results, being far from conclusive, only partially support the hypothesis that there might exist a form of adaptation to color rotation and color constancy. Proving such flexibility in color vision would substantiate the investigators' attempt to localize their research outcomes in the context of philosophical theories of enactive perception. In spite of some limitations, the study exhibits a worthy and novel approach to the old question of color inverted experience, intended to provide an interdisciplinary account that is both empirically sensitive and philosophically potent. For the progress of the current investigation it would be constructive not only to conduct empirical follow-up studies, but also to conceptually refine the notion of "phenomenal adaptation", which is the central phenomenon studied here.

Based upon a distinction between phenomenal conservatism that accepts only perceptual phenomenology with sensory contents and phenomenal liberalism that acknowledges higher-level contents of perception and cognitive phenomenology, I differentiate between adaptation of the sensory sort and adaptation in the cognitive aspects of experience.

This distinction is used to highlight two different ways of understanding the notion of "phenomenal adaptation", exhibited by the target article and this commentary. Grush et al. seem to suggest that phenomenal and (non-phenomenal) semantic adaptation are different forms of a more general phenomenon of adaptation. However, they do not give any explicit example of the genus of adaptation of which these types are a species. I contend, in turn, that there is no need to produce such subclasses of the notion; semantic adaptation involving higher-level non-sensory states may also be understood as phenomenal. This follows from phenomenal liberalism. I argue that what is being processed in the course of phenomenal adaptation is phenomenal character understood in an expansive way that includes high-level contents. The claim may have an important effect on related empirical work. As a result, enactive sensorimotor adaptation does not have to be seen as adaptation of the sensory sort, but as adaptation in the cognitive aspects of experience, such as altered expectations, or beliefs about or sensitivity to kinds of objects encountered in perceptual experience. This phenomenally liberal reading would provide an appropriately more capacious notion than the adaptation of the sort offered by Grush et al.

Finally, I claim that the lessons for enactive theories of color perception may be expanded beyond the implications of the color rotation study. This is demonstrated by turning to confirmatory and challenging cases of atypical perceptual conditions and color modifications, such as synesthetic color experiences.

1 Introduction

Philosophical thought experiments focusing on different kinds of visual spectrum manipulation and color inversion were initiated with John Locke's hypothetical case of strawberries producing visual experiences of cucumbers (Locke 1689/1979). They still influence not only philosophical theories of color perception and color qualia inversion (e.g., Shoemaker 1982; Clark 1985; Levine 1988; Block 1990; Casati 1990; Broackes 1992; Hardin 1993; Tye 1993, 2000; Nida-Rümelin 1993, 1996; Byrne & Hilbert 1997; Hurley 1998; Hilbert & Kalderon 2000; Cohen 2001; Myin 2001; McLaughlin 2003; Noë 2005; Churchland 2005; Macpherson 2005; Cohen & Matthen 2010; Burge 2010; O'Regan 2011), but also psychological research on the various ways in which our conscious experience can be modified and adapted to changes in visual input, such as space or luminance inversion (Heuer & Rapp 2011; Anstis 1992), or removing or enhancing colors (Belmore & Shevell 2011). However, a systematic interdisciplinary study on adaptation to an inverted or rotated color spectrum has been lacking until now.

The target article aims to lay the foundation for this, by presenting an experimental pilot study, along with some preliminary results and a brief discussion of its theoretical implications. Like many other pilot studies, it faces some limitations. These are: the small number of subjects tested; experimenters acting as test persons; and a complete lack of control conditions in the experimental protocol. The investigators are aware of these constraints and provide convincing reasons for the choices and strategy, e.g., their use of a novel, unpredictable, long-lasting, and inconvenient test protocol. Despite some difficulties relating to both empirical and conceptual aspects, the study demonstrates an original, interesting, and most importantly interdisciplinary approach to the topic of color perception and constancy, making an effort to combine psychological research with philosophical enactive theories.

The main objective of this commentary is to discuss what the sensorimotor account of perceptual consciousness could learn from in-

vestigations into phenomenal adaptation in atypical visual conditions such as color rotated spectrum and synesthesia. In the first section, after pinpointing the conceptual and methodological difficulties involved in defining and testing phenomenal adaptation in Grush et al.'s study, I shall deepen our understanding of phenomenal adaptation and analyze various possible readings of this phenomenon. Such readings depend on different interpretations of the contents that are admissible to perceptual consciousness (cf. Hawley & Macpherson 2011). In the second section, the relationship between the color rotation study and the enactive account of color vision is examined in order to demonstrate what consequences the sensorimotor theory may expect from results that confirm it in some respects, but not others. Finally, in the last two sections, I claim that the lessons for enactive theories of color perception may be expanded beyond the implications of the color rotation study. This is verified by looking at confirmatory and challenging cases provided by atypical perceptual conditions and color modifications such as synesthetic color experiences.

2 Phenomenal adaption

The notion “adaptation”, being central to the target article, while used comparably to analogous work on perceptual effects of systematic alteration of sensory input, does not obviously correspond to the unambiguous physiological notion of adaptation, i.e., a decrease over time in the responsiveness of sensory receptors to changed, constantly applied environmental conditions (e.g., Held 1965; Noguchi et al. 2004; Smithson 2005). Distinguishing semantic adaptation (a remapping of color terms and building immediate semantic connections to their proper object referents) from phenomenal adaption, Grush et al. focus on phenomenal aspects of regaining both stimulus constancy and original color arrangement in spite of changes in input. Given that adaptation to numerous alterations in visual input has already been reported in various studies (Kohler 1962, 1963; Anstis 1992; Heuer & Hegele 2008), Grush

and colleagues also hypothesize the possibility of some form of adaptation to a version of the color-inverted spectrum. They designed a series of experiments to assess phenomenal adaptation of visual experience under color rotation by 120°, which leads to “tomatoes [...] causing red qualia again, even if the subject is wearing the rotation gear” (Grush et al. [this collection](#)). The definition of “phenomenal adaptation” in the target article is “a return to normalcy” and “a gaining of color constancy under rotation”. Phenomenal adaptation then, can be understood as the regaining of phenomenal qualities of the pre-rotated color experience while using the rotation equipment for some time, such that experienced colors are stable, constant, and non-rotated, i.e., just like in normal color vision under standard conditions. But there are reasons to think that adaptation is not necessarily a phenomenally-conscious phenomenon. Such an assumption is supported by research with blindsight patients exhibiting, in their unconscious perception, spectral wavelength sensitivity and several other features of color vision adaptation (Stoerig & Cowey 1989, 1991). In addition, adaptation should not be confused with habituation, which is an attentional phenomenon over which subjects reveal some conscious control (Webster 2012). This could help to explain some of the difficulties Grush et al. encountered when trying to prove the occurrence of phenomenal adaptation under color rotation—which are described below.

2.1 Conceptual problems — Defining phenomenal adaptation

For most of the target paper, Grush et al. treat “phenomenal adaptation” as if it has a single, obvious, and straightforward meaning. Only at the end do they briefly hint at different readings of such adaptation depending on the understanding of the notions “phenomenal” or “qualia”. That is, their investigation is driven by certain implicit assumption of phenomenal qualities. However, these terms are quite controversial in philosophy and one may wonder what actually is examined in the study.

Philosophers denying the existence of phenomenal qualities or qualia (e.g., Churchland

1985, 1989; Tye 1995, 2000; Dennett 1988) may understand them in a specific and narrow sense, either as consciously-accessible properties of non-physical mind-dependent phenomenal objects, mental images called sense data (Lewis 1929; Robinson 1994), or intrinsic non-representational properties (Block 1990; Peacocke 1983), or non-physical, ineffable properties of experiences given to their subjects incorrigibly (Dennett 1988, 1991). Nonetheless, qualia may be endorsed in a broader sense, namely as phenomenal character. This use of the term generally refers to introspectively accessible qualitative aspects of one’s mental life, and it is hard to deny that these exist. Phenomenal character of an experience is “what it is like” for a subject to undergo the experience (Shoemaker 1994, 2001; Chalmers 1996; Nagel 1974). While engaging in introspection and focusing attention on the phenomenal character of experience, one is aware of and gets access to certain phenomenal qualities that make up the overall phenomenal character of the experience.

Since there is no single definition of the term “phenomenal qualities” or “qualia”, there might be also more than one reading of the notion of “phenomenal adaptation”. Depending on the particular understanding of phenomenality and the sort of mental states that can have phenomenal qualities or enter phenomenal consciousness, there seem to be different ways of interpreting the phenomenon of adaptation and thus the possibility of different kinds of adaptation. A related matter discussed in the philosophy of perception—between those supporting phenomenal liberalism and those who propose phenomenal conservatism (expansive and restrictive conceptions of the domain of phenomenal consciousness)—is whether there are high-level properties in the content of perception and whether cognitive states have a distinctive and proprietary phenomenology (Bayne 2009; Prinz 2012).

Phenomenal conservatism (e.g., Tye 1995, 2000; Carruthers 2005; Braddon-Mitchell & Jackson 2007; Nelkin 1989), proposing austere perceptual phenomenology, i.e., that the contents of perception are exclusively of the sensory sort, promotes sensory adaptation. Phenom-

enal adaptation, understood as sensory adaptation, has been described in the literature as adaptation to various distortions and systematic alterations of sensory input employing single or multiple modalities. For example, subjects wearing prismatic goggles or lenses inverting a visual scene in terms of color and spatial arrangement can adapt in the course of time to these new settings and become able to act normally, because they develop new visuo-tactile contingencies that allow them to get around and efficiently see and reach for objects (Held 1965). Importantly, such an adaptation directly affects perceptual experience and cannot be explained by correcting judgments. But this may not be the whole story about phenomenal adaptation, since phenomenal character does not have to be limited to sensory experiences, although traditionally it is said to be. In line with phenomenal liberalism, contents of perception may contain high-level properties such as kind properties (e.g., the property of being a tiger; recognizing that something belongs to a certain kind—seeing a tree as a pine tree; Siegel 2006; Bayne 2009), but also causal (the property of one thing's causing another; Strawson 1985; Siegel 2006; Butterfill 2009), and generic properties (the property of being nonspecific; Block 2008; Grush 2007). These properties are abstract, generalized, and cognitive in their nature, yet they can enter into phenomenal contents. Consequently, a liberal conception, allowing cognitive states to possess phenomenal qualities, and phenomenal character to be ascribed to conceptual contents, endorses cognitive phenomenology and thus would opt for phenomenal adaptation in the cognitive aspects of experience.

The debate surrounding cognitive phenomenology involves many different versions and strengths of the claim that the domain of phenomenology extends beyond the sensory (Strawson 1994; Siewert 1998; Pitt 2004; Bayne & Montague 2011; Horgan & Tienson 2002; Kriegel 2002, 2007). Irrespective of its particular varieties, such a view raises alternative interpretations of Grush et al.'s results. It suggests that phenomenal adaptation may be present not only in sensory but also in cognitive aspects of experience. Both perceptual and cognitive states

determine how we experience the world and adapt to changes in our surroundings, because they both exhibit their own phenomenal characters—something it is like to be in such a state for the subject (Chalmers 1996, p. 10; Strawson 1994; Montague & Bayne 2011).

Moreover, conceptual contents seem able to modify the phenomenal character of perceptual states; they can cognitively penetrate our perception (Raftopoulos 2005; Macpherson 2012; Siegel 2012). An interdisciplinary approach to the cognitive penetrability of perception assumes that there are various ways in which conscious perception can be affected by cognition—i.e., by thoughts, beliefs, desires, judgments, intentions, moods, emotions, expectations, knowledge, previous experiences, and memories (Frith & Dolan 1997; Bar 2003; McCauley & Henrich 2006; McCauley & Henrich 2006; Raftopoulos 2009; Vuilleumier & Driver 2007; Stokes 2012; Deroy 2013; Wu 2013; Vetter & Newen 2014; Briscoe 2014; Nanay 2014; Lupyan 2015). In other words, higher cognitive states not only have causal influence on the contents of perception, they are also explanatorily relevant in accounting for the processing of perceptual systems. It has been shown that semantic contents and categories play a critical role in perception, even in early sensory processing (cf. Mroczko et al. 2009; Mroczko-Wąsowicz & Nikolić 2013). This may be exemplified in the connection between language and color vision. For example, languages with a larger number of generic color terms such as Russian have an impact on color perception (Winawer et al. 2007).

Such an integrative cogno-sensory approach, combining high-level cognitive and low-level sensory aspects, is also manifested in recent theories of concepts relating the possession of concepts to perceptual adaptation in various ways (Machery 2009; Prinz 2010; Noë this collection). For instance, being sensitive and showing a discriminative response to certain kinds of objects or combinations of features corresponds to having concepts for the related kinds of objects (Machery 2009; Deroy 2013, 2014). According to the ability-based account of conceptuality, one can reveal skillful understanding of

concepts in a perceptual, practical, or emotional way, meaning that the possession of concepts is a condition that informs and is informed by our able engagement with things (Noë 2012, [this collection](#); cf. Wittgenstein 1953). This indicates a close interdependence between conceptuality and sensorimotor processing.

Consequently, phenomenal adaptation, in light of the enactive theory, would mean enactive adaptation and learning a new set of skills in the form of new sensorimotor contingencies and related dependencies, such as behavioral dispositions, predictive possibilities, and cognitive, aesthetic, and emotional reactions. Enactive adaptation would entail an application of sensorimotor skills to conceptual understanding, and as such it could be seen as adaptation in the cognitive aspects of experience with altered expectations or beliefs about or sensitivity to kinds of objects encountered in perceptual experience. This phenomenally liberal reading would provide an appropriately more capacious notion than the adaptation of the pure sensory sort offered by Grush et al.

To sum up, departing from a distinction between phenomenal conservatism that accepts perceptual phenomenology with solely sensory contents and phenomenal liberalism that acknowledges higher-level contents of perception and cognitive phenomenology (Bayne 2009; Montague & Bayne 2011), I differentiate between adaptation of the purely sensory sort and adaptation in the cognitive aspects of experience. The distinction is used to show the contrast in understandings of the notion of “phenomenal adaptation” between the target article and this commentary. Grush et al. seem to suggest that phenomenal and (non-phenomenal) semantic adaptation are different forms of a more general phenomenon of adaptation. However, they do not give any explicit example of the genus of adaptation of which these later are a species. I contend, in turn, that there is no need to produce such subclasses of the notion; semantic adaptation involving higher-level non-sensory states may also be understood as phenomenal. Thus, the reading of adaptation I put forward pertains jointly to the phenomenal and semantic aspects of regaining of stimulus

constancy; it assumes a recovery of prototypical color-object associations both in phenomenal experience and in semantic reference in spite of changes in input. This follows from phenomenal liberalism.

The proposed view is that being processed in the headway of phenomenal adaptation is phenomenal character, understood in an expansive liberal way that includes high-level contents. Therefore phenomenal adaptation is considered to be the adjustment of cognitive aspects of experience.

2.2 Methodological problems

Dissociating semantic from phenomenal adaptation is problematic. This is because they are interconnected. It is hard to think about the occurrence of semantic adaptation without phenomenal adaptation taking place and vice versa – semantic adaptation is methodologically necessary for detecting phenomenal adaptation. This presumed correlation might be the reason why, when faced with difficulties finding phenomenal adaptation to a color-rotated scene, the investigators could not confirm any reliable Stroop results for semantic adaptation. In addition, it should be noted that Stroop-type tasks contain two components of competition—semantic and perceptual (Stroop 1935; Nikolić et al. 2007; Mroczko et al. 2009)—and as such they exhibit limitations in differentiating between semantic and perceptual aspects of the phenomena tested.

To assess the occurrence of phenomenal color adaptation under rotation, that is, the process of the normal phenomenal appearance of objects returning, Grush et al. used the memory color effect (Hansen et al. 2006), aesthetic judgments of food and people, and subjective reports from their test persons.

It has often been assumed that subjective introspective reports are a generally reliable mode of first-person access to one’s current conscious states or processes (Descartes 1984; Locke 1689/1979; Hume 1978; Brentano 1973; Husserl 1982; Chalmers 2003; Gertler 2001; Horgan et al. 2006; Horgan & Kriegel 2007; Varela 1996; Rees & Frith 2007; Hurlburt &

Schwitzgebel 2007; Hohwy 2011). However, this assumption is also problematic. Arguments for introspective scepticism or even criticism of introspective methodology pose genuine threats to the trustworthiness of this approach (see Bayne [this collection](#), for a discussion of such views). Because of this ambivalence one needs to be careful when using subjective reports as a source of or support for the results presented.

Certain doubts about whether subjective reports are trustworthy enough come from the fact that introspection delivers solely first-person, unverifiable, private data, and thus it is unscientific and often fallible (Dennett 1991; cf. Zmigrod & Hommel 2011). In addition, subjects tested are often uncertain or disagree about what the introspective access actually provides (Bayne & Spener 2010; see also Bayne [this collection](#)) and have difficulty describing their own conscious experiences (Schwitzgebel 2008). Nonetheless, this is not to deny that they have *some* first-person knowledge of phenomenal consciousness.

The specific reasons one may have for doubting the findings in the context of Grush et al.'s study are related to the fact that investigators were also the test subjects. We should avoid involving persons who know the hypothesis when conducting the experiments, who in this case tested and evaluated themselves at the same time. Knowing the research question and the expected or desired results may bias any study.

3 Implications of the color rotation study for sensorimotor enactivism

Grush et al.'s work could be extended to manifest a broader range of philosophical implications than those they have mentioned; but, as the authors state at the end of their article, this has been left for future philosophical and psychological investigation. Referring to a general theoretical framework of perception such as the enactive approach, Grush and colleagues apply the lessons of their study to sensorimotor enactivism of perception without considering other options such as ecological and active perception approaches as potential targets (Gibson 1979;

Ballard 1991; Mossio & Taraborelli 2008; Taraborelli & Mossio 2008). However, since their hypothesis focuses on the nature of perception based on couplings between sensory stimulation and motor activity, it appears justified to focus on the sensorimotor version of the enactive account, which emphasizes an active exploration of the environment determining in this way the content and modality of conscious experience (O'Regan & Noë 2001; Noë 2005).

Sensorimotor theory has been supported by research on sensory substitution (Proulx & Störig 2006) and adaptation in haptic perception, as observed in mirror therapy for phantom limb pain and in the rubber hand illusion (Ramachandran & Rogers-Ramachandran 1996; Botvinick & Cohen 1998). Most relevantly, supporting evidence for the sensorimotor theory of color perception was found in a study on adaptation to half-split colored goggles (left-field blue/right-field yellow), which introduced an artificial contingency between eye movements and color changes (Bompas & O'Regan 2006b; cf. Kohler 1962). These results have left the possibility of similar sensorimotor adaptation to any arbitrarily-chosen colors open. According to the account of enactive vision, sensorimotor principles are fully capable of explaining adaptation to alterations in spatial or color-relevant features of input (Noë 2005). The adaptation can be achieved by resuming constancy through learning a new set of sensorimotor contingencies, i.e., patterns of dependence between sensory stimulation and movements, corresponding to new features of the input. Understanding these dependencies provides the required sensorimotor knowledge that enables perceptual experience.

The experimental protocol of Grush et al.'s study directly refers to an enactive account of color (O'Regan & Noë 2001; Noë 2005; Bompas & O'Regan 2006a, 2006b). The authors' hypothesis regarding color constancy and phenomenal color adaptation under color rotation is compatible with predictions made by sensorimotor enactivism; the induced adaptation to a remapped spectrum was supposed to imitate a naturally-occurring process of learning sensor-

imotor contingencies. The results obtained in this pilot study, although not entirely usable and interpretable, may yet provide food for thought to enactive theory, since they offer some interesting insights into supportive evidence and the difficulties that the theory needs to integrate and deal with.

3.1 An enactivist explanation of the results

Subjective reports concerning adaptation to color constancy, understood as achieving stability of color experience irrespective of visual conditions, confirm what the enactive theory would expect. This means that when switching between standard visual conditions and color rotation, and at the same time being active in the color environment through altering color-critical conditions such as illumination, viewing angles, or movements, the test persons exhibited temporary disruption of color constancy leading to an immediate change of perceived hues. This is allegedly due to the change of sensorimotor contingencies involved in this experience.

However, when a new set of sensorimotor regularities becomes established, color constancy is resumed, so that the subjects gain the capacity for color constancy under rotation and then come back to normal color constancy when having non-rotated visual input, i.e., the colors that are stable are different in the two conditions. Hence, after a period of time for learning new dependencies, color constancy is restored and the mentioned modifications of visual conditions, such as lighting, have no effect on the phenomenal character of color experience.

An interesting observation and an important point for further deliberation on the development of phenomenal color adaptation is delivered in the subjective report of one of the test subjects, who at the end of his six-day color rotation period suddenly began to be confused about whether his visual input was still rotated or not, because everything appeared normal. Since he ceased to feel a sense of novelty and strangeness, he was not sure if he was in a situation of (1) normal color vision, or rather (2) adaptation to color constancy under rotation—at least until he expli-

citly reflected on the colors of the surrounding objects. Although he was evidently in state (2), thus experiencing stability of rotated colors, one may suppose that his confusion about which colors were ‘normal’ in which condition might also indicate the time in which subjects could begin to develop an ability amounting to (3) phenomenal color adaptation under rotation with colors akin to genuine colors in situation (1). Speculations envisioning the occurrence of this adaptation after a longer period than the duration of the current test do not seem completely unjustified. What would be needed here are further studies that not only cover a longer time frame of color rotation, but also focus on searching for a characteristic marker signaling when, within a very smooth transition between (2) and (3), phenomenal adaptation under rotation (stage(3)) actually begins. This would be similar to “the feeling of novelty/strangeness”-marker within the transition between (1) and (2), signaling color rotation. The lack of this marker and the occurrence of the feeling of normality would indicate that color constancy under rotation has arisen.

The memory color effect was used by Grush et al. as a method of assessment for phenomenal color adaptation under rotation. It is an effect of processing colors of objects with typical colors that affects the experience of pairings of colors and shapes (Hansen & Gegenfurtner 2006; Hansen et al. 2006). The authors explain the effect by top-down influences of expectations. But it may also be explained by, for example, cognitive penetration of color experience by beliefs (Macpherson 2012) or sensory adaptation through exposure manifesting itself by responding differently to various kinds of objects or co-occurring features (e.g., arrangements of objects’ shapes and their typical colors; Deroy 2013, 2014). All these descriptions express some aspect of the phenomenal liberalism discussed earlier, and as such they seem more or less equally plausible for supporting the proposed reading of phenomenal color adaptation under rotation as adaptation in the cognitive aspects of experience. In standard visual conditions, the memory color effect may suggest that expectations or beliefs about a proper color for a certain kind of objects exert top-down influence on the actual color pro-

cessing of these objects, their shapes, etc. Thus, the lessened magnitude of the memory color effect under color rotation, as found in the study, shows that the associations of objects with their prototypical colors become weaker and may even get replaced by other associations with new prototypical colors.

This outcome is interestingly combined by Grush et al. with the aforementioned confusion stage (between (1) and (2)) acquired at the end of the color rotation period, when the subject stops having the feeling of novelty and therefore confuses his rotated color experiences with the normalcy felt when perceiving in standard visual conditions. Both of these results imply not only a decreasing strength of the old prototypical color associations, but also the emergence of new associations. Such an emergent set of dependencies is clearly compatible with enactive predictions. The adaptation that took place due to color rotation and that has been demonstrated by the memory color effect appears to be general. This means it is not just a matter of specific associations of colors with particular objects seen during rotation. The adaptation refers to the perceptual system as a whole and its expectations, beliefs, or sensitivity, contributing to a discriminative response to kinds of objects in general. For example, the adaptation might manifest itself as the regaining of a grasp of the way things are colored, as altered cognitive states (cognitive aspects of experience) about what red things generally look like or what red is like.

3.2 Problems with a definitive confirmation of enactivist ideas

Obviously the study protocol would have been more plausible if color constancy had been tested in a controlled way with a relevant objective method and not only confirmed by first-person reports. For example, brain imaging techniques would be suitable for detecting temporary changes in perceptual states. Also, comparing the effect with a proper control group, matching the test group for gender, age, and color-related experience (e.g., education, profession), would certainly increase the strength of the findings, providing more evidence for sen-

sorimotor adaptation to color constancy. Because transformations in qualitative experience may be explained in terms of a dynamic model of interdependence between sensory inputs and embodied activity (Hurley & Noë 2003), phenomenal differences between color experiences can be accounted for by different actions. Therefore to exclude the sensorial interpretation, the control group would not be actively exploring their color environment, would not change the rotated visual input through their own actions, and thus according to the enactive theory would not develop new sensorimotor dependencies allowing stable color perception.

For genuine phenomenal color adaptation different results were observed, i.e., the regaining of non-rotated color constancy while using the rotation equipment was not successfully established—subjective reports and objective assessments made with the memory color effect and aesthetic judgments of color-rotated food and people have shown that subjects only started to adapt in late-rotation, at the end of the possible adaptation period. Difficulties in robustly confirming phenomenal color adaptation under rotation are certainly not encouraging news for the enactive view of color. They could even be interpreted as a falsification of this theory. However, according to the investigators, this is still not decisive, and they speculate that the reason for this unfavorable outcome could be the lack of time allowed for relearning the relevant sensorimotor regularities. Indeed, for someone whose phenomenal color qualities remained rotated and did not revert to the genuine color phenomenology, i.e., for whom tomatoes continued to look blue, but did not reappear as red, this may be the case, because perceptual learning, here resulting in action-sensation coupling, is a relatively slow process and its timing varies from one individual to another (Goldstone 1998; Seitz & Watanabe 2005). Such an explanation remains in line with the sensorimotor account of perception and cannot be excluded without further studies. On the other hand, it may be also possible that the development of adaptation under rotation took place unconsciously and therefore was not reported by the subjects.

4 Atypical color conditions in synesthesia

The lessons for enactive theories of color perception, pointed to by Grush et al. in their target article, may also be expanded by including challenges constituted by other atypical color conditions, namely synesthetic color experiences.

Synesthesia is traditionally considered to be a phenomenon in which the stimulation of one sensory or cognitive pathway (the inducer) elicits involuntary and consistent sensory experiences (the concurrent) in the same or another modality (Baron-Cohen et al. 1987; Baron-Cohen & Harrison 1997; Ramachandran & Hubbard 2001a, 2001b). As a result, the stimuli corresponding to the inducer and the experiences associated with the concurrent form a highly integrated percept—a phenomenally-unified experience which may cover not only sensory modalities, but also various mental domains including conceptual, emotional, bodily, and motor aspects (Mroczko-Wąsowicz & Werning 2012; Mroczko-Wąsowicz 2013). Such unification incorporates the central system and early stages of processing. Some synesthetes see colors when dealing with letters or numerals. Individuals with another kind of synesthesia perceive colored patterns in space when hearing sounds. The prevalence of the phenomenon depends on the particular type of synesthetic association, with grapheme-color synesthesia being the most common (Cytowic & Wood 1982; Mroczko-Wąsowicz & Nikolić 2013).

Color sensations are the most frequent synesthetic concurrents (Marks & Odgaard 2005), demonstrating color opponent properties and neural representations more or less similar to veridical color experiences (Nikolić et al. 2007; Hubbard et al. 2005; cf. Hupé et al. 2012; Van Leeuwen et al. 2010). For some forms of synesthesia color concurrents may also originate from information processing in regions of the cortex other than the visual. Recent neuroimaging studies demonstrate that synesthetic colors for numbers or mathematical formulas may also be produced when the visual cortex is not involved, i.e., by the activation of temporal, parietal, and frontal brain areas (Bor et al. 2007;

Hupé et al. 2012; Brogaard et al. 2013). This suggests that information processing in non-visual brain regions may be a source of concurrent colors and therefore some forms of synesthesia can be seen as high-level perception proceeding via non-standard mechanisms. Such high-level synesthetic color perception for mathematical skills, though quite unusual, may provide supportive evidence for the conception of phenomenal liberalism and cognitive phenomenology.

5 Synesthetic colors and sensorimotor enactivism

Given that synesthesia, similarly to the color rotation gear, involves systematic distortions of color perception that are consciously experienced by the subjects, analyzing synesthetic experiences appears relevant in the context of the present discussion. This is why proponents of the sensorimotor theory of color perception might be interested in examining whether their postulates also apply in cases employing such synesthetic color-addition gear (cf. Hurley & Noë 2003; Fingerhut 2011; Mroczko-Wąsowicz & Werning 2012; Seth 2014; Ward 2012). The relevant propositions of enactivism may be stated as follows:

- a. determining the modality of perceptual experience by specific sensorimotor signature (i.e., dependency between sensory stimulations and the activity of the perceiver, including their motor actions, bodily changes, or behavioral skills), as well as a necessary possession of such sensorimotor knowledge of contingencies enabling any perception;
- b. flexibility of perceptual experience manifested in the ease of its modification and adaptation based on learning a new set of sensorimotor contingencies (Noë 2005);
- c. and finally epistemic reliability of conscious perceptual experiences and their counterfactual richness (Metzinger 2014; Seth 2014; see also Seth this collection).

The above basic assumptions underlying sensorimotor enactivism of perception may be challenged by synesthesia in the following way:

- A. Synesthetic concurrent percepts (e.g., visual experiences) are generated internally, not via a direct relation of a synesthete with the surrounding environment. They are triggered without employing the regular sensorimotor signature related to these concurrents, like eye saccades in normal vision. For such permanent inducer-concurrent couplings, the concurrent modality and its experiences are never related to their normal sensorimotor signature.
- B. Synesthetic associations cannot be learned or adapted to, in contrast to various manipulations of sensory input such as, for example, spatial displacement, color inversion, or auditory-visual sensory substitution (sometimes called an artificial synesthesia), which are used by sensorimotor enactivists as examples of the perceptual system's adaptation involving an appropriate adjustment of sensorimotor contingencies. Unlike the majority of learned pairings, synesthetic associations are rigid and not flexible enough to adapt, irrespective of the amount of exposure to contradictory experiences or training (Baron-Cohen et al. 1993; Deroy & Spence 2013).
- C. As a final point, although synesthetic colors are reported to be as vivid as non-synesthetic colors, synesthetes immediately detect the difference between them, which confirms the absence of perceptual presence or phenomenal transparency in synesthesia, meaning its opacity or experiential unrealness, which is the availability of earlier processing stages to attention (Metzinger 2003a, 2003b, 2014; Seth 2014).

As a kind of reply to these challenges, sensorimotor enactivists could claim that enactivism focuses on standard perceptual mechanisms and therefore has difficulties explaining perception-

like experiences in synesthesia, as well as that synesthetic concurrents (often colors) lack some important features of typical perceptual experiences and properties of sensorimotor engagement, e.g., corporeality. However, this would not really be explanatory. One possible way of vindicating how the enactive theory could accommodate such atypical non-adaptive color conditions is to claim that there is actually no need for synesthetic colors to adapt, because they do not carry any information about the colors of objects in the synesthetes' environment—whereas adaptation is a retrieval of how things are colored. To put it in enactive terms, synesthetic colors do not figure in patterns of appearance reflecting dynamic relations between perceiver, object, and light (Ward 2012). Unlike the rotation gear, synesthesia does not determine the way things appear to the perceiver; i.e., the way worldly objects and surfaces modify the light is not affected.

6 Discussion

As concluded by Grush et al. the results obtained in their study show that color experiences changed in the early stage of application of the rotation gear and became stable, that is, they adapted to color constancy in the late rotation stage, without however consistently showing significant phenomenal adaptation by the end of the test. The investigators leave open a potential explanation of this outcome. The difference between this result and other studies, in which achieving phenomenal adaptation to spatial displacement or luminance inversion was more successful, may suggest that color sensations are special properties of early visual processing relatively difficult to phenomenally adapt as well as more resistant to penetration and manipulation by cognition (Fodor 1983; Pylyshyn 1999; Brogaard & Gatzia forthcoming; but cf. Macpherson 2012; Siegel 2012; Vetter & Newen 2014). At least this seems to be the case for the general population.

Synesthesia, although not considered to be an adaptive plastic phenomenon, may be a case in which some modifications take place, such as cognitive penetration of perception including

early sensory processing. Synesthetic colors are frequently modified by cognitive operations, conceptual contents, contextual expectations, linguistic modulation, cultural factors, and other semantic knowledge mechanisms (Dixon et al. 2000; Simner 2007, 2012; Meier 2013; Mroczko et al. 2009; Mroczko-Wąsowicz & Nikolić 2013, 2014). Since synesthetes are able to penetrate this early aspect of vision it would be interesting to investigate whether synesthetically-perceived colors change under rotation. If so, is this in the same or in a different way to non-synesthetic, phenomenally-transparent colors?

Synesthetic colors are in some respects similar to the color experiences of rotation-gear wearers. In both cases, subjects are aware of the fact that what they see is not reliably colored, i.e., that their abnormal color experiences are not actual colors of the surroundings.

On the other hand, these color experiences differ remarkably from each other. Whereas rotation gear wearers' color experiences are able to adapt to fall in line with what the subjects know to be true about colors of the things around them, synesthetes' color experiences do not display such flexibility. Thus, a theoretically founded hypothesis is that irrespective of the form of color synesthesia to be used in a color rotation experiment (e.g., grapheme-color, sound-color, time unit-color synesthesia) synesthetic colors would not alter.

Admittedly, the sensorimotor theory of color has difficulties explaining many of the features of the phenomenon of synesthesia, but this does not mean it is completely useless in the context of synesthesia. The theory could be used to account for the asymmetry in adaptation capability between those experiencing synesthetic and non-synesthetic colors. From the perspective of the enactive view of color, it could be proposed that the rotation gear interferes with regular color perception, because the equipment introduces a new set of sensorimotor dependencies. This is the reason why after wearing the rotation gear for some time and acclimatizing to the conditions, the rotated colors begin to appear normal, that is, the subjects' ability to perceive original colors returns

—such that phenomenal color adaptation under rotation takes place. Unlike the rotated color perception of non-synesthetes, synesthetic subjects (associators) do not experience their additional colors as attributed to perceived objects but as seen in their “mind’s eye”. Therefore the concurrent colors do not affect their ability for regular color vision. An explanation of why there is no phenomenal color adaptation in synesthesia could be that synesthetic colors just fail to adapt because they do not need to make room for non-synesthetic colors (cf. Ward 2012). Thus, in line with the sensorimotor account, we could interpret the difference between ordinary color perception and color synesthesia as a difference between real and seeming engagement. However, another type of synesthetes, projectors, who see colors as projected onto inducing objects, may require a different explanation. Since this group of synesthetes demonstrates an external frame of reference for their synesthetic colors, projectors' phenomenal color adaptation under rotation might be comparable to the adaptation of non-synesthetes. A testable empirical prediction here would be that it is possible for projector synesthetes' colors to adapt after using a rotation equipment specially adjusted to interfere with internally-generated concurrent color experiences. Depending on the outcome of this prospective study, which could be designed in such a way that it would take into account all the differences related to color phenomenology, the sensorimotor theory of color may gain new insights into the threat of synesthesia.

What sensorimotor enactivism can also learn from studies on phenomenal adaptation in various perceptual conditions is that the notion of “phenomenal adaptation” applies to some conditions, but not others. There may also be different senses of the notion, and apart from “adaptation of the sensory sort” a rigorous analysis should consider “adaptation in the cognitive aspects of experience”—an expansive interpretation supported by phenomenal liberalism and cognitive phenomenology. In addition, the extent to which the phenomenon of adaptation may develop varies among various perceptual conditions. No matter the exact magnitude of

the adaptive effects discussed, the very existence of phenomenal adaptation to alterations of sensory input, or its general lack, needs to be fully integrated by philosophical theories, especially by sensorimotor enactivist theories of perception that attempt to account for all the dynamics related to perception. This adaptation highlights that perceptual experience is more flexible and variable than usually presumed.

Phenomenology, Methodology, and Advancing the Debate

A Reply to Aleksandra Mroczko-Wąsowicz

Rick Grush

The following topics are briefly discussed: First, the different senses of what counts as phenomenal, and in particular how this might influence how our results are described; second, the methodological limitations of our original study; and finally, some ways that the commentary by Mroczko-Wąsowicz charts out potential theoretical advancement of the results we presented in our study.

1 On the nature of phenomenology

First, as Mroczko-Wąsowicz quite rightly points out, there are different understandings of what *phenomenology* is, with concomitant differences in what *phenomenal adaptation* might mean. The distinction drawn is between phenomenal conservatism, and phenomenal liberalism; the former being constrained to the vicinity of sensory features, and the latter including various cognitive phenomena, such as expectations and associations, among others.

We chose to use the term in the more restrictive sense for a number of reasons. First, as the more restrictive of the two, it is less controversial that what is included counts as genuinely phenomenological. Second, in many circles at least, the more restrictive understanding seems to be what people generally have in mind. The more liberal understanding is one that is endorsed more commonly only among specialists.

What I am about to say may be a matter of splitting hairs – and so I ask for forgiveness

in advance. I am in complete agreement that the distinction is a valuable one to make, and that in our original article we just ran with the more restrictive definition. That said, it doesn't seem to me that with this distinction in hand one is raising "alternative interpretations" of our results; rather one is providing a different way of *describing* the same result. On a conservative definition of what counts as phenomenal, we did not find phenomenal adaptation. But if one adopts a liberal understanding of the term that includes various cognitive phenomena, then it would be correct to say that we did, in fact, find some phenomenal adaptation. So long as there is clarity on what exactly was found, and on how one intends to use the key terms, then this shouldn't be cause for confusion or concern.

Where things could get interesting would be on a possible third way to understand phenomenal – call it the *radical* understanding. On the radical view, there is nothing to phenomenology other than the sort of cognitive phenomena that the liberal view intended to add to the more narrowly sensory understanding. For one who holds such a view, we may very well have found the beginnings of phenomenal adaptation *tout court* when we found the beginnings of elements of cognitive adaptation.

This hairsplitting aside, I couldn't agree more with Mroczko-Wąsowicz's point that when getting into the details of discussions about phenomenal adaptation, a solid understanding of the different ways that the key terms might be understood is crucially important, and in this respect her commentary is an excellent supplement to the discussion we provided.

2 On methodological limitations

Mroczko-Wąsowicz goes on to, quite reasonably, point to some of the shortcomings of our pilot study. In fact, we pointed out many of these same shortcomings ourselves. There are a couple however that are worth saying at least a bit about.

Mroczko-Wąsowicz points out that some of our findings are based on subjective report, and that there are "doubts about whether subjective reports are trustworthy." While in general this is

entirely correct, there is a sense of phenomenal adaptation according to which what we were studying is precisely *how things would seem to the subject*. It is undoubtedly the case that even in such situations one is not *limited to* what subjective report might have to say on the matter. Indeed, this is among the reasons we included other experiments as part of the protocol. But the phenomenon that I *subjectively notice and can report on* when I adapt to the spatial distortion of new corrective glasses, or to the color distortion of blue-blocking sunglasses is an interesting one, and one might reasonably wonder if one can get an analogous adaptation effect – the same subjectively noticeable and reportable effect – with respect to rotated colors.

This is related to a second point. Mroczko-Wąsowicz echoes our claim that it is a shortcoming of the study that the researchers themselves were subjects. Surely it is the case that knowledge of the experiment and the phenomena to be studied can bias the results. Of course I agree completely with that.

Nevertheless, I am reminded of a point made in conversation by Vilayanur Ramachandran. In a moment of venting about some objections made to some of his results, he hypothesized that he could show psychologists a talking pig and they would scoff that it was an n of 1.

In the present case, it is true that having the experimenters themselves be subjects effects the results. But even so, if it turned out that I or the other subject JK did end up in a state that seemed to us to be one of phenomenal adaptation, then this would still be interesting, because if nothing else it would demonstrate that we could get the effect in anyone if we just briefed them on the experiment beforehand. If I hypothesize that hitting myself on the head three times with a baguette will make me able to speak fluent French, and I do the experiment and it *does*, this is an interesting result even if I was both experimenter and subject.

In any case, Mroczko-Wąsowicz and I are in a great deal of agreement about the limitations created by the methodology of our pilot study, and these limitations need to be kept firmly in mind when anyone ventures to interpret our findings or follow up on them.

3 Advancing the debate

The final set of points made by Mroczko-Wąsowicz concerns synesthesia, and in particular how the phenomenon presents an interesting complement to the sort of phenomenon we studied. When we were initially brainstorming the experiment we discussed what might happen if a synesthete were to wear the rotation gear. But that line of speculation never got past the brainstorming stage, since just doing it with ourselves proved enough of a challenge. While it has some significant differences from synesthesia, we did make an attempt to see whether the McCollough effect would adapt. But the subjective effect was very small, and didn't last long enough into the protocol to get any data at the time when there might have been some adaptation.

Mroczko-Wąsowicz makes some fascinating points about how our study and synesthesia complement each other in interesting way that would be strong motivation for anyone following up on our study to try to include some synesthetes among the test subjects.

4 Conclusion

We tried to make our initial article streamlined and not burdened with too much detailed theoretical discussion. Since we hope the interested parties will include not only philosophers but also psychologists and cognitive scientists, the thought was to present the results, which we thought were quite interesting and suggestive, and leave the more detailed theoretical discussions and possible follow-up experiments to others. In this respect Mroczko-Wąsowicz's commentary is exactly the sort of detailed theoretical follow-up we hoped others might be inspired to produce on the basis of our results. I am grateful to her for fantastic commentary.

An Information-Based Approach to Consciousness: Mental State Decoding

John-Dylan Haynes

The debate on the neural correlates of visual consciousness often focuses on the question of which additional processing has to happen for a visual representation to enter consciousness. However, a related question that has only rarely been addressed is which brain regions directly encode specific contents of consciousness. The search for these core neural correlates of contents of consciousness (NCCCs) requires establishing a mapping between sensory experiences and population measures of brain activity in specific brain regions. One approach for establishing this mapping is multivariate decoding. Using this technique, several properties of NCCCs have been investigated. Masking studies have revealed that information about sensory stimuli can be decoded from the primary visual cortex, even if the stimuli cannot be consciously identified by a subject. This suggests that information that does not reach awareness can be encapsulated in early visual stages of processing. Visual imagery representations and veridical perception share similar neural representations in higher-level visual regions, suggesting that these regions are directly related to the encoding of conscious visual experience. But population signals in these higher-level visual regions cannot be the sole carriers of visual experiences because they are invariant to low-level visual features. We found no evidence for increased encoding of sensory information in the prefrontal cortex when a stimulus reaches awareness. In general, we found no role of the prefrontal cortex in encoding sensory experiences at all. However, the improved discrimination of sensory information during perceptual learning could be explained by an improved read-out by the prefrontal cortex. One possible implication is that prefrontal cortical regions do not participate in the encoding of sensory features per se. Instead they may be relevant in making decisions about sensory features, without exhibiting a re-representation of sensory information.

1 Introduction

Neural theories of visual consciousness frequently focus on the question of what is needed for a visual stimulus to enter consciousness. A common notion is that representations and processes in sensory regions of the brain can operate outside of conscious perception, and that some “extra property of processing” has to come on top in order to let these representations enter conscious experience (e.g., [Dehaene & Naccache 2001](#)). This extra processing property can range from neural synchronization of neurons encoding the stimulus ([Engel & Singer 2001](#)), recurrent and feedback processing ([Lamme 2006](#), [this collection](#); [Pascual-](#)

[Leone & Walsh 2001](#); [Singer this collection](#)), to participation in a global coherent process, known as neuronal workspace theories ([Baars 2002](#); [Dehaene & Naccache 2001](#)). Discussion of the neural correlates of consciousness (NCC) has often focused on this extra ingredient needed to bring a stimulus representation into consciousness. However, a related, but somewhat different question has often been neglected: Which neural representations (can) precisely participate in encoding the various dimensions of conscious experience? For this it is not enough to establish a correlation between conscious perception and neural signals.

Glossary

Neural encoding	The representation of a sensory feature in a population of neurons.
Mental state decoding	Inferring the representational content of a mental state from a brain activation pattern, typically using multivariate pattern classification.
Neural correlate of a content of consciousness	The brain signal that encodes a specific aspect of conscious experience. The brain signal is the carrier, the specific aspect of consciousness constitutes the phenomenal representational content carried (in short, its “phenomenal content”).
Multivariate pattern classification	A mathematical procedure for identifying patterns of brain activity, the labels of which have been previously learned.
Mapping	The assignment of brain activation patterns to the representational content of mental states.
Low-level visual features	Simple dimensions of visual experience that are encoded in early visual brain regions (e.g., contrast, orientation). If consciously represented, they may constitute corresponding simple forms of phenomenal content.
High-level visual features	More complex dimensions of visual experience that are encoded in downstream visual brain regions (e.g., object identity) and that are to some degree independent of the low-level features by which they are defined.

That would yield a far too large set of candidate brain regions, including, say, signal patterns in the retina that also correlate with conscious perception. Instead, it would be desirable to identify which neural representations most closely encode specific contents of consciousness and can be used to explain dimensions of conscious perception under as many different conditions as possible, and down to the level of single contents. This article will focus on how to identify such core neural correlates of contents of consciousness (NCCCs; [Chalmers 2000](#); [Block 2007](#); [Koch 2004](#)).

It is desirable that studies of visual awareness take NCCCs into account because specific theories of visual awareness make specific predictions regarding the encoding and distribution of sensory information (e.g., [Dehaene & Naccache 2001](#); see also [Baars 2002](#)). In the following, I will first outline the more standard techniques for identifying NCCCs, along with their shortcomings. The next step proposes to use multivariate decoding techniques (reviewed e.g., in [Haynes & Rees 2006](#)) as a tool to identify NCCCs. Decoding can serve as an empirical technique that can establish which brain regions bear most information about specific contents of visual experience. This is an important first step towards establish-

ing a more rigid mapping between visual phenomenal states and content-encoding brain signals. Then, several examples will be presented where multivariate decoding of visual experiences can help inform specific questions regarding NCCCs, such as whether information in V1 participates in visual awareness, whether imagery and perception share the same underlying neural codes, or whether the prefrontal cortex contains any dynamic NCCCs for coding specific dimensions of conscious experience.

2 Why content matters: Binocular rivalry and the multiple levels of conscious experience

In 1996 [Nikos Logothetis & David Leopold](#) published a landmark study on the neural mechanisms of visual awareness. They presented their participating monkeys with a very elaborate visual stimulus display, which allowed them to show one image to one eye and another image to the other eye. For example, the left eye might be stimulated with a line pattern tilted to the left, and the right eye might be stimulated with a line pattern tilted to the right. In such cases, where conflicting input is presented to

Figure 1: Binocular rivalry and levels of perception. (a) Two conflicting stimuli, one presented to the left and one to the right eye, lead to a perceptual alternation between phases where the input of either the left or right eye is consciously seen. In monkey single-cell electrophysiology, this perceptual alternation has a correlate in higher-level visual regions of the temporal lobe, but activity in earlier visual regions shows only small changes in activity patterns. Presumably, signals in the temporal cortex encode the complex figural properties of the stimuli, such as the left being a sunburst pattern and the right being an image of a monkey face. However, due to the invariance of brain responses in higher-level visual regions to low-level features, this cannot explain the perceptual difference between the rivalry of the left and of the right sunburst pattern shown in (b), where the central circle has changed colour but the entire shape remains similar (monkey illustration by Chris Huh, Wikimedia Commons).

the two eyes, human participants don't experience a fusion between the two images. Instead, conscious visual perception alternates between phases where one of the eyes' inputs become visible and phases where the other eye's input are seen. Perception waxes and wanes more or less randomly between two perceptual experiences—despite constant stimulation. Similarly, the monkeys that were exposed to these binocular rivalry stimuli indicated behaviorally by pressing levers that their perception alternated between the inputs to the two eyes.

In parallel, Leopold & Logothetis (1996) investigated what happened to the firing patterns of single neurons in the monkeys' brains. Their setup allowed them to not just look at one location in the brain, but to assess neural correlates in several visual brain regions. They found only a small percentage of single neurons in early visual cortex (V1/V2) whose firing pattern was modulated by the stimulus that was currently dominant. In contrast, in a higher-level visual area—V4—they found that many more cells changed their firing rates with changes in perception. This establishes a clear dissociation between early visual areas where neural signals seem not to correlate with awareness and high visual areas where they do. In a follow-up experiment, Sheinberg & Logothetis

(1997) investigated the involvement of even higher visual regions in the temporal cortex in binocular rivalry. Because cells in these regions preferentially respond to more elaborate visual features, they used complex shapes and images, such as, for example, an abstract sunburst pattern or a picture of a monkey face (Figure 1a). They found that in the superior temporal sulcus and in the inferior temporal cortex, a large percentage of cells modulated their firing rate with perceptual dominance. Taken together, these studies seem to suggest that visual awareness affects signals only at late stages of the visual system.

But what does it mean exactly that visual awareness only affects late stages of visual processing? Does it mean that high level visual areas contain all the neural correlates of contents consciousness (NCCCs), in a way similar to a CD encoding the contents of a piece of music? If the signals in these high visual areas are really responsible for encoding all contents of visual experiences then any aspect of conscious perception that changes during binocular rivalry should be explainable by changes in signals in these higher-level brain regions. There are reasons to believe that this cannot be the case. Consider the two images as shown in Figure 1a. At one instant the monkey might

consciously see the face image. This percept would be encoded in activity patterns in the higher visual areas. In the next instant the monkey might see a sunburst pattern, and this experience would also be encoded in the higher visual cortex. At first sight this seems reasonable. Higher-level visual areas are specialized for complex visual information and object features (Sáry et al. 1993). So cells that have a preference for faces might respond during dominance of the face image, and cells with a preference for sunburst patterns might respond during the dominance of that pattern. But there is one difficulty in this interpretation. The images have a high-level interpretation as complex shapes, but they are also composed of a multitude of minute visual features, edges, surfaces, colours, etc. During rivalry, our perception does not only change according to the abstract interpretation, with respect to abstract, high-level interpretation, but also in terms of the minute, fine-grained details of visual experience (see Figure 1b).

This poses a problem because responses in higher-level visual areas are invariant with respect to low-level features (Sáry et al. 1993). Cells in higher-level visual areas in the inferior temporal cortex respond selectively to specific object features in an invariant pattern (Figure 2). A cell specialized for detecting, say, a circle, will respond to this circle irrespective of the low-level features by which it is defined (here brightness, contrast, and colour contrast). This means that such a cell disregards the low-level features and does not convey information about them any more. While cells in high-level visual areas might be able to explain why we see a face one moment and a sunburst pattern the next, they cannot explain why the sunburst pattern is yellow instead of red, or why it is one specific visual pixel collection out of the many possible that would be seen as a sunburst pattern. Thus, visual experience is a multilevel phenomenon, and a theory of the neural correlates of visual awareness will have to be able to explain all the levels of our experience, not just one. This clearly shows the importance of a content-based approach to visual consciousness.

Figure 2: Invariance of single-cell responses in higher-level visual areas. Responses in low-level visual areas (top) are tuned to low-level features such as colour or luminance. In contrast, responses in higher-level object-selective regions (bottom) are largely invariant with respect to these low-level features (Sáry et al. 1993).

3 Approaches to content-selectivity in human neuroimaging and their problems

The limited resolution of current neuroimaging techniques poses a substantial problem for the investigation of the encoding of contents in the human brain, and thus for studies on NCCCs in the human brain. The most important format in which information is coded in the brain is the cortical column (Fujita et al. 1992). Cortical columns consist of small groupings of cells with similar tuning properties, clustered together at a scale of around half a millimetre. Even functional magnetic resonance imaging (fMRI) does not routinely have a sufficient resolution to selectively study the activation of individual cortical columns (but see e.g., Yacoub et al. 2008 for recent progress). For this reason, most research into perceptual contents has relied on experimental “tricks” that allow the tracking of contents indirectly.

In *frequency tagging*, a visual stimulus is tagged with a specific and unique flicker frequency. This then allows for tracing of the processing of this stimulus by searching for brain signals that exhibit the same flicker frequency. This approach has been used to study binocular rivalry, but in quite a different way to that undertaken by Leopold & Logothetis (1996). Tononi et al. (1998) tagged the inputs of the two eyes with different frequencies. They found that the currently dominant percept was accom-

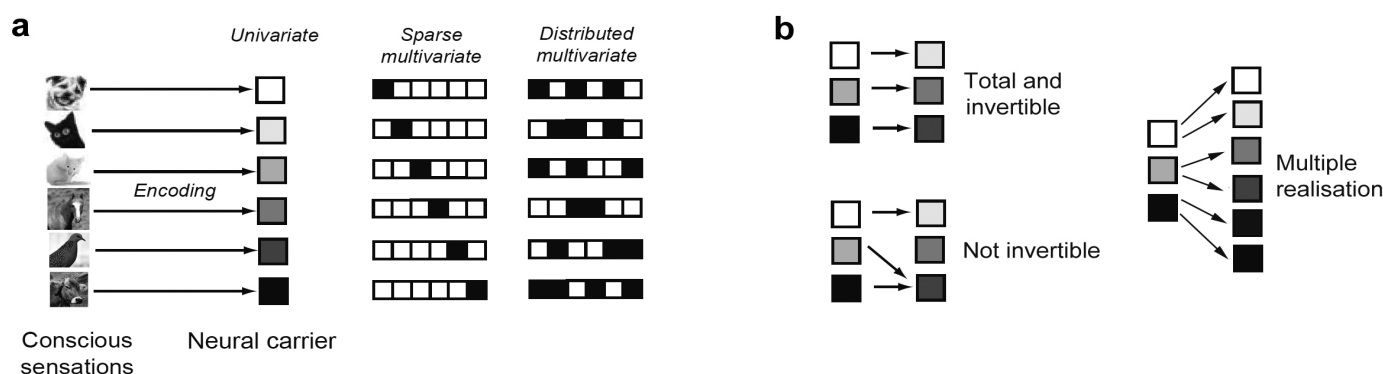

Figure 3: Principles of mapping between mental states and brain states (see text; adapted from Haynes 2009 with additional images from Wikipedia).

panied by wide-spread increases in Magnetoencephalography (MEG)-signals at the tagged frequency across multiple brain regions, mostly in the early visual and temporal cortex. This is a very powerful approach and it reveals how wide-spread the effects are when a stimulus reaches visual awareness. However, it is not always clear whether these findings indicate that the corresponding perceptual features of the stimuli, in this case the orientation of line elements, really are distributed throughout the brain. The key problem is that the feature that is traced (the frequency) is not the main feature that is perceptually relevant (orientation). One could imagine, say, that activity in higher-level brain regions that exhibits the frequency of the dominant stimulus might not be involved in coding the sensory content, but instead in detecting the presence of a change in the visual image, irrespective of what the corresponding feature is. The frequency-tagging approach does not allow for distinguishing between these alternatives.

Another approach to tracking content-selective processing is to use stimuli that are known to activate specific *content-selective brain regions* (Tong et al. 1998; Rees et al. 2000). For example, in a study on binocular rivalry, Tong et al. (1998) used faces and houses as rivalry stimuli. These stimuli are known to activate different brain regions, the fusiform face area (FFA) and the parahippocampal place area (PPA). They found that activity in a content-selective region increased when the corresponding stimulus became perceptually dominant. This goes further than the frequency-tag-

ging approach in that it allows for drawing the plausible conclusion that awareness leads to increased activity in content-selective regions. However, this approach again suffers from several problems. First, it only allows us to address the hypothesis related to very specific stimuli (typically faces and houses) and to very specific brain regions. Because the approach relies on the existence of macroscopic content-selective regions, it would not be possible to test whether, say, the prefrontal cortex, receives sensory information when a stimulus reaches awareness. A further problem is that the high selectivity of FFA and PPA has long been questioned (Haxby et al. 2001).

4 Mapping and decoding

It seems a different, more direct, and generic approach is necessary in order to identify the neural correlates of the contents of consciousness. It may help to start in the simplest possible way. If we want to explain the occurrence of a conscious experience E_1 with the occurrence of a brain state B_1 then—roughly speaking—the experience and the brain state should always happen together. If we want to explain N experiences $E_{1..N}$ with brain states, we will need N different brain states $B_{1..N}$ in order to encode the different experiences. If brain data from a specific area only adopts one of five states every time a participant has one of ten experiences it is impossible to explain the experiences through the different brain states. Ultimately this boils down to a *mapping* problem (Haynes 2009; Figure 3).

A set of conscious sensations, here visual percepts of six different animals, can be encoded in a neural carrier in multiple ways. Three principles are illustrated in [Figure 3a](#). One hypothetical way to code these six animals would be to use a single neuron and to encode the objects by the firing rates of this neuron. One would assign one specific firing rate to each of the different animals, say 1Hz to the dog, 2Hz to the cat and 3Hz to the mouse, etc. This approach is also referred to as a *univariate* code, because it uses only one single parameter of neural activity. It has the advantage of requiring only a single neuron. In *principle* it is possible to encode many different objects with a single neuron. The idea would be very similar to a telephone number, if one thinks of different numbers corresponding to different firing rates. In theory it would be possible to encode every single telephone in the world in this way, provided that the firing rates could be established very precisely and reliably. The disadvantage with this approach—even if firing rates could be established with great precision—is that it can only handle *exclusive* thoughts, i.e. it has no way of dealing with a superposition of different animals, say a cat together with a dog.

A different approach is not to use a single neuron to encode different thoughts, but instead to use a set of neurons to encode a set of thoughts. This population-based approach is also termed “multivariate”. One way to encode thoughts about six different animals would be to assign one specific neuron to the occurrence of each thought. Neuron one, say, might fire when a person thinks about a dog; neuron two would fire when they were thinking about a cat, etc. Here the firing rate is irrelevant; only a threshold is needed, such that one has a way of deciding when a neuron is “active” or “not active”. This specific coding scheme is variably termed “sparse code”, “labelled line code”, “cardinal cell code” or “grandmother cell code” (see e.g., [Quiroga et al. 2008](#)). It has the advantage of being able to handle arbitrary superpositions and combinations of thoughts, say thoughts about a meeting of a dog, a cat, and a mouse. A disadvantage is that a different neuron is needed for the encoding of each new entity. N

neurons can only encode N different thoughts. Given that the average human brain comprises 86 billion neurons ([Azevedo et al. 2009](#)) this might not seem too big a problem. A different way to use a population of neurons to encode a set of thoughts would be a *distributed* multivariate code. Here, each mental state is associated with a single activation pattern in the neural population, but now arbitrary combinations of neurons are possible for the encoding of each single thought. This allows for the encoding of 2^N thoughts with N neurons, if each neuron is only considered to be “on” or “off”.

There are various examples of these different types of codes. The encoding of *intensity* follows a univariate code: The difference between a brighter and a darker image is encoded in a higher versus a lower firing rate of the corresponding neurons in the visual cortex (see e.g., [Haynes 2009](#)). However, to date, I am not aware of any example where different higher-level interpretations of stimuli are coded in a univariate format. There are many examples of labelled line codes. The retinotopic location within the visual field is encoded in a sparse, labelled line format (e.g., [Serenio et al. 1995](#)). One position in the visual field is coded by one set of neurons in the early visual cortex; another position is encoded by a different set of neurons. If two objects appear in the visual field simultaneously, then both of the corresponding sets of neurons become active simultaneously. A similar coding principle is observed for auditory pitch, where different pitches are coded in different cells in the form of a tonotopic map ([Formisano et al. 2003](#)). The somatosensory and motor homunculi are also examples of labelled line codes, each position in the brain corresponding to one specific position in the body ([Penfield & Rasmussen 1950](#)). A distributed multivariate code is, for example, used to code different objects ([Haxby et al. 2001](#)) or different emotions ([Anders et al. 2011](#)).

When identifying the mapping between brain states and mental states one is generally interested in identifying which specific population of neurons is a suitable candidate for explaining a particular class of visual experiences. For this it is possible to formulate a number of

constraints (Haynes 2009). First, the mapping needs to assign one brain state to each mental state in which we are interested. In other words, the mapping has to be total (Figure 3b). This should be easy—it just means that we can assign one measured brain state to each different mental state. Second, the mapping cannot assign the same brain state to two different mental states. Otherwise the brain states would not be able to explain the different mental states. Technically this means the mapping has to be invertible, or injective. Every brain state should be assigned to no more than one mental state. However, it is possible—in the sense of multiple realisation—that multiple brain states are assigned to the same mental state, as long as neither of these brain states co-occurs with other mental states. The brain states referred to here only mean brain states that are relevant for explaining a set of mental states. If we want to explain thoughts about six animals, say, it might not be necessary that brain states in the motor cortex are different for the different animals. However, if one wants to propose one set of neurons (say, those in the lateral occipital complex, Malach et al. 1995) as a candidate for explaining animal experiences, then this can only hold if the abovementioned mapping requirements are fulfilled.

In practice it will be very difficult to establish this mapping directly. One major problem is that we can't measure brain states in sufficient detail with current neuroscience techniques. Non-invasive measurement techniques such as electroencephalography (EEG) or functional magnetic resonance imaging (fMRI) have very limited spatial resolution. fMRI for example resolves the brain with a measurement grid of around 1–3mm, so that each measurement unit (or voxel) contains up to a million cells. And the temporal resolution of fMRI is restricted because fMRI measures the delayed and temporally-extended hemodynamic response to neural stimulation. While it is possible—to some degree—to reconstruct visual experiences from fMRI signals (e.g., Miyawaki et al. 2008), fMRI cannot resolve temporal details of neural processes, such as the synchronized activity of multiple cells. But it is not only EEG and fMRI

that have limited resolution: Invasive recording techniques are typically restricted to individual well-circumscribed locations, where surgery is performed. And even with multielectrodes it is not possible to identify the state of each individual neuron in a piece of living tissue.

Another important limitation lies in our ability to precisely characterize and cognitively penetrate *phenomenal states* (e.g., Raffman 1995). There is currently no psychophysical technique that would allow us to characterize the full details of a person's visual experiences at each location in the visual field. Verbal reports or button presses can convey only a very reduced picture of the true complexity of visual experiences. So ultimately, the mapping requires precision from both psychology and neuroscience, and any imprecision in either approach will blur the mapping and distort the interpretation.

The next best option short of establishing full mapping is to use decoding techniques that follow a similar logic. Brain-based decoding is also referred to as “brain reading” or “multivoxel pattern analysis” (see Haynes & Rees 2005 for a review). The basic idea is to see to which degree it is possible to infer a mental state from a measurement of a brain state. Say you want to test whether the lateral occipital complex is a suitable candidate for encoding visual thoughts about animals. You test if it is possible to infer which animal a person is currently seeing by training a classifier to learn the association between animal and brain activation pattern, and then one needs to test whether the classifier can correctly assign the animal that belongs to a new measurement of brain activity. In the following, this approach will be explained in detail.

Take for example a hypothetical fMRI-measurement of the human brain within a three by three grid of locations, amounting to nine voxels (Figure 4a). These nine voxels can be systematically resorted into a column of numbers (or vectors), where each entry denotes the activation at one location (high values correspond to strong fMRI responses). Say one was interested in testing whether these nine voxels contain information about two different visual

images, perhaps a dog and a cat. The question that needs to be addressed is whether the response patterns (i.e., the vectors) are sufficiently different to allow for distinguishing between the animals, based on these brain activity measurements alone. The vector is not a useful way to see whether this classification is possible. It can help to visualize the same information in a two-dimensional coordinate system. Take the responses to the dog. One can think of the first and second entries in the vector as x- and y-values that define points in a coordinate system. The response in the first voxel (x) to the dog is a low value (2), while the second value (y) is a high value (8). When plotted in a two-dimensional coordinate system (Figure 4b), this yields a point in the top left of the coordinate system, shown here in red. Repeated measurements of the brain response to the dog yield a small cloud of red points. Repeatedly measured brain responses to the cat have high values in voxel 1 (x) and low values in voxel 2 (y). In the two-dimensional coordinate system this yields a cloud of blue points in the bottom right of the coordinate system. Clearly the responses are separable in this two-dimensional coordinate system, so the two animals enjoy reliably separate neural representations in this set of nine voxels. In this hypothetical example, each of the two voxels alone would be sufficiently informative about the category of animal. By collapsing the points for voxel one onto the x-axis it becomes clear that the two distributions of points (red and blue) are sufficiently different to allow for telling the two apart. The same holds for voxel two by collapsing to the y-axis. This is akin to a labelled line code, with one line for “dog” and one line for “cat”.

However, there are cases where the two distributions will not be so easily separable. Figure 4c shows an example where the individual voxels do not have information about the animals. The collapsed or “marginal” distributions largely overlap. There is no way to tell a cat response from a dog response by looking at either voxel one or two alone. However, by taking into account the *joint activity* in both voxels, the two animals become clearly separ-

able. Responses to the dog all cluster to the top left of the diagonal and responses to the cat cluster to its bottom right. This joint consideration of the information contained in multiple voxels is the underlying principle of *multivariate decoding*. The line separating the two distributions is known as the decision boundary. Decision boundaries are not necessarily straight lines. Many other types of distributions of responses are possible. Figure 4d, for example, shows a non-linear decision boundary. Finding the optimal decision boundary is the key objective in the field of machine learning (Müller et al. 2001), where many different types of classifiers have been developed (most well known are support vector classifiers). In order to identify the decision boundary the available data are split into training and test data. The test data are put aside and only the training data are then used to find a decision boundary, as, for example, is shown in Figure 4e. The crucial test is then performed with the remaining test data. The classifier is applied to these data to see to which degree it is able to correctly assign the labels. Depending on which side of the decision boundary a test data point falls upon, it will yield either a correct or an incorrect classification.

Please note the similarity between the mapping of mental states and brain states. The red cloud of points in Figure 4b shows a two-dimensional response pattern that corresponds to the neural code for percepts of dogs. The spread of the point cloud (i.e. the fact that repeated measurements don’t yield identical values) could mean two things. Either the spread reflects *noise and uncertainty* that is typically inherent in measurements of neural data. This could, for example, reflect the fact that single fMRI voxels can sample many thousand cells, only few of which might be involved in processing. Additionally, physiological background rhythms can influence the signals and contribute to noise (Fox et al. 2006). Alternatively, however, the spread of the points could also be an inherent property of the representation. This would suggest that every time a person sees or visual imagines a dog, a slightly different activation pattern is observed in the brain. This would then

be evidence of *multiple realization*. Current measurement techniques do not have sufficient precision to distinguish between these two accounts. One difference between the multivariate mapping shown in Figure 3a (right) and the classification in Figure 4 is that the classification shows response distributions where each individual variable (voxel, channel) can adopt a graded value, whereas the values in Figure 3a (right) are only binary.

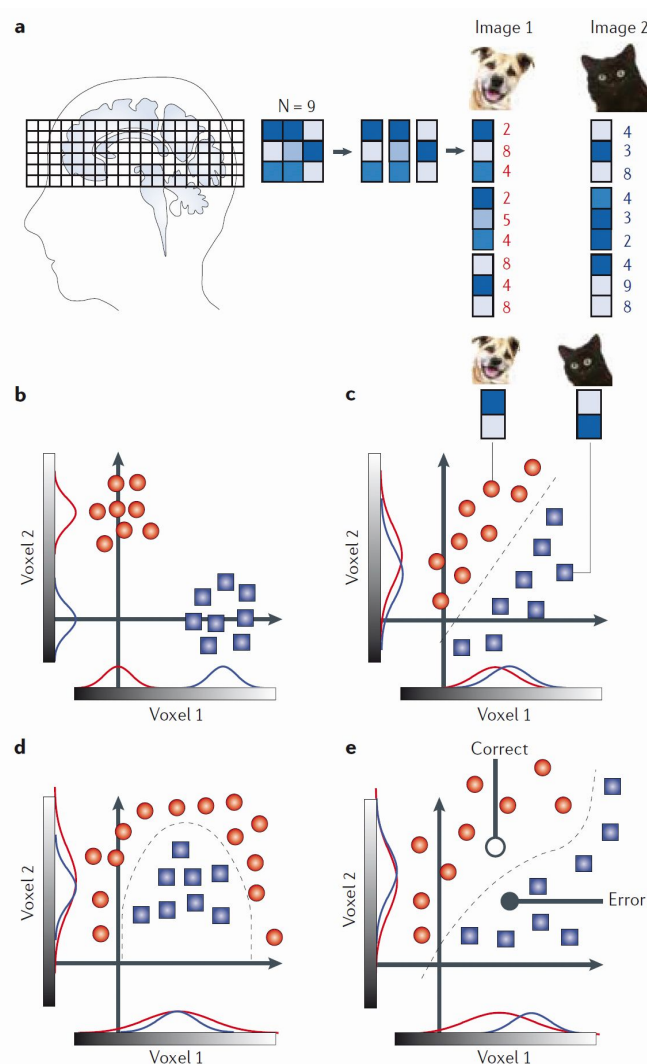

Figure 4: Mental state decoding using classification techniques (image adapted from Haynes & Rees 2005).

5 What does multivariate decoding reveal about NCCCs?

The importance of information theory for understanding the neural correlates of consciousness has been stressed repeatedly, most notably

by Giulio Tononi (2005). His information integration theory focuses on the information-based properties of neural processes and uses these special properties to provide a general explanation of consciousness. In contrast, the multivariate decoding account presented here attempts to solve the much more basic question of which neural populations provide the best account for which visual experiences. As mentioned above, this can be thought of as a search for the core neural correlates of the contents of consciousness (NCCCs), which have been postulated in similar forms by previous authors (Chalmers 2000; Block 2007; Koch 2004). While these proposals for core NCCCs have been influential in theoretical discussions on consciousness, they have only rarely been directly linked to neuroscience research, which requires spelling out how the NCCC can be established in empirical data. In the following, various studies of multivariate decoding from our lab will be presented that have implications for identifying NCCCs.

5.1 Example 1: Encapsulated information in V1

There has long been a debate as to whether the primary visual cortex (V1) is a neural correlate of visual consciousness. Crick & Koch (1995) postulated that V1 does not encode visual experiences for several reasons. First, V1 does not have the anatomical projections to the pre-frontal cortex that would allow for a direct read-out of information in V1. This would be required to explain a key distinguishing feature of conscious experiences: that we can voluntarily act upon them. A second reason is that V1 encodes information of which we are not aware. Psychophysical experiments, for example, show that V1 can encode orientation information of which we are not aware (He et al. 1996). We thus directly assessed the link between information encoding in V1 and visual awareness (Haynes & Rees 2005). Specifically, we investigated the effects crossing the threshold to awareness has on the neural coding of simple visual features. Participants viewed oriented “grating” images (Figure 5) and had to tell whether they were tilted to the left or to the right. In one

condition the images were clearly visible, in the other condition they were rendered invisible by rapidly alternating the orientation stimulus with a mask. In this condition participants were not able to tell the difference between the two orientation stimuli (Figure 5).

Figure 5: Decoding the orientation of invisible grating stimuli from patterns of activity in early visual areas. Target stimuli were line patterns that were either tilted top left to bottom right, or top right to bottom left. They were rapidly alternated with mask stimuli so that participants were unable to identify the target orientation. The classification accuracy for these “invisible” gratings was above chance in area V1, but not in V2 or V3. For visible orientation stimuli the classification was above chance in all three early visual areas (figure taken from Haynes & Rees 2005).

We then applied a classifier to fMRI-signals from early visual regions V1, V2, and V3 to see if it would be possible to decode the orientation of stimuli. We found that orientation for the visible stimuli could be decoded from all early visual regions, V1, V2, and V3 (Figure 5, right). This is in line with previous research on encoding of orientation information in early visual areas (Bartfeld & Grinvald 1992). Interestingly, we were able to decode the orientation from V1 even for invisible stimuli. This means that V1 presumably continues to carry low-level feature information even when a participant can’t access this information. V2 and V3, however, only had information for visible stimuli, not for invisible stimuli. Please note that an alternative interpretation could be that subjects perceive the subtle differences between masked stimuli, but they cannot report or reason about them. However, in psychophysics an absence of

discriminability is typically considered a strong criterion for absence of awareness. This finding is interesting for several reasons. First, it demonstrates that information can be encapsulated in a person’s early visual cortex, without them being able to access this information. This suggests that V1 is not an NCCC for conscious orientation perception. Second, it shows that one explanation why stimuli are rendered invisible by visual masking is that the information that is available at early stages of processing (V1) is not passed on to the next stages of processing in V2 and V3. Similar encapsulation of information has also been observed for parietal extinction patients in higher-level visual areas with more conventional neuroimaging approaches (Rees et al. 2000).

5.2 Example 2: Imagery and perception

There has also been a long debate on the neural mechanisms underlying visual imagery. One important question is whether the NCCCs underlying imagery are the same—or at least overlapping—with those for veridical perception. One study (Kosslyn et al. 1995) found that imagery activated even very early stages of the visual cortex. This fits with a mechanism that encodes visual images as a replay of representations of veridical percepts. However, this does not reveal whether the activation of the early visual cortex really participates in encoding the imagined contents. Instead, these regions might be involved in ensuring the correct spatial distribution of attention across the visual field (Tootell et al. 1998). The question of whether the neural representations of veridical percepts are the same as those for visual imaginations needs to be established in addition.

We conducted a study to directly address the overlap of NCCCs for veridical perception and imagery (Cichy et al. 2012). Participants were positioned inside an MRI scanner and had to perform one of two tasks: Either they were asked to *observe* visual images presented to the left or right of fixation (Figure 6), or they were asked to *imagine* visual images in the same locations. Twelve different images from four categories were used: three objects, three visual

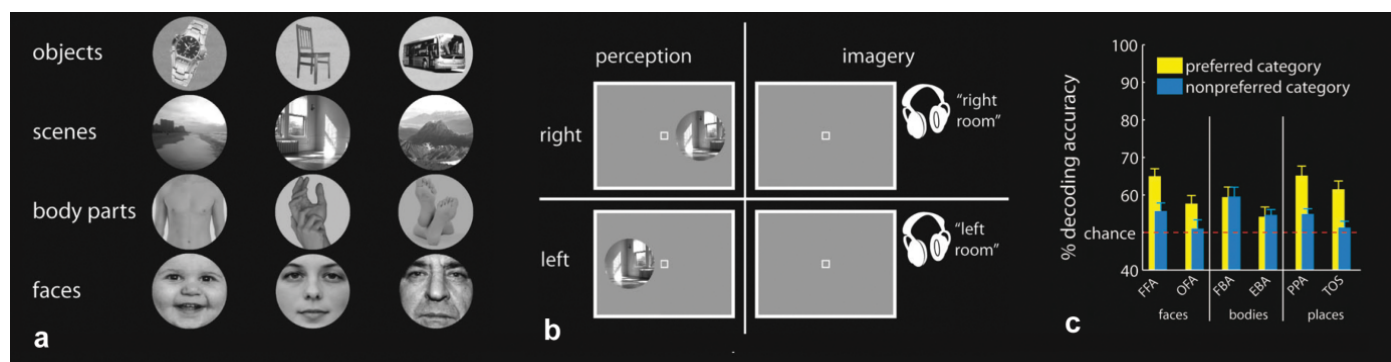

Figure 6: Visual imagery. (a) Visual stimuli used in the experiment consisted of three selections from four categories. (b) In different trials participants either saw the images to the left or right of fixation or they received an auditory instruction to imagine a specific image. (c) A classifier trained on the brain responses of different imagined images could be used able to correctly cross-classify which image a person was currently seeing on the screen in the perception condition. Information was higher for the images “preferred” by a visual area, but there was still information, esp. in FBA, about the non-preferred categories (FFA=fusiform face area; OFA=occipital face area; FBA=fusiform body area; EBA=extrastriate body area; PPA=parahippocampal place area; TOS=transverse occipital sulcus)(figure from Cichy et al. 2012).

scenes, three body parts, and three faces. We found that multiple higher-level visual regions had information about the images. Furthermore, it was possible to decode seen visual images using a classifier that had only been trained on imagined visual images. This suggests that imagery and veridical perception share *similar* neural representations for perceptual contents, at least in high-level visual regions. Please note, however, that the cross-classification between veridical perception and imagery is not perfect. It is currently unclear whether this reflects imperfections in the measurement of brain signals with fMRI, or whether it reflects residual differences in the contents of consciousness between imagery and veridical perception, for example the higher vividness of perception based on external visual stimuli (Perkey 1910).

5.3 Example 3: Perceptual learning

Another interesting riddle of sensory awareness is perceptual learning (Sagi 2011; see also Lamme this collection). When we are first exposed to a novel class of sensory stimuli our ability to differentiate between nuances is highly limited. When one tastes the first glass of wine, all wines taste the same. But with increased exposure and experience we learn to distinguish even subtle differences between different wines.

The interesting question here is whether the sensory information was there all along, and we just failed to notice it, or whether the sensory representation of the wines actually improves (see Dennett 1991).

We addressed this question, but with visual grating stimuli instead of different wines (Kahnt et al. 2011). Participants performed two fMRI sessions, where they had to distinguish small differences in the orientation of lines presented on the screen. They had to tell whether they were rotated clockwise or counter-clockwise with respect to a template. During the first fMRI session their ability to distinguish between the line patterns was quite limited. Afterwards we trained them in two sessions outside the MRI scanner on the same line patterns, and their performance continually improved. In a final second fMRI session they had then substantially improved their ability to tell even subtle differences between the orientations apart. But what explains this improvement: Better sensory coding, or better interpretation of the information that was there all along?

To address this question we first looked into the responses in the early visual cortex to the different line stimuli. As expected from our above-mentioned study on orientation coding (Haynes & Rees 2005), it was possible to decode the orientation of the line elements from signals in early

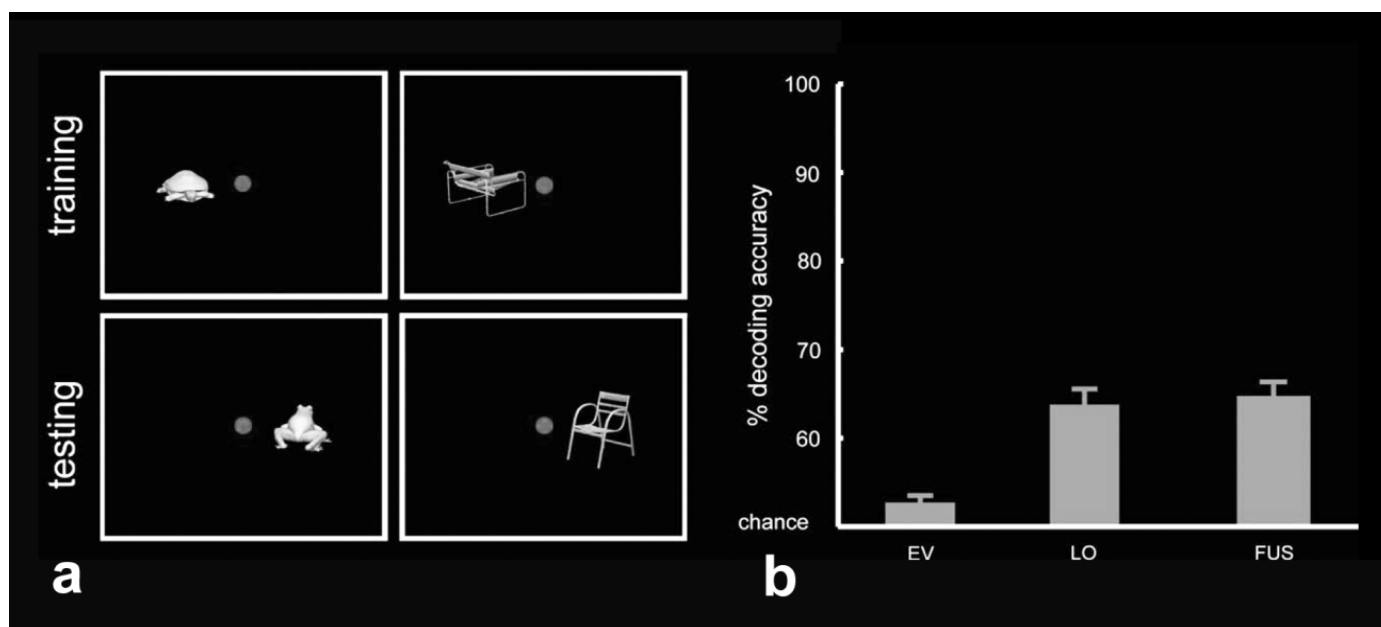

Figure 7: FMRI evidence for invariance of object-representations in the high-level visual regions lateral occipital (LO) and fusiform gyrus (FUS) as compared to early visual cortex (EV; figure from [Cichy et al. 2011](#)).

visual areas. It is well established that these areas have information about such simple visual features ([Bartfeld & Grinvald 1992](#)). However, we found no improvement in our ability to decode the orientation of the stimuli with learning. There is some divergence in the literature with some studies finding effects of learning in early sensory areas (see [Sasaki et al. 2010](#)). Other recent findings in monkeys are in line with our findings and do not find improved information coding in sensory areas (e.g., [Law & Gold 2009](#)). In our case, it seems as if the sensory representation of orientation remains unchanged and that some other mechanism has to be responsible for the improvement in perceptual discrimination. We found a region in the medial prefrontal cortex where signals followed the learning curve, thus suggesting that the improvement was not so much a question of stimulus coding but of the *read-out* of information from the sensory system. This study suggests that representation of a feature in an NCCC might not automatically guarantee it enters visual awareness.

5.4 Example 4: Invariance in human higher-level visual cortex

As mentioned above, one important challenge to the idea that the contents of visual awareness

are encoded exclusively late in the visual system is the invariance of responses to low-level visual features ([Sáry et al. 1993](#)). We directly investigated the invariance of fMRI responses in the regions lateral occipital (LO) and fusiform gyrus (FUS) of the higher-level object-selective visual cortex ([Malach et al. 1995](#); [Grill-Spector et al. 2001](#)). In this study ([Cichy et al. 2011](#)) participants viewed objects presented either to the left or the right of the fixation spot ([Figure 7](#)). These objects consisted of three different exemplars from four different categories (animals, planes, cars, and chairs). For example, the category “animal” contained images of a frog, a tortoise, and a cow. With these data we were able to explore two different aspects of invariance. First, we wanted to know whether object representations are invariant to changes in spatial location. This is important because a low-level visual representation that focuses exclusively on the distribution of light in the visual field would not be able to generalize from one position to another. So we assessed whether a classifier trained to recognize an object at one position in the visual field would be able to generalize to another position in the visual field. We found that a classifier was able to generalize to a different position, however with reduced accuracy. This indicates that the representations

were at least partially invariant with respect to low-level visual features. Next, we investigated whether the representations would generalize from one exemplar to another. This goes even further in testing for the level of abstraction of the representation. A classifier that can generalize not only to a different location but even to a different exemplar (say from a frog to a cow) needs to operate at a higher level of abstraction that is largely independent from low-level visual features. Again we found that the classifier was able to generalize between exemplars of the same category, further supporting the abstraction of representations in the higher visual regions LO and FUS (Figure 7). This makes it again less plausible that the contents of visual awareness are encoded exclusively in the higher-level visual cortex. Encoding in these regions is invariant (or at least tolerant) to low-level feature changes, and thus this level of perceptual experience has to be encoded at a different, presumably lower, level of visual processing.

5.5 Example 5: No sensory information in PFC

A further case where multivariate decoding might inform theories of visual awareness becomes apparent when we confront the question of whether sensory information is distributed throughout the brain when a stimulus crosses the threshold of awareness. The global neuronal workspace theory (e.g., Dehaene & Naccache 2001; see also Baars 2002) posits that sensory signals are made globally *available* across large-scale brain networks, especially in the prefrontal and parietal cortices, when they reach awareness. An interesting and open question is whether this global availability of sensory information means that the sensory information about a stimulus can be actually decoded from these prefrontal and parietal brain regions to which the information is made available. In theory, one might be able to distinguish between a “streaming model” of global availability, where information is broadcast throughout the brain (e.g., Baars 1988), and which should thus be decodable from multiple brain regions; an alternative would be an “on demand” model of global

availability, where sensory signals are only propagated into prefrontal and parietal cortex when selected by attention (e.g., Dehaene & Naccache 2001).

We performed three fMRI studies to test this question (Bode et al. 2012; Bode et al. 2013; Hebart et al. 2012). In the first study (Bode et al. 2012), participants were briefly shown images of pianos and chairs that were temporally embedded in scrambled mask stimuli. There were two conditions. In one condition, the timing of visual stimuli was chosen such that the target stimuli were clearly visible. In the other condition, the timing of scrambled masks and targets was such that the targets were effectively rendered invisible. We attempted to decode the sensory information about the presented objects. Under high visibility we were able to decode which image was being shown from fMRI signals in the so-called lateral occipital regions of the human brain, where complex object recognition takes place. Under low visibility, there was no information in these brain regions. This suggests a possible mechanism for explaining why the stimuli failed to reach awareness. Presumably their sensory representations were already cancelled out at the visual processing stages. The “streaming model” mentioned above would mean that sensory information about the object category is distributed into parietal and prefrontal brain regions when the stimulus crosses the threshold of awareness. However, we found no information in the prefrontal cortex—under either high or low visibility (Bode et al. 2012). This finding was repeated in two different studies, one also using objects as stimuli (Bode et al. 2013) and one using drifting motion stimuli (Hebart et al. 2012). In contrast, in animal studies sensory information has been found in the prefrontal cortex (Pasternak & Greenlee 2005). It is currently unclear whether this reflects a species-difference or whether it is due to limitations in the resolution of human neuroimaging techniques.

5.6 Example 6: Unconscious processing of preferences

It is well known that unattended and even invisible visual stimuli can undergo substantial processing. We investigated whether informa-

tion about high-level, more interpretative and subjective properties of visual stimuli would also be traceable using decoding techniques. For this we aimed to decode the degree to which *preferences* for certain visually presented images of cars can be decoded, even when these stimuli were unattended and were not task-relevant (Tusche et al. 2010).

For this experiment we carefully pre-selected our participants, who were self-reporting car-enthusiasts. Then we ensured that we chose stimuli where different participants had maximally-divergent opinions as to which car they preferred. This was necessary in order to de-correlate the classification of the preference from the classification of the specific vehicles. Subjects were divided into two groups. Participants from the first group were presented with the car images in the scanner and had to actively evaluate whether they liked them. The second group was also presented with the car images, but they were distracted from them. They were required to solve a very difficult task that required them to focus their attention elsewhere in the visual field, on fixation. The car stimuli were thus task-irrelevant and presented outside of the attentional focus. This group of subjects could not recall which cars had been shown during the experiment, suggesting that they were indeed not actively deliberating about the cars. After the experiment, participants from both groups were asked to rate how much they would like to buy each car. This served as a gold standard for their preference.

We then tried to decode whether individual subjects liked the cars or not. For this, we looked into patterns of brain activity throughout the brain, to see where there might be information regarding preferences. This was done in order to reduce the bias when only looking into pre-specified brain regions. We found that it was possible to decode the preferred cars with 75% accuracy from brain regions far outside the visual system, in the medial prefrontal and in the insular cortex. This was true for the subjects who had been actively deliberating about their preferences for the cars, but also for the participants who been distracted from thinking about them. Presumably, this

means that the brain automatically processes the car-images all the way up to the stage of encoding preferences, even in the absence of visual attention. Please note that this finding of *preference* information in the prefrontal cortex is quite different to that in the previous experiment, where there was no *sensory* information in PFC. Here, in contrast, there is information in PFC, but (a) not about a sensory property and (b) even for unattended stimuli. Thus, it appears that the informational dividing line between sensory and prefrontal brain regions is not one of awareness, but rather one of the type of information coded.

6 Complicating factors

When searching for the neural correlates of contents of consciousness (NCCCs), there are several complicating factors. One might a priori have an assumption of modularity, meaning that one feature is encoded in one dedicated NCCC area. The idea that such single, maximally-informative regions exist for different features, however, is no more than an assumption. It might turn out that perceptual coding—even for single features—inherently involves processes in multiple brain regions.

Empirically, it is known that information about objects is distributed across multiple regions. One question is whether one brain region can have information about more than one content (e.g., Haxby et al. 2001; Cichy et al. 2013). In a study inspired by Haxby et al. (2001) we investigated whether object-selective brain regions have information only about objects from their preferred category (Cichy et al. 2013). Participants viewed images from four different categories: objects, visual scenes, body parts, and faces. These categories were chosen because faces, body parts, and places are believed to be processed by highly selective brain regions. We found that a classifier not only contained information about a region's preferred category: take the example of the face-selective region FFA. It was not only possible to classify faces from this region, it was also possible to classify the difference between other, non-face-related objects, say between a chair and a window. The

flipside of this finding that individual regions encode multiple contents is that individual perceptual contents were found in multiple regions. For example, information about faces was also found in supposedly “non-face-selective” brain regions (e.g., in the PPA). This presents a challenge to the idea that each content is represented in one region only.

However, the problem might not be as severe as it first appears. It is actually expected that multiple regions will contain information about each type of content. Different brain regions do not exist in isolation, but are densely causally interconnected (Felleman & van Essen 1991). Furthermore, in the visual pathway, stimulus-related information will reach higher-level brain regions by way of low-level regions. Even if the FFA is the visual region that responds most (albeit not fully) selectively to faces, the presence of a face could also be inferred from the discharge pattern of ganglion cells in the retina. Thus, vertical and horizontal propagation of information is expected. One crucial criterion, which has not received much attention, is whether the information in different regions is *redundant* or whether it is *independent* with respect to a person’s perceptual experience. If one hypothetical brain region, say the uniform unicorn area (UUA), is directly responsible for visual experiences of unicorns, it should have more information about a person’s unicorn experiences than any other region.

The relationship between information in the UUA and other areas will reveal a lot about the nature of representation. If other regions also have information about unicorn experiences, and they receive their information about unicorn experiences via the UUA, then the unicorn-related information in the other regions should be partially redundant to that in the UUA. A classifier should not be able to extract more information about a person’s unicorn experiences by additionally taking other regions into account, over and above the information available from the UUA. If, in contrast, other regions have information that goes beyond that in the UUA that allow the system to improve the classification of unicorn experiences, it is likely that the representation itself is distrib-

uted across multiple brain regions. Another way to put it is to distinguish between representational and causal entanglement. A change in neural activity in one region will typically be propagated to any neighbouring regions with which it is connected. This *causal* entanglement, however, does not directly implicate *representational* entanglement. Only if it were not possible to find an individual region where neural activity patterns is not fully informative of a specific feature, and if taking into account the joint activity of this region and another region did provide full information, would this provide evidence for representational entanglement.

7 Putting it together

As outlined above, when attempting to identify the neural correlate of a particular content of conscious experience, it is important to ensure that brain representations in any candidate region fulfil certain mapping requirements. Because we have no direct way of establishing this mapping, multivariate decoding provides a rough approximation that allows the linking of perceptual contents to population brain responses in different regions, and allows us to explore their properties. The data from our lab provide several constraints for a theory of NCCs. Consistent with previous suggestions (Crick & Koch 1995), the very early stages of processing in V1 are presumably not directly involved in encoding visual experiences. Representations in these regions have more detail than enters consciousness (Haynes & Rees 2005) and might not change their information content during perceptual learning when contents are successively represented with more detail in consciousness (Kahnt et al. 2011). Please note that early regions beyond V1 have to be NCCs, because higher-level visual areas are invariant to low-level visual features. This has not only been shown in animals (Sáry et al. 1993), but also in humans using classification techniques (e.g., Cichy et al. 2011). This invariance means that high-level regions cannot simultaneously encode the high-level, more abstract phenomenal properties (such as whether a cloud of points resembles a dog or a cat) and the low-level phe-

nominal properties (colour or brightness sensations). Multiple regions are needed to account for the full multilevel nature of our perceptual experience. While V1 is presumably excluded from visual awareness, early extrastriate regions (such as V2) are likely to be involved, because they still encode low-level visual information. They also appear to filter out sensory information that does not enter awareness, thus again closely matching perceptual experience. For example, V2 and V3 do not encode the orientation of invisible lines, whereas V1 does (Haynes & Rees 2005). Similarly, neural object representations in the lateral occipital complex were wiped out by visual masking that rendered an object stimulus invisible (Bode et al. 2012). The role of extrastriate and higher-level visual areas in visual awareness is further highlighted by the fact that they exhibit a certain convergence of different aspects of awareness. Most notably, they employ a shared code for visual perception and visual imagery (Cichy et al. 2012).

While extrastriate and higher-level visual regions jointly encode different feature levels of visual awareness, there is evidence that a representation in these regions is not sufficient for visual awareness. For example, our experiments on perceptual learning (Kahnt et al. 2011)—where subjects are unable to access certain details of visual stimuli—show that improved sensory perception is not necessarily associated with improved representation of information in these early areas. The mechanism through which perception of details might be improved lies beyond the sensory encoding stage, in the prefrontal cortex. The mechanism of this improvement is not an improved sensory representation in the prefrontal cortex. Contrary to several experiments on animals (Pasternak & Greenlee 2005), our experiments consistently fail to show any sensory information in the frontal cortex. For example, when a stimulus survives visual masking and is consciously perceived, there is no evidence for the additional distribution of information into the prefrontal cortex (Bode et al. 2012; Bode et al. 2013; Hebart et al. 2012) as would be expected if information is indeed made globally available in the sense of a “streaming model” of a global

workspace (Dehaene & Naccache 2001). Even in a more conventional experimental task, based on visual working memory, we were not able to identify sensory information in the prefrontal cortex. Thus, the direct encoding of the visual contents of consciousness, the NCCCs appear to lie in sensory brain regions, at least as far as can be told with the resolution of non-invasive human neuroimaging techniques. On the other hand, our results suggest that the prefrontal cortex is involved in the decision-making—as has been suggested before (Heekeren et al. 2004)—and in learning about sensory contents (Kahnt et al. 2011). Thus, it appears to do so without re-representing or encoding sensory information itself.

What's up with Prefrontal Cortex?

A Commentary on John-Dylan Haynes

Caspar M. Schwiedrzik

The prefrontal cortex is perhaps one of the most intriguing areas of the brain, and considered by many to be involved in a whole battery of higher cognitive functions. However, evidence for a direct involvement in conscious perception, although often postulated, remains inconclusive. In his paper, John-Dylan Haynes presents results from experiments using multivariate decoding techniques on human functional magnetic resonance imaging data that speak against the assertion that prefrontal cortex broadcasts the contents of consciousness throughout the brain. I consider potential reasons for these null results, as well as where else we may look for the neural correlates of consciousness. Specifically, I propose that conscious perception arises when distributed neurons are bound into coherent assemblies—a process that does not require relay through specific brain areas.

1 Introduction

There is a striking parallel between the hierarchical organization of behavior and the hierarchical organization of the cerebral cortex (Botvinick 2008). It is thus tempting to assign consciousness, at least historically often considered to be one of our highest functions (Jackendoff 1987; Markowitsch 1995), to the prefrontal cortex (PFC), which is positioned at the top of the cortical hierarchy. While the idea that consciousness can be localized to a single brain area has now been discredited, many current theories of consciousness still consider the PFC a key player in the emergence of conscious perception (Dehaene & Changeux 2011; Lau & Rosenthal 2011). And indeed, a multitude of

neuroimaging studies has shown differential activation for perceived vs. unperceived stimuli in various parts of the PFC (Dehaene et al. 2001; Lau & Passingham 2006; Sahraie et al. 1997; Schwiedrzik et al. 2014). A very prominent theoretical proposal on the neural correlates of consciousness, the Global Neuronal Workspace (GNW) model by Stanislas Dehaene and colleagues, posits that the PFC (in conjunction with parietal cortex) serves to distribute information that is processed in unconscious modules to the entire brain, and that it is this broadcasting of information that gives rise to conscious experience (Dehaene & Changeux 2011). The PFC may be particularly well equipped to

do so, for example because it hosts an abundance of neurons with long-distance connections, so called “von Economo” neurons, which seem ideally suited to both receive and deliver information from all areas of the brain to all areas of the brain (Dehaene & Changeux 2011). A prediction that can be directly derived from this account and that has been eloquently put forward by John-Dylan Haynes is that the PFC should at least temporarily represent the information that we consciously perceive, i.e., it should directly encode the contents of consciousness (Haynes 2009; this collection). To test this idea, Haynes and his coworkers have used a neuroimaging technique that allows for exquisite access to perceptual content, namely multivariate pattern analysis (MVPA) of functional magnetic resonance imaging (fMRI) signals. In this technique, powerful machine learning algorithms are used to analyze spatially-distributed patterns of brain activity, and a brain region is said to represent the content of interest if its activity patterns allow the reliable classification—in the case of consciousness—of which stimulus the subject perceived on a given trial. This contrasts with previous fMRI studies not using MVPA: because these studies do not directly address content, activity in the PFC (and other regions) that differentiates perceived from not perceived trials could in principle reflect other aspects of conscious experience, for example the allocation of attentional resources or working memory. The stunning result of Haynes’ investigations is that while MVPA shows that perceptual content can be decoded from higher sensory areas, PFC activity does not yield decoding accuracies higher than chance level. So what’s up with PFC?

2 Neuronal representations in the PFC

Indeed, the inability to decode perceptual content from the PFC runs counter intuitions about PFC functions we have from animal models such as the macaque monkey, where representations of (perceptual) content can be even more directly assessed than with MVPA, by using electrophysiological recordings from single neurons. These studies show that PFC neurons

are tuned for and thus represent perceptual features such as visual motion direction (Zaksas & Pasternak 2006) or somatosensory flutter frequency (Romo et al. 1999). Even more direct evidence for the representation of perceptual content in the PFC comes from a recent study by Theofanis Panagiotaropoulos et al. (2012), which shows that single PFC neurons exhibit stimulus-specific activity modulations as a function of subjective perception under flash suppression, a technique that can render visual stimuli temporarily invisible.

In the absence of direct electrophysiological recordings from human PFC, one possible explanation for this discrepancy is that the macaque brain is organized in a totally different way to the human brain. But while theoretically possible, this seems highly unlikely (Passingham 2009; Roelfsema & Treue 2014). Alternatively, one may consider whether certain properties of the neural representations in the PFC may pose limitations to the ability of the fMRI MVPA technique to decode their content. This is in light of the fact that decoding of content from human PFC has been unsuccessful not only in the context of conscious perception, but also in the context of working memory, which has led to a radical reinterpretation of the role of the PFC in this domain (Sreenivasan et al. 2014).

It has been hypothesized that successful decoding of stimulus features such as orientation or motion direction from sensory areas relies upon the presence of orderly spatial arrangements of these features in cortical columns or maps (Freeman et al. 2011; Kamitani & Tong 2005). It is thus worth asking the question whether PFC exhibits a similar map-like structure, or whether the spatial arrangement of features in the PFC already renders the likelihood of decoding any kind of information from its fMRI activity unlikely. For example, while maps representing space have been identified in the human PFC, they are much smaller than retinotopic maps in early visual areas, and intersubject variability in their location is much higher (Hagler & Sereno 2006). Furthermore, it is known from experiments in monkeys that only a subset of the neurons within the PFC subregions in which these maps have been found ac-

tually displays any spatial preference (Funahashi et al. 1989; Rainer et al. 1998). Importantly, the PFC also has a more complicated cytoarchitecture than sensory areas, with longer and more complex dendrites that allow for sampling of information from a wider range of inputs (Jacobs et al. 2001), which may affect the spatial scale at which information is represented and can be read out. Nevertheless, the overall picture that arises from studies employing optical imaging and microstimulation in monkeys is that at least several subregions of the PFC are topographically organized in a similar fashion as sensory areas (Roe 2010). However, while the topography of the PFC may be favorable to MVPA, neural representations in the PFC seem to exhibit more complex features and dynamics on a single neuron and population level than the representations in sensory areas where MVPA has been particularly successful. For example, recent studies in monkeys show that PFC representations are very high dimensional (Rigotti et al. 2013), that selectivity is not fixed but can be acquired (Bichot et al. 1996), that selectivity can change over time even within a trial (Stokes et al. 2013), and that populations of PFC neurons represent multiple stimulus dimensions at the same time even if one dimension is unattended (Mante et al. 2013). Thus, the dimensionality and temporal instability of neural representations in the PFC may pose a serious challenge to fMRI MVPA experiments, given that they rely on an inherently slow, hemodynamic signal that integrates neural activity over time.

Putting these and other (Anderson & Oates 2010; Vilarroya 2013) potential limitations of the MVPA approach aside, what other evidence do we have that the PFC is actually involved in conscious perception? In particular, is there *causal* evidence for a role of the PFC in conscious perception?

3 Beyond decoding: Causal evidence for a role of the PFC in conscious perception?

Early studies in macaque monkeys have found that lesions to the PFC can increase the lumin-

ance threshold (Latto & Cowey 1971) and degrade detection performance (Kamback 1973). More recently, studies in humans using transcranial magnetic stimulation have similarly found that stimulation of the PFC can impair the visibility of stimuli (Rounis et al. 2010), but also improve detection rates during visual masking (Grosbras & Paus 2003). Finally, Antoine Del Cul et al. have shown that perceptual thresholds are increased in patients with relatively small prefrontal lesions even when attentional effects are tightly controlled for (2009). However, none of these studies has shown dramatic impairments, but rather modulations of performance or perception. Total blindness has only been reported after removing the entire frontal cortex including (parts of) the underlying cingulate cortex in monkeys, and only lasted for a few days in several cases (Nakamura & Mishkin 1986). Importantly, other lesion studies in humans have not reported perceptual deficits at all (Heath et al. 1949; Markowitsch & Kessler 2000). Taken together with the fact that the PFC is also active during unconscious processing (Diaz & McCarthy 2007; Lau & Passingham 2007; van Gaal et al. 2008), not deactivated under Thiopental anesthesia (Veselis et al. 2004), but deactivated during rapid eye movement sleep when vivid (non-lucid) dreams can be experienced (Braun et al. 1998; Desseilles et al. 2011; Muzur 2002), this indicates that the evidence for a direct, specific involvement of the PFC in conscious perception is currently inconclusive at best.

4 An alternative to localization

Luckily, we can do without PFC, at least for the purposes of explaining conscious perception, while still maintaining many of the other, more compelling aspects of the GNW model. One central component that the GNW model shares with several other proposals about the neural correlates of consciousness (for example Melloni & Singer 2010; Tononi 2004; von der Malsburg 1997) is the concept of global integration of information. In light of the modular organization of the brain, a mechanism is required that brings information together such that an integrated, coherent percept

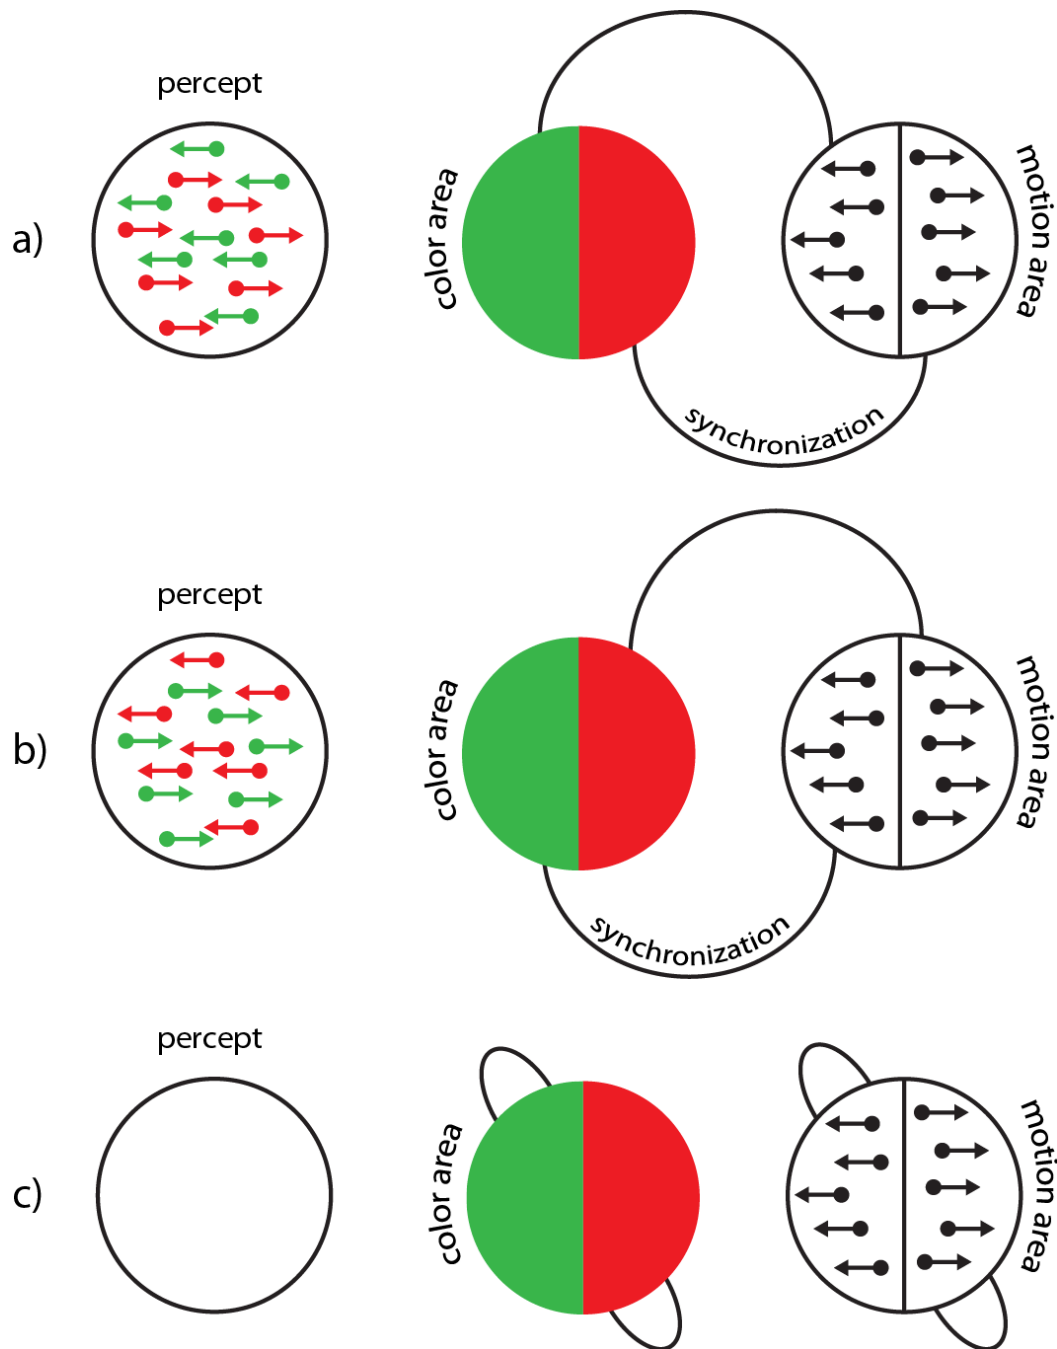

Figure 1: Neuronal synchrony binds distributed neurons into coherent assemblies, giving rise to conscious experience. Consider an experiment in which the subject is confronted with two superimposed, transparent surfaces of moving dots, as shown in the first column. **(a)** The dots on one surface are green and move to the left, and the dots on the other surface are red and move to the right. The two colors of dots are represented in a brain area coding for color, while the two motion directions are represented in an area coding for motion. If the neurons coding for green in the color area synchronize with the neurons coding for motion to the left in the motion area, and the neurons coding for red synchronize with the neurons coding for motion to the right, the two surfaces are consciously perceived. **(b)** A change in experience does not require a change in activity levels within areas, but a change of which neurons are synchronized. The opposite percept of (a) arises if neurons coding for green are synchronized with neurons coding for motion to the right, and if neurons coding for red are synchronized with neurons coding for motion to the left. Such content-specific synchronization between neurons has for example been observed in working-memory tasks in monkeys (Salazar et al. 2012). **(c)** Even when activity is synchronized within the color or motion area, respectively, a coherent conscious percept does not arise unless the areas are synchronized with each other.

can be formed. One attractive neural mechanism that can account for this requirement is neuronal synchrony (Bosman et al. 2012; Bressler et al. 1993; Salazar 2012). As has been discussed in greater detail elsewhere (Melloni & Singer 2010; Melloni this collection; Singer this collection), areas can be brought into *direct* contact with each other by synchronizing their neuronal activity, for example by phase alignment of neuronal oscillations, thus binding them into a functionally coherent assembly that forms a distributed representation of perceptual content. This self-organizing process can flexibly create and dissolve assemblies on top of a fixed anatomical architecture and does so without the need for anatomical convergence or broadcasting bottlenecks.

For example, imagine that a subject is confronted with two superimposed, transparent surfaces of moving dots (Figure 1). The dots on one surface are green and move to the left, and the dots on the other surface are red and move to the right. The two colors of dots are represented in a brain area coding for color, while the two motion directions are represented in an area coding for motion. For the subject to become conscious of the two surfaces, the neurons coding for green in the color area would need to synchronize their activity with the neurons coding for motion to the left in the motion area, and the neurons coding for red would need to synchronize with the neurons coding for motion to the right (Figure 1a). If the dots change direction, a new state of synchronization needs to be established, this time linking neurons coding for green with neurons coding for motion to the right, and neurons coding for red with neurons coding for motion to the left (Figure 1b). Hence, while the contents of the subject's experience are determined by the specific neuronal assemblies being active, conscious perception would be an emergent property of the state of synchronization. Recent tracing and modelling work in the macaque brain suggests that the kind of direct connectivity required to flexibly instantiate numerous, high-dimensional combinations of features is indeed afforded by high-density, reciprocal connections between brain areas (Markov et al. 2013).

Theoretical considerations and empirical evidence further suggest that the critical feature

differentiating conscious from unconscious processing is the spatial scale at which information is exchanged: while the integration of information in local modules, even in higher sensory areas (Sterzer et al. 2008), does not give rise to conscious experience by itself, large-scale integration over long distances does (Del Cul et al. 2007; Melloni et al. 2007). In the example of the transparent surfaces, this implies that even when activity is synchronized within the color or motion area, respectively, a coherent conscious percept cannot arise unless the areas are synchronized with each other (Figure 1c). Taken together, functional connectivity between distributed brain areas (i.e., connectivity that does not imply that one drives or controls the other) is an attractive alternative to localization in PFC as a candidate for the neural correlate of consciousness.

Coming back to the MVPA technique, this proposal makes a clear prediction that could be tested using decoding algorithms: specifically, one would predict that the large-scale connectivity patterns *between* brain regions for different percepts should differ, even if only slightly, for different conscious contents, and hence that conscious content should be decodable from them. This may well be the case in light of the fact that, at a much coarser scale, the neural correlates of auditory and visual awareness involve different brain networks (Eriksson et al. 2007), and that higher decoding accuracy for a subject's percept can be achieved if the joint activity patterns of several areas are considered instead of only singular patterns (Pessoa & Padmala 2007). The MVPA technique could in principle also be applied to other neuroimaging techniques that afford higher time resolution, such as electro- or magnetoencephalography or electrocorticography, thus potentially resolving the problem that arises because the representational carriers of perceptual content are highly dynamic and thus require a time-resolved analysis.

5 Conclusions

In summary, a complete theory for the neural correlates of consciousness should be able to account for the neural implementation of the contents of consciousness. John-Dylan Haynes has proposed a

clever experimental approach to localizing the contents of consciousness in the human brain, and has found that the PFC does not seem to be involved in this representation. Although surprising at first sight, this null result lines up well with the overall inconclusive evidence for a direct involvement of the PFC in conscious perception. However, it remains to be seen whether localization is the most fruitful approach to identifying the neural correlates of consciousness, or whether a more dynamic view that embraces the importance of communication between brain areas will bring us closer to solving the enigma of consciousness in the brain.

Can Synchronization Explain Representational Content?

A Reply to Caspar M. Schwiedrzik

John-Dylan Haynes

Multivariate decoding provides an important tool for studying the representation and transformation of mental contents in the human brain. Specifically, decoding can be used to identify the neural correlates of contents of consciousness (NCCs). Decoding of functional magnetic resonance imaging (fMRI) signals has so far mostly revealed content-selectivity in sensory brain regions, but not in prefrontal cortex. The limitations of fMRI-decoding only permit cautious conclusions because fMRI signals are only indirectly related to neural coding. However, the role of prefrontal cortex in visual awareness is also questioned by other findings, reviewed in [Schwiedrzik \(this collection\)](#). Neural synchronization might offer an alternative to solving the binding problem by providing a computational means of integrating information encoded in distributed brain regions. However, it is unclear whether synchronization in itself serves as a coding dimension for visual features. Furthermore, other alternatives to synchronization, especially the role of spatial codes, need to be considered as potential solutions to the feature binding problem.

1 Introduction

Information-based approaches to brain function have been very successful in recent years ([Pouget et al. 2000](#); [Haynes & Rees 2006](#); [Kriegeskorte et al. 2006](#)). Most importantly, they allow to study how mental contents are represented and transformed during information processing in the brain. My target article in this volume ([Haynes this collection](#)) emphasized the importance of an information-based approach for the study of human consciousness, especially for understanding the neural mechanisms of

visual awareness. Whereas many previous studies mainly aimed to establish which additional processing needs to occur for a stimulus to reach awareness, a second question is equally important: how and where the brain encodes the specific contents of consciousness. Research on these neural correlates of the contents of consciousness (NCCs; [Chalmers 2000](#); [Block 2007](#); [Koch 2004](#)) has been sparse. For identifying NCCs, simply establishing that a brain area responds stronger under conscious than un-

der unconscious processing is not sufficient, because this could merely reflect unspecific processes such as attention or memory (Corbetta & Shulman 2002; Goldman-Rakic 1995). Instead, for identifying the neural code of contents several specific questions need to be addressed: Which brain regions encode sensory information in a representational space that exactly matches perception? And under which circumstances does a crossing of the threshold to awareness involve changes of representations in these specialized coding spaces?

2 The role of prefrontal cortex

One example of the importance of considering content-based processing is the global workspace theory (Dehaene & Naccache 2001; Baars 2002). In specific readings of the theory, consciousness involves a distribution of sensory information from sensory cortices to parietal and prefrontal cortex (Haynes this collection). Increased activity in frontoparietal regions under conscious perception is seen as evidence for such a “broadcasting” of sensory information (Baars 2002). However, without additional support by information-based or representational analyses, increased activity in frontoparietal regions with increased awareness might simply reflect unspecific processes, say as in detecting or reporting a change in perception, rather than coding the sensory information itself. In several studies with functional magnetic resonance imaging (fMRI) we found no evidence for changes in prefrontal representation of sensory information under increased levels of awareness (reviewed in Haynes this collection). Thus, we found no evidence that sensory information is re-represented in prefrontal or parietal cortex.

At this important point, the comment by Schwiedrzik (this collection) adds further important details on the potential role of prefrontal cortex (PFC) in visual awareness (Crick & Koch 1995; Dehaene & Naccache 2001). In a first line of arguments Schwiedrzik provides more detail on a point briefly sketched in the original article (Haynes this collection), whether absence of decodable information in PFC might reflect limitations of fMRI-based pattern classi-

fication. fMRI decoding will only be able to access neural information that is encoded in specific formats and topologies (Chaimow et al. 2011). For example, if neurons with different tuning properties are randomly distributed within a voxel, then the voxel will not be able to pick up any information about these properties. Thus, a macroscopic clustering of cells with similar tuning properties is required for fMRI-decoding to pick up information. So information could be present in prefrontal cortex, but in a format that is not accessible to fMRI, not even with the increased sensitivity of multivariate analyses. This might explain the discrepancy between the absence of information in many fMRI studies and differential responsivity to stimulus features of cells in PFC in non-human primates (Pasternak & Greenlee 2005). Please note, however, that most of the evidence for sensory tuning in PFC is obtained under working memory paradigms, which also includes temporal two-alternative forced choice tasks (Romo et al. 1999). Thus, it is unclear whether this generalizes to “realtime” perceptual experience.

There are further challenges in accessing neural information. Schwiedrzik (this collection) brings forward an important point already raised previously (Duncan & Owen 2000): coding in prefrontal cortex might be dynamic and thus the code might change across time. Such dynamically changing coding spaces might again not be detectable in classification analyses that assume a constant population code across the period analysed (Stokes et al. 2013). These points raised by Schwiedrzik are fully valid: It is highly important to consider these limitations when interpreting the results of fMRI decoding studies. To some degree these challenges might be alleviated with future technical developments. For example, columnar-level information can be accessed following recent advances in high-resolution fMRI (Yacoub et al. 2008). However, many limitations of fMRI will remain due to its vascular origin that only samples neural information indirectly. Please note that the limitations go far beyond the points raised by Schwiedrzik (this collection). For example, fMRI might not only miss information, but it might

also tap into information that is not available at the level of single neurons. Say, if an fMRI voxel samples a homogenous group of cells with highly similar tuning properties, the voxel might reflect a degree of averaging that is not available at the level of single neurons.

Please note, that the target article was not restricted to decoding approaches in fMRI alone. Instead, the aim was to outline a more general approach to studying the neural correlates of the contents of consciousness. If suitable recording techniques were available the information could be assessed based on a whole family of potential representational signals, including especially axonal and dendritic population activity. Please further note, that any recording technique has its blind spots. For example single-cell electrophysiology is biased towards large cells (Bartels et al. 2008), or optical imaging with voltage sensitive dyes is restricted to the surface of the brain (Grinvald & Hildesheim 2004). Thus, only a combination of techniques will be able to provide a full picture of the changes in neural coding with varying levels of visual awareness. Importantly, in a second line of argumentation Schwiedrzik (this collection) provides additional support and plausibility to the finding that the absence of information in PFC is real. For example the effects of lesions in PFC on visual recognition can be strikingly weak, which would not be expected if representation or routing of information in PFC were a necessary condition for awareness.

A third line of argumentation brings neural integration between spatially separated brain regions into play as a different potential mechanism of visual awareness (Engel & Singer 2001). The basic idea is that representation might involve a dynamic binding involving a synchronization of neural activity. According to this model, as Schwiedrzik points out, a distribution of sensory information into prefrontal brain regions might not be necessary. Many studies have related changes in neural synchronization to changes in visual awareness (see e.g., Engel & Singer 2001; Uhlhaas et al. 2009). However, it is important to look more closely at the explanation that can be obtained by changes in synchronization, specifically if the aim is to

provide an explanation of the neural correlates of contents of consciousness (NCCCs). Typically, synchronization is not viewed as a coding dimension for contents, but as a code for binding and integration of features that are distributed across multiple content-specific regions (von der Malsburg 1999). The example provided in figure 1 of the comment by Schwiedrzik illustrates this nicely. A person views two superimposed clouds of moving dots, one green cloud moving left and a red cloud moving right. The features are encoded in content-specific fashion with two different activation patterns in the color area coding the two colors and two different activation patterns in the motion area coding the two motion directions. Synchronization between the neural representations of “green” and “left” on the one hand and “red” and “right” enables a separate binding of these two distributed features and also allows them to jointly be more effective in activating any downstream brain regions (König et al. 1996). Here, the contents are represented as differential activation states in the content-specific regions and their binding is achieved by synchronization. In this example representation and binding are separable problems based on separate computational mechanisms. However, Schwiedrzik (this collection) also goes one step further by suggesting that the large-scale connectivity patterns between brain regions might themselves code for different conscious contents. It has already been shown with fMRI that connectivity patterns between remote brain regions reflect changes in visual awareness (e.g., Haynes et al. 2005; Imamoglu et al. 2012). It has also been shown that connectivity matrices obtained with fMRI can be used to classify cognitive states (Richiardi et al. 2011; Heinzle et al. 2012). However, to date I am not aware of any evidence that fine-grained perceptual contents are encoded in differential patterns of brain connectivity. Furthermore, synchronization sometimes fails to explain perception (Thiele & Stoner 2003) and there other solutions to the binding problem besides synchronization. For example, high-level content-selective brain regions that achieve a certain degree of tolerance to variations in spatial location, still have con-

siderable information about the spatial location of features (e.g., [Cichy et al. 2011](#)). Thus, the spatial maps and their associated differential anatomical (as opposed to functional) connectivity patterns provide a plausible alternative hypothesis to synchronization ([Treisman & Gelade 1980](#)).

3 Conclusions

Prefrontal cortex is often considered vital for visual awareness ([Crick & Koch 1995](#); [Dehaene & Naccache 2001](#)), however multivariate decoding studies have revealed a marked absence of sensory information in prefrontal cortex ([Haynes this collection](#)). Neural synchronization ([Schwiedrzik this collection](#)) might provide an alternative account for feature binding and selective routing of information. However, it is currently unclear whether any form of functional connectivity can itself code specific sensory contents.

Beyond Illusions

On the Limitations of Perceiving Relational Properties

Heiko Hecht

Explaining the perception of our visual world is a hard problem because the visual system has to fill the gap between the information available to the eye and the much richer visual world that is derived from the former. Perceptual illusions continue to fascinate many researchers because they seem to promise a glimpse of how the visual system fills this gap. Illusions are often interpreted as evidence of the error-prone nature of the process. Here I will show that the opposite is true. To do so, I introduce a novel stance on what constitutes an illusion, arguing that the traditional view (illusion as mere discrepancy between stimulus and percept) has to be replaced by illusion as a manifest noticed discrepancy. The two views, unfortunately, are not necessarily related. On the contrary; we experience the most spectacular illusions where our perception is pretty much on target. Once our interpretation of the sensory data is off the mark, we usually no longer experience illusions but live happily without ever noticing the enormous perceptual and conceptual errors we make. The farther we move away from simple pictorial stimuli as the subject of our investigations, the more commonplace a discrepancy between percept and reality does become—and the less likely we are willing to call it illusory. Two case studies of our perception of relational properties will serve to illustrate this idea. The case studies are based on the conviction that perceiving is more than mere sensation, and that some degree of (unconscious) judgment is a necessary ingredient of perception. We understand little about how to balance objects and we make fundamental mistakes when perceiving the slipperiness of surfaces. All the while, we never experience illusions in this context. Thus, when dealing with simple percepts, illusions may be revealing. But when it comes to percepts that involve relational properties, illusions fail to arise, as perception is not concerned with veridicality but appears to be satisfied with the first solution that does not interfere with our daily activities.

1 Illusion?

1.1 The underspecification problem (UP)

Visual perception can be seen as the process by which the visual system interprets the sensory core data that come in through the retinæ of the eyes (see e.g., [Hatfield & Epstein 1979](#)). The sensory core is not sufficient to specify the percept; that is, there is an explanatory gap between the information present at the retina—which is in essence two-dimensional (2D)—and the information present in the three-dimensional (3D) objects that we see. Let us call the prob-

lem that arises in having to fill this gap the “underspecification problem” (see [Hecht 2000](#)). Figure 1 illustrates the UP (underspecification problem). A given object can only project one particular image onto the projection surface (retina); however, a given projection could have been caused by an indefinite number of objects in the world. Because of this anisotropy in the mapping between the 3D object and its 2D projection, information is lost during the projective process, which cannot be regained with certainty. One could argue that the history of per-

ception theories is more or less the history of finding solutions to reconstruct the 3D object that has caused a given projection.

Figure 1: Underspecification: The 3D origin of a given image on the retina (here approximated by the vertical projection screen) is provided by an indefinite number of objects at various orientations in space. Illustration from [Gibson \(1979\)](#).

In order to assess the quality of the solution offered by a given perceptual theory, we have to evaluate how it describes the gap between sensory core and percept and the mechanism by which it suggests that the gap is being bridged. The Gibsonian theory of direct perception aside—which denies the problem altogether (e.g., [Gibson 1979](#))—we have a variety of theories to choose from. They are all constructionist in the sense that the sensory data have to be interpreted and arranged into the configuration that is most likely or most logical. The theories differ in the mechanisms they make responsible for the reconstructive process. For instance, [Hermann von Helmholtz \(1894\)](#) supposes inferences of unconscious nature that arrive inductively or maybe abductively at a preferred solution. [Roger Shepard \(1994\)](#), on the other hand supposes a recurrence to phylogenetically-acquired knowledge. He takes the regularities of the physical world or of geometry to have been internalized through the course of evolution and to be used to disambiguate competing solutions. An example of such internalized knowledge is the fact that light usually comes from above (see [Figure 2](#)). A shading gradient from light (at the top of an object) to dark (at its bottom) would thus be compatible with a convex but not with a concave object.

Figure 2: Solution of the underspecification by drawing on internalized knowledge that light comes from above. The sphere in the right panel looks convex because it is lighter at the top, whereas the same image rotated by 180° (left panel) looks concave. Have we created an illusion by juxtaposing them?

Others have proposed that the system considers statistical probabilities by defaulting to contextually appropriate, high-frequency responses ([Reason 1992](#)) or by applying the Bayes-theorem (e.g., [Knill & Richards 1996](#); [Kersten et al. 2004](#)), or predictive processing ([Clark this collection](#); [Hohwy this collection](#)). Here we are not concerned with the exact nature of how the construction is accomplished. Note, however, that all the solutions that have been proposed abound with cognitive ingredients. The process of constructing a 3D object from the 2D retinal input is usually thought to draw on memory and on some sort of inferencing, albeit unconsciously. The next step to arriving at meaningful percepts on the basis of the 3D object—which is just as essential in perception—involves even more cognitive elements, be they unconscious or amenable to consciousness.

Here I would like to include a brief aside, which may seem obvious to the psychologist but not so obvious to the philosopher. Perceiving cannot be dissected successfully into a sensational part and a judgmental part when we are dealing with the everyday perception of meaningful objects. Perceiving is always judgmental when we see a stick or a bird, or when it comes to seeing that we can pick up the stick and that it falls down when we release it. In other words, pure sensations may be possible introspectively—sensing red, sensing heat etc.—but they are

no longer possible in everyday object perception, that is a separation of sensation and judgment is not ecologically valid. Take, for instance, the falling object as given in phenomenal perception. In the sub-field of experimental psychology called “intuitive physics”, investigators have doctored physical events to contradict Newtonian physics and presented visual animations to novice or expert observers. Many of the latter do not see anything wrong with objects falling straight down when released, as opposed to following the proper parabola that they should (see section 1.3.1 on so-called cognitive illusions). This perception is reflected in motor action—people release the object in the wrong place when trying to hit a container; this perception arises in toddlers unable to reflect upon the event, and it persists after formal physics training in cases where observers have to make quick decisions. Thus, a separation into a sensation and perceptual judgment is not meaningful here. Perception of (everyday) objects and events necessarily includes a judgmental aspect, which may or may not enter consciousness.

Now, we are concerned with the question of whether the errors that arise during the perceptual process can be used to gauge where the visual system fails to capture the 3D world. We will argue that this is not the case. Research focusing on so-called optical illusions is particularly ill-suited to gain insight into how the visual system solves the UP. Illusions typically arise when errors are rather small, thus the presence or magnitude of an illusion is no predictor of the size of the UP. By and large, perceptual error is rather small when it comes to simple object properties, such as size, distance, direction of motion, etc. Errors become much larger, more interesting, and potentially dangerous when it comes to relational properties, such as seeing if an object can be lifted or if I will slip and fall when treading on a given surface. The case studies below will show that in the context of relational properties we make errors but we do not experience illusions.

1.2 The Luther illusion

Please take a close look at this painting of Martin Luther. You have certainly seen pictures of

the great protestant reformer before. Does anything about this painting strike you as strange?

Figure 3: Martin Luther as painted by Lukas Cranach the Elder (1529), Hessisches Landesmuseum Darmstadt.

You may have found that he looks well nourished, as is appropriate for a monk whose enjoyment of worldly pleasures is well documented. However, I am sure you did not notice the illusion. Well, I have photoshopped the photograph and made it 15% wider than it should be. There is a discrepancy between the painting (or veridical photograph thereof) and the picture presented in Figure 3. Such discrepancies are typically considered to be the essence of illusion. For instance, [Martinez-Conde & Macknik \(2010, p. 4\)](#) define an illusion as “the dissociation between the physical reality and the subjective perception of an object or event”. The physical reality of the picture is distorted by 15%, but your perception was that of a correct rendition of a famous painting. Now let us add another twist to the Luther illusion (Figure 4).

Figure 4: Martin Luther right side up and upside down.

Have I taken the original photograph or have I turned around the 15% wider version? Surely, Luther looks to be slimmer in the panel on the right. If you turn the page upside down, you will see that both panels show the same picture that is 15% wider than the original. Let us assume that the inversion effect—also named fat-face-thin-illusion by Peter Thompson (Thompson & Wilson 2012)—is exactly 15 % in magnitude. Has the illusion that I introduced initially been nullified by the inversion?

The fictitious Luther illusion is meant to make the point that the mere discrepancy between physical reality and a percept should not be conceived of as illusory. It may not even be reasonable to conceive of it as an error. The stretched image may be a better representation of what we know about Luther than the “correct” picture. For instance, the picture may typically be viewed from an inappropriate vantage point that could make the stretched version more veridical even when compared to the actual Luther, were he teleported into our time. Take Figure 5. I have stretched Luther by another 50%. Now he seems a bit distorted, but not to an extent that would prevent us from recognizing him or from enjoying the picture. There is a fundamental property that needs to be added for something to be considered an illusion. I contend that this is a dual simultaneous percept that tells us that what we see is so and not so at the same time (for a detailed defence of this position see Hecht 2013). For an illusion¹

to be called thus, it has to be manifest immediately and perceptually. Calling something an illusion is only meaningful if it refers to a discrepancy that we can see. It is not meaningful if it refers to some error that we have to infer.

Figure 5: Martin Luther stretched by another 50%.

Take for instance the often-cited stick in the water that looks bent. The static image presented in Figure 6 is not an illusion. We see a bent stick; note that its shadow is bent as well, and without recourse to our experience of refraction that occurs where two media adjoin, we would not know if the stick were actually bent or if some effect of optics had created the percept. However, the moment we move the stick up and down we see the illusion_m. We see the stick being bent and being straight at the same time. The illusion becomes manifest. That is, the discrepancy if not contradiction between the two percepts (here the straight and the bent stick) is available in our working memory, we become aware of it, often without being able to resolve which of the two discrepant percepts is closer to reality. In the case of the stick, the location of the bending at water level reveals that

fest illusion that is perceived rather than inferred with the help of physics text books). I will only refer to illusion_m as illusion, whereas I will refer to illusion_d as mere error or discrepancy. See also the related distinction between phenomenally opaque and phenomenally transparent illusions (e.g., Metzinger 2003a, 2003b). My distinction between illusion_d and illusion_m is meant to be merely perceptual.

¹ Note that I will differentiate between illusion_d (being the old notion of discrepancy between object and percept) and illusion_m (the mani-

the stick is really straight; however, in most cases the illusion_m remains unresolved, as for example in the case of the Ebbinghaus illusion.

Figure 6: Is the stick bent?

1.3 Thesis: Illusions_m are not evidence of error but rather unmasking of error

It would make no sense to call the circles in Figure 7 an illusion_m, even if a researcher could show with a large dataset that the inner circle is reproduced 2% bigger than it was on the picture. However, as soon as we allow for a direct comparison and put a ruler to the center circles in Figure 8, the illusion_m arises (see Wundt 1898; an interactive demonstration of the Ebbinghaus illusion can be found at <http://michaelbach.de/ot/cog-Ebbinghaus/index-de.html>).

Illusions_m are perceptually immediate but they appear to require some form of comparison and judgment, which supports the argument that phenomenal perception cannot be divided into a merely sensational core and a cognitive elaboration. For instance, in the case of a Necker cube or a bi-stable apparent motion quartet, the illusion_m can become manifest by a mere deliberate shift of attention.

Given the severity of the UP, we should not be fascinated by the existence of error (illusions_d), but should instead be fascinated by the fact that our perceptions are pretty much on target most of the time. It is truly amazing that among the enormous range of possible interpretations of the retinal image, we usually pick the appropriate

one. Illusions_m are rare special cases of ubiquitous small errors that become manifest because of some coincidence or another. Note that this assessment does not only apply to visual perception but also to other sensory modalities in which sensory information has to be interpreted and integrated. For instance, the cutaneous rabbit illusion_m arises when adjacent locations on the skin of our arm are stimulated in sequence. We experience one coherent motion (a rabbit moving along our arm) rather than a sequence of unrelated taps. This “inference” can be explained by probabilistic reasoning (Goldreich 2007) and may be considered the tactile analogue of apparent motion: just as we cannot perceptually distinguish a sequence of static stimuli from real motion in the movie theater. As a matter of fact, the pauses between the intermittent frames of the movie are indispensable for motion pictures to look smooth and continuous.

Figure 7: Is the circle in the middle perceived to be bigger than it really is? Possibly an illusion_d.

Gestalt psychologists have described the constructive process by which meaningful objects emerge from the various elements in our sensory core (see e.g., Max Wertheimer 1912 for the case of apparent motion). For good reason, they have avoided the term illusion, and introduced the term emergent property for the phenomenal result of the (unconscious) process of perceptual organization. It would violate our everyday experience to call something we see an illusion just because we know a little

bit about the underlying physics. Just because we know that our continuous motion percept is derived from a sequence of discrete images, this does not make the percept an illusion (neither illusion_m nor illusion_d).² By the same token, knowing that light is a wave (or a stream of photons) does not make objects in the world illusory. In fact, a discrepancy between what is really there and what we perceive is the norm, not the exception. Given my conceptual distinction, I will show how the perceptual system deals with the ubiquitous discrepancy, with the normal case of illusion_d . The relatively rare cases illusions_m arise as a by-product of this process. For something to deserve the name illusion, this discrepancy has to become manifest. The Ebbinghaus illusion only turns into an illusion_m when we perceive a conflict, when the inner circles are seen (or inferred) to be equal in size and they look different in size at the same time. Thus, it is not the ubiquitous presence of error that makes an illusion_m but the rather unusual case where this error is unmasked by a perceptual comparison process.

Figure 8: Is the circle surrounded by smaller circles perceived to be bigger than it really is, or is the center circle on the right perceived to be too small? This is the famous Titchener illusion_m that was invented by Hermann Ebbinghaus and first reported by Wilhelm Wundt (1898).

² Note, that a discrepancy between stimulus and percept is necessary but not sufficient for an illusion_m . Thus, all illusions require an illusion_d but will only become illusions_m in some cases. My distinction is capable of sorting out illusions as relevant to perceptual psychology, it does, however, not speak to the question of how we can describe the physical stimulus in the first place, i.e., the grand illusion argument (see <http://www.imprint.co.uk/books/noe.html>).

1.3.1 A note on so-called cognitive illusions_d

In our everyday perception, once we consider that objects are often in motion and carry meaning at the perceptual level (see Gibson's concept of affordance, e.g., 1979) the UP is exacerbated but not changed. I argue that the nature of perceptual error is akin to cognitive error when it comes to the more complex and meaning-laden percepts of everyday perception, as opposed to line drawings that are typically referred to in the context of illusions_m . Just as with perceptual errors, cognitive errors often do not become manifest. However, if they do become manifest, they can typically be corrected with much greater ease than can perceptual illusions_m , which may well be the distinguishing feature between perceptual and cognitive error. Cognitive errors become noticeable more indirectly by recurring to a short-term memory of a dissenting fact or by reasoning—which is often faulty by itself. The literature about cognitive error is enormous. To give one classical example, we have trouble with simple syllogistic reasoning, in particular if negations are used. Wason's famous selection task (Wason & Johnson-Laird 1972) shows how limited our abilities are (Figure 9). Imagine you have four envelopes in front of you. You are to test the statement “if there is sender information on the back side then there is a stamp on the front”. Which of the 4 envelopes do you have to turn over? Do not turn over any envelope unnecessarily.

Figure 9: Which envelopes do you have to turn to test the statement “If there is sender information on the back side then there is a stamp on the front”?

Well—it is easy to see that envelope 1 has to be turned (modus ponens), but then it gets harder. Many observers think that envelope 2 needs to be turned. However, this is not the case. Only 4 has to be turned in addition to 1.

A sender on its back would violate the rule (modus tollens). The majority of college students fail to solve this problem, but as soon as the context is changed, all mistakes can be eliminated. In the context of screening for drinking underage, all observers perform accurately (see Figure 10). Here again 1 and 4 need to be “turned over”. Only by thinking the problem through or by noticing that the problem structure is identical to the envelope scenario and the wine drinking scenario does the error become manifest. We may or may not want to call it a cognitive illusion. This term is not widely used for such mistakes or fallacies, with the exception of Gerd Gigerenzer and his research group (see e.g., Hertwig & Ortmann 2005). However, even if we call these mistakes cognitive illusions, they are different in nature from perceptual illusions_m (which typically contain a judgmental aspect). We do not readily notice cognitive illusions. Although the distinction between perception and cognition has outlived itself (and cannot be made with clarity to begin with, see above), for practical convenience, I will continue to use the terms to emphasize cases where deliberate thought processes enter the equation. We happily live with many a fallacy without ever noticing. Millions went through their lives believing in impetus theory and seeing the sun circle around the earth, let alone holding seemingly absurd beliefs about the shape of our planet.

Figure 10: Whom do you have to query about age or beverage type to test if “Only adults have alcoholic beverages in their glass”? It is obvious that the juice drinker and the elderly person need not be queried.

Errors only turn into illusions_m when we become aware of them and at the same time cannot correct the error (easily). Just try to see the earth rotate rather than see the sun rise. It is impossible. We continue to see the sun rise

above a stable horizon, never the other way around. And we continue to misjudge implication rules or widen the grasp of our fingers a tad more when reaching for an Ebbinghaus stimulus even if we know about the illusion (see Franz et al. 2000). Other errors can only be spotted when large data samples are collected and analyzed statistically. For instance, to expert golfers, the putting hole on the green looks larger than it does to novices (Witt et al. 2008; Proffitt & Linkenauger 2013). They will never become aware of this fact, although the fine-grained scaling of perception as function of skill might be functional during skill acquisition. Spectacular as they may be, such errors of which we are unaware should not be called illusions_m because almost all our perceptions and cognitions contain some degree of error. We may believe that a rolling ball comes to a stop because it has used up its impetus, or we may hold that we should aim where we want a moving ball to go rather than using the appropriate vector addition to determine where to aim. As long as our action results do not force us to reconsider, our convictions will remain unchanged. One could say that we have a model of the world, or its workings, that suffices for our purposes.

Figure 11: Technical illustration explaining the trajectory of a cannon projectile by Daniel Santbech (1561): *Problematum Astronomicorum*, Basel.

Why are so many researchers willing to call a small manifest discrepancy between two percepts of the same object an illusion, while gross deviations of perception or conception from physical reality are not deemed to deserve the same name? Take the straight-down belief (not illusion). Many observers take an object that is being released from a moving carrier to fall straight down rather than in a parabola (McCloskey et al. 1983). Figure 11 illustrates this belief as it was state-of-the-art physics knowledge from Aristotle through the Middle Ages. It persists today in cognition and perception. Even when impossible events of straight down trajectories are shown in animated movies, to some observers they look better than do the correct parabolas (Kaiser et al. 1992).

Note that there was a discussion at the time whether or not the transition from the upward impetus to the downward impetus was immediate or if a third circular impetus inserted itself, such that there were be two trajectory changes. The intermediary could only be thought of as linear or as a circular arc—anything else would have been too far from divine perfection. Presumably, the more principled physicists before Galileo favored the simple transition. Others, such as Aristotle himself, presumably preferred the interstition of the circular arc, as it would reconcile trajectory observation with the physics of the time. The pre-Newtonian thinking about projectile motion nicely illustrates that we see the world as in accord with our actions. To the medieval cannoneer, what he saw and understood about projectiles was sufficiently accurate, given the variance introduced by the inconsistent quality of the gunpowder and the fluctuation in the weight of cannon balls at the time.

Thus, we have argued that visual illusions_m, just as cognitive illusions_m, have to become manifest to be called such. They are a special and rare case in which the discrepancy between a percept and what an ideal observer should have seen instead is noticed. Normally this discrepancy goes unnoticed. We will now take a look at why it goes unnoticed and argue that an illusion_d will only alter perception if it interferes seriously with our action requirements. As the latter vary among

people, illusions_d can be private and may be very far from the truth—as, for instance, in the context of projectile motion (see Hecht & Bertamini 2000). The private aspect of perception is to be taken as unconscious in the sense of Helmholtz. For instance, we do not only think that a baseball thrown toward a catcher will accelerate after it has left the thrower's hand (which may even be incompatible with impetus theory), but doctored visual scenes in which the ball does accelerate are judged as perfectly natural looking. This amounts to the perceptual analogue of what Herbert Simon (1990) has called satisficing in the domain of reasoning and intuitive judgment. The visual system searches until it has found a solution that is satisfactory, regardless of how far away it is from a veridical representation of the world.

To conclude this section, we believe that perception of objects, be it the stick in the water or a falling brick, is a solution to the underspecification problem. Perception is always fraught with error in the sense of a discrepancy between the percept and the underlying physics. This error only becomes manifest when a simple perceptual judgment or comparison reveals a contradiction. In all other cases the error goes unnoticed. Two such cases will now be described at length to make the point that perceptual illusion_d is the rule rather than the exception.

2 Two case studies or how we deal with error

The study of geometric illusions or overestimation of slope, distance, and size as a function of situatedness misleads us into believing that perception normally reveals the true state of affairs. The finding that golf holes look slightly bigger to experts as compared to inexperienced golfers is spectacular because and only if we assume that perception is normally veridical. This is, however, not the case. Normally, our grasp of the physical world is rather limited. I present novel data from two everyday domains that differ from the standard examples of intuitive physics in a crucial way. They deal with the understanding (first case study) and the perception (second case study) of relational properties, rather than with more straight-forward perception of simple properties.

Seeing the color of an object or its size, predicting its motion trajectory, etc., refer to simple properties. Most everyday activities, however, involve relational properties. We need to see and predict how we might interact with objects in the world. This interaction depends on our own makeup, on the object's properties, and on the relation between the two. For instance, to judge whether a slope might be too slippery for us to walk on depends on the quality of the soles of my shoes, the surface texture of the slope, and also on their interaction. A polished hardwood ramp may be slippery if I am wearing shoes with leather soles, but it may be very sticky if I am barefoot.

Figure 12: Task 1: The rod on the left is light, it is made of wood; the rod on the right is heavier because it is made of iron. If they begin to tip over at the same moment in time, which one will fall faster?

The two case studies that follow are intended to illustrate in detail how limited our understanding of relational properties is in general, and to show that we have to make decisions in the face of poor perception that may have serious consequences.

2.1 Case study: Balancing as a relational property

Before you read on, please take a minute to solve six questions about the depicted falling rods. Solutions will be provided later. Note that in tasks 1

through 3 (see Figure 12, 13, 14), the scenario is as follows. Two rods are held upright, but they are very slightly tipped to one side (by exactly equal amounts), such that they will fall once released. They are released at exactly the same moment. Which one will hit the ground sooner? In tasks 4–6, you are to judge the ease of balancing such a rod on the tip of your index finger.

Figure 13: In Task 2 the rods are equally heavy but have different lengths. The left rod is made of wood; the rod on the right is shorter but has the same weight as it is made of steel. Which one will fall faster?

Task 4 asks about the same rods as in Task 1, but the question is whether the wooden or the steel rod would be easier to balance on the tip of your index finger.

Task 5 asks whether the short steel rod or the longer wooden rod of equal weight would be easier to balance on the index finger. And finally, Task 6 asks whether a weight attached to a given rod would make it easier to balance, and if so, where it best be attached (top, center, bottom). In a large survey, we tested the intuitive knowledge of a large number of college students about these tasks. Note that we tested such that each subject only had to solve one of the six tasks.

2.1.1 Methods detail

180 college students (123 women, 57 men, age $M = 24.9$ $SD = 5.9$, ranging from 18 to 53

years) volunteered to participate in the survey. We used a paper-and-pencil test to investigate the subjects' knowledge and to obtain their estimates about which objects would be easier to balance. The six tasks were explained carefully and illustrated with drawings similar to those shown in Figure 12, 13 and 14.

Figure 14: In Task 3, the two rods are identical in material, length, and weight. An additional weight is attached either at the bottom or at the top. Which rod will fall faster?

Each task was presented to 30 students. Tasks 1–3 were used to test intuitive knowledge without referring or alluding to the act of balancing. Merely the process of falling from an almost upright position to a horizontal position had to be judged. In the first task (Figure 12), subjects saw two rods of equal length (1m) but of different material and weight. The wooden rod was said to weigh 40g, the steel rod 400g. The accompanying information text indicated that both rods were slightly tipped over at the exact same time, for instance by a minimal breeze. The wooden rod was to take exactly 1.5 seconds to fall from its upright position to the horizontal. We had tested the falling speed of such rods and measured it to be approximately 1.5s. The subjects were asked to estimate the fall-duration of the steel rod. The second (Figure 13) task showed two rods of equal mass (40g) but different length (rod 1 = 100cm, rod

2 = 36cm). The information text was the same as in Task 1. The third task (Figure 14) showed two rods of equal length (1m) and weight (220g). However, an additional small object (220g) was placed respectively toward the top or the bottom of the rod (rod 1 = 10cm from the bottom, rod 2 = 90cm from the bottom). The accompanying information text indicated that both rods would be tipped over by a minimal breeze and that it took rod 1 exactly 1.5 seconds to fall to a horizontal position. Subjects were to estimate the fall-duration of rod 2.

Tasks 4–6 used the same rods but the questions about them were couched in the context of balancing. This should evoke experiences that subjects may have made when balancing or hefting objects. Thus, rather than asking which rod would fall quicker, we asked which would be easier to balance.

The fourth task showed the same two rods of equal length (1m) but different weights (wooden rod = 40g, heavy steel rod = 400g) that had been used for Task 1 (Figure 12). The subjects were asked to indicate which rod they thought they could better balance on the tip of one finger, typically the index finger. The possible answers ranged from 1 (“rod 1 much better than rod 2”) to 7 (“rod 2 much better than rod 1”). The fifth task (Figure 13) showed two rods of equal weight (40g) but different length (rod 1 = 100cm, rod 2 = 36cm). Again, the subjects were asked to indicate which rod they could better balance with one finger. Task 6 showed one rod (length = 1m, weight = 220g). Subjects had to indicate the position that they would place an additional small object (mass = 220g) to get optimal balancing characteristics (from 10cm = bottom to 100cm = top). It was made clear that the weight would not come into contact with the balancing hand even when it was placed at the bottom.

2.1.2 Results

People who cannot draw on formal physics training to answer the six tasks have a rather poor intuitive understanding of falling rods. Neglecting air resistance, the rate of falling is determined by how high the center of gravity

(barycenter) is above the ground. The rod's mass is irrelevant. Thus, rods of equal length (mass distribution is assumed to be uniform) fall at the same rate, but the shorter rod falls quicker than its longer counterpart. By the same token, a weight attached to the tip of the rod should cause it to fall more slowly because it moves the barycenter closer to the tip.

In general, the subjects estimated their knowledge in the natural sciences to be moderate when asked to judge it on a six-point scale ranging from very poor (1) to very good (6). Mathematics knowledge ($M = 3.62$, $SD = 1.13$) was judged better ($t(179) = 11.98$, $p < .001$) than physics knowledge ($M = 2.56$, $SD = 1.26$). The men estimated their knowledge somewhat higher than did the women, for physics ($t(178) = 8.8$, $p < .001$) and mathematics ($t(178) = 2.34$, $p < .05$).

Task 1: In reality, both rods fall with the same speed, as Galileo Galilei showed in 1590 with the help of several experiments about free fall (e.g., [Hermann 1981](#)). The falling speed is independent of their mass as long as air resistance is negligible. Thus, 1.5 seconds was the right answer. 40% of the test subjects answered correctly. 43.3% estimated that the heavier rod would fall faster, while 16.7% estimated that it would fall more slowly.

Task 2: Because of the lower barycenter the shorter rod falls faster and its fall-duration is briefer than 1.5 seconds. 46.7% of the test subjects indicated this. 44.3% thought that the fall-duration would be the same and 10% estimated that the shorter rod would fall more slowly.

Task 3: Because of the higher barycenter, the second rod falls more slowly. Therefore, its fall-duration is longer than 1.5 seconds. Only 20% of the subjects chose the right answer. 50% estimated that the rod with the higher barycenter would fall faster and 30% estimated that it would fall at the same rate.

There is a direct link between the fall-duration of an object and the ability to balance this object. The longer the fall-duration, the more time there should be to move the balancing finger right underneath the barycenter, and hence the easier to balance (a moderate weight

assumed). We confirmed this hypothesis empirically in several experiments where subjects actually had to balance different rods to which weights were attached at different heights. Thus, we can predict the ability to balance different objects by comparing their fall-duration.

Task 4: Here, the rods (same length, different weight) had the same fall-duration—so the ability to balance them can be assumed to be the same, too. This was recognized by only 3.3% of the test subjects, while 73% favored the heavier rod, and 23.3% the lighter one.

Task 5 (two rods, same weight, different length): Because of the longer fall-duration the longer rod is easier to balance. This was assumed by 56.7% of the subjects. 20% estimated both rods to be equal and 23.3% thought the shorter one would be easier to balance.

Task 6 (additional weight): The higher the barycenter the longer the fall-duration—and with it the ease of balancing. Therefore, the additional object should be placed at the top of the rod. This was indicated by 33.3% of the test subjects. The majority of 43.3% chose the bottom for placing the object, and 23.3% chose positions between bottom and top.

In sum, the intuitive knowledge about the fall of different objects is rather spotty. About half of the subjects knew that fall-duration is independent of mass (Task 1) and that shorter objects fall faster (Task 2), only 20% realized that the position of the barycenter is relevant and that the fall-duration increases when the barycenter is shifted to the upper end of the rod (Task 3). This is remarkable because on a daily basis we handle objects whose barycenter differs from the geometrical center, for instance a filled vs. an empty soup ladle, top-heavy tennis rackets, etc.

Asking directly about the act of balancing did not reveal superior understanding. When asked about their ability to balance objects, people do know that longer objects are easier to balance than shorter ones, but they do not seem to realize that the mass of the object is irrelevant (Tasks 4 and 5). In other words, although a majority of our subjects was able to recognize that mass is irrelevant for fall duration, they failed to see the irrelevance of mass in the rela-

tional balancing task. The involvement of the own motor action appears to have made the judgment task more difficult. The important role of the position of the barycenter (i.e., mass distribution, Task 6) went equally unnoticed in the falling and the balancing tasks. In general, knowledge about balancing properties and the underlying physical principles can be described as rather moderate. Do experts have a superior understanding of these principles?

2.2 Extending the case study: Comparing physics experts with non-experts

As all subjects had judged their physics knowledge to be rather limited, we chose to test a group with formal physics training on the balancing questions. We also tested a social science control group and added two new tasks. Tasks 1–3 were dropped from the study, while Tasks 4–6 were included. To test for a specific heuristic, namely that heavy objects are harder to balance, the following two tasks were added:

Figure 15: In Task 8, the four rods labeled A–D should be sorted according to the difficulty of balancing them. The correct order is C–B–D–A or C–D–B–A.

Task 7: The question “Does a weight help and if so, where would you place it?” was posed with respect to the much lighter wooden rod ($m = 40\text{g}$). Thus, Task 6 was replicated with a lighter rod. Finally, a more fine-graded question

was added to assess by how much expert knowledge would be superior to normal knowledge, if at all:

Task 8: The eighth task showed four rods of the same material (steel, length 90cm). On three of them, a weight was attached at different positions (as shown in Figure 15). The subjects had to order them according to which would be easiest to balance on the tip of one finger. Note that the height of the barycenter matters. It is equally located in the center of rods B and D.

2.2.1 Methods detail

Participants: 84 college students, mainly of Psychology (69 women, 15 men, age ranging from 19 to 66 years) and 113 college students of Physics, Mathematics, and Chemistry (41 women, 72 men, age ranging from 18 to 27 years) were tested. The students of mathematics, physics, and chemistry estimated their knowledge in mathematics ($M = 2.65$, $SD = 1.02$) and physics ($M = 2.68$, $SD = 1.07$) to be moderate. The men estimated their knowledge of physics to be higher than did the women ($t(111) = -4.34$, $p < .001$). No difference was found for self-assessed maths skills ($t(111) = -.22$, $p = .83$).

A paper-and-pencil test was used to investigate the assumptions subjects held about the effect of various object properties on how easily the respective rods could be balanced. The test booklet included eight tasks: one per page. Each task consisted of a hypothetical scenario illustrated by a drawing. Different pseudo-random orders of the eight tasks were executed by all students. Tasks that built upon one another were kept in their logical order. Once a given task was finished, the page had to be turned. It was not permitted to go back to a previous page. Depending on the task, subjects had to make a binary choice (pick one or answer yes or no) or they had to grade their answers on a seven-point scale, according to how sure they were that one alternative would win over the other (certain win, very likely, somewhat likely, equal chance, somewhat unlikely, very unlikely, certain loss).

2.2.2 Results and discussion

Task 4 (equal length, different weight of the rods): Only 3.6 % of all social science students produced the correct solution and stated that the wooden and the steel rod would be equally hard to balance. Half of them thought that the steel rod would be easier to balance, and the remaining subjects chose the wooden rod. This corresponds well to the results obtained with the first large student sample. The physics students, in contrast, performed better albeit nowhere near perfection. 22% of them chose the correct answer. 21% thought the wooden rod would be easier to balance, and 57% thought the steel rod would be easier to balance. Thus, social scientists equally chose one or the other whereas physicists preferred the metal rod, and at most one fifth of them knew the correct answer (provided they were not just guessing better than the social science students).

Task 5 (equal weight, different length): Half of the social science students (53%) correctly thought that the longer rod would be easier to balance, and less than 2% thought that length did not matter. The physics students did noticeably better: 76% chose the longer rod, and only 20% thought the shorter rod would be easier to balance. 4% thought it would be the same with both rods.

In **Task 6** (attach weight to steel rod): 60.7% of the social scientists thought that a weight would make it easier. When asked to place the weight, only 9.5% put it in the top third (for analysis purposes the rod was divided in three equal parts), and 44% placed it at the bottom third. Physics students fared a little better. A mere 44 % thought that a weight would improve balancing, but those who did correctly placed the weight at the top (40% of all physics students).

Task 7 (attach weight to light wooden rod): Not surprisingly, performance was very similar to Task 6 ($r = 0.76$). If anything, the rod's being lighter improved performance. 77.4% of the social scientists thought that a weight would make it easier. When asked to place the weight, only 19% put it in the top third. 45.2% put the weight in the bottom sec-

tion, and the remaining students placed it in the middle section of the rod. Physics students fared a little better. 81% thought that a weight would improve balancing. However, the correct placement at the top was made by only 40%. Thus, in light of the results from Task 6, it seems that those who knew the correct answer were unimpressed by the weight of the rod. However, among those experts who merely guessed and suspected that weight would make a difference, they guessed so more often when the rod was lighter—increasing the salience of the weight.

Task 8 (order the rods): Social science students: According to the reasoning that a greater moment of inertia should facilitate balancing (note that this will not hold for much heavier rods), the correct order is C, B = D, A. Not a single subject produced this answer. 16.7% chose the order A, B, D, C; another 16.7% chose A, D, B, C. Only one subject considered a tie, albeit with a wrong ordering (B, D, A=C).

Physics students: Notably, 6% of the subjects did give the correct answer of CBDA or CDBA. 94% of the subjects answered incorrectly. Thus, the physics students were somewhat more knowledgeable than the social science students.

In sum, the errors we make in perceiving the balancing properties of simple objects are large. The important variable of mass distribution is ignored entirely. We plainly do not see how an object is best balanced until we try it out, even though we balance objects on a daily basis. Most if not all observers are unable to correctly imagine or remember past balancing acts. Formal physics training has surprisingly little effect on the paper-and-pencil task for assessing falling and balancing of rods. Note that the classical mechanics knowledge that would help solve the problem should have been held by all natural science students involved in the study. The fact that their answers were only slightly superior to novice intuitions is stunning. Why is the textbook knowledge of classical mechanics so frail that it has not been internalized, such as to inform our intuitive judgments or at least facilitate our textbook learning?

Throughout evolution we had to handle and wield objects by balancing them. One might argue that such knowledge is not available to the ventral processing stream (see [Milner & Goodale 2008](#)). However, in further tests we confirmed that performance in our tasks did not improve when we let subjects wield a rod before filling out the questionnaire. Even though observers are able to feel how long a stick is when wielding it while being blindfolded (see [Turvey & Carello 1995](#)), they are unable to exploit the available perceptual cues that inform them about the balancing properties of an object. Thus, although we know shockingly little about balancing, it seems to be sufficient to guide our daily actions. We correctly see longer sticks as being easier to balance, but we fail to see the importance of mass distribution. Even when educated by formal physics training, our performance becomes only slightly more sophisticated. The gap between percept and reality closes merely by a small amount. It appears that the visual systems of different observers adopt different private models that often include rod length but not mass distribution.

2.3 The second case study: Visual cues to friction

Let us now look at another relational property that may have more serious consequences for our health: friction. If we misbalance an object, we may break it, but if we misjudge the slipperiness of the surface we walk on, we may get hurt. We need to avoid accidents on slippery ground and we have to estimate the force we need to apply to hold an object. Importantly, we often cannot wait for haptic cues to make this information available, but typically we have to make the underlying judgment of slipperiness on the basis of visual cues. The mere look of a wet slope may be all we have to guide our decision to tread forcefully or to hold on to a hand-rail and walk gingerly. The human ability to make such visual assessments of slipperiness is not well explored. We hold that this is because friction is not a simple surface property but rather a relational property, which can only be determined by relative characteristics of two

surfaces. In other words, the fact that a surface is rough does not imply high friction, and the fact that a surface is smooth does not imply that it is slippery. Plastic for instance, can be very sticky on human skin but very slippery on wool or felt.

In what follows, we provide an overview of friction perception and briefly introduce venues to visual and haptic roughness perception. Then we report two experiments that were conducted to assess visual and haptic judgments of friction between surfaces.

2.3.1 Friction as a relational property vs. surface roughness

Some surfaces afford walking on whereas others do not. The information that allows the organism to make potentially critical decisions about where to tread or how strong a grip should be is based on a variety of perceptual dimensions (see e.g., [Michaels & Carello 1981](#)). Even when ample opportunity is given to haptically explore the surface, its felt roughness is not necessarily the same as the friction between the exploring hand and the surface, let alone the friction between the sole of the shoe and the surface. For instance, if our hand is moist we feel high friction when exploring a polished marble floor and at the same time we feel it to be very smooth. We may even perceive it as slippery—factoring in the effect of dry vs. moist hands.

Tactile competence regarding perceptual access to roughness of surfaces appears to be rather sophisticated (for a state-of-the-art review of haptic perception see [Lederman & Klatzky 2009](#)). In essence, haptic perception of surface roughness is better when the surface is explored dynamically as opposed to statically. Errors are generally rather small. More interestingly, several studies have demonstrated that cross-modal sensory information (e.g., vision and touch) can lead to better estimates of a texture's roughness (e.g., [Heller 1982](#)). Other research has also shown that different sensory modalities are weighted about equally when estimating the roughness of textures ([Lederman & Abbott 1981](#); [Lederman et al. 1986](#)).

Even by mere visual inspection, observers are able to see how rough a surface is (Lederman & Klatzky 2009). Such findings may have tempted researchers to unduly reduce friction to surface roughness. For instance, in the ergonomics context of accident analysis, slipperiness of work surfaces is typically operationalized by surface roughness, with the implicit or explicit assumption that roughness is good enough an approximation of friction (see e.g., Chang 1999; Chang et al. 2001; Grönqvist et al. 2001). However, friction is a rather complicated property between surfaces, for one because it is subject to change with the amount of pressure one applies or with the speed at which the surfaces move relative to one another. And people appear to have some difficulty judging friction (Joh et al. 2007).

Let us consider the case of a square block of cement on a large wooden surface. The heavier the block, the higher the friction coefficient. And the rougher the surface of the block the higher the friction coefficient. Thus, friction is a function of the force applied to a given surface, of area, and of roughness. Children and adults seem to be able to perceptually appreciate some but not all of the above-mentioned three components of friction. This intuitive knowledge develops with age. Adults have some insight into the multiplicative relation between the weight of an object and its surface texture in cases where the object is pulled across a surface, whereas nine-year-old children seem to assume a simpler additive relationship (Frick et al. 2006).

Friction is defined by the interaction between two surfaces, and its estimation requires knowledge about how different surfaces can interact. Thus, the seemingly simple visual percept that we have of a surface as “slippery” is a rather complex physical relation that pertains between properties of the surface and the contact object. Physically, slipperiness is indicated by the friction coefficient between two surfaces, which is usually measured by placing an object on an adjustable ramp. As the steepness of the ramp increases, one determines the angle at which the object starts to slip (static friction) or when the object starts to move uniformly (kinetic friction).

We can haptically judge the roughness of surfaces, and we are also able—to some degree—to haptically judge the friction between surfaces. Grierson & Carnahan (2006) have shown that individuals can haptically perceive slipperiness; that is estimates were significantly correlated with the friction coefficients between an object’s surface and skin. In their first experiment, they showed that tangential motion is required to judge the friction coefficient realistically. In a second experiment, they examined the force people applied to lift an object with a certain weight and surface structure. The applied force was often higher than necessary. Next to nothing is known about our ability to judge slipperiness based on visual information.

2.3.2 Slipperiness Experiment: Visual cues to friction of familiar surfaces

Vision has been shown to improve haptic judgments in endoscopic surgery. Within a simulated endoscopic environment, Perreault & Cao (2006) tested the effects of vision and friction on haptic perception by measuring for how long participants held on to the objects with the surgery tool. In a second experiment, participants had to compare the softness of pairs of simulated tissue. The experiments showed that visual and haptic feedback were equally important for the task. This suggests that visual cues can be exploited to judge slipperiness.

Presumably the main visual cue for predicting slipperiness or friction is shine (gloss, reflection, etc.) of a surface. Joh, Adolph, Campbell & Eppler (2006) explored which visual information can serve as a warning of low friction surfaces. They asked their participants which cues they use to identify slippery ground, and tested whether visual information is reliable for the judgment of slipperiness under different conditions (indoor and outdoor lightening). Walkers seem to rely on shine for selecting a safer, less slippery path, even though shine is not a very reliable visual cue for indicating slippery ground.

With two experiments we attempted to assess, in more general terms, the ability to perceive slipperiness. In our first experiment, we tried to

find out to what extent visual and haptic information enables us to estimate friction between two surfaces and, in particular, how far visual cues in isolation decrease the ability to judge friction. In our second experiment, we manipulated the visual appearance of given surfaces to explore the effects of glossiness, contrast, and undulation on perceived friction.

Every day we encounter different types of surfaces with which we are in contact. In these situations we do not really think about how much force is to be exerted in order to create sufficient friction, be it between the fingers and the object we are grasping or between the sole of our shoes and the surface of the road we tread. Nonetheless, we rarely accidentally drop an object or slip on the road. Thus, we must have some degree of intuitive knowledge about the friction of surfaces. The experiment sought to find out, first, if this is really the case, and then which sensory information might guide our estimates of friction.

2.3.3 Methods detail

33 female and 31 male subjects between 18 and 52 years of age ($M = 25.3$; $SD = 6.6$) volunteered and were paid for participating in the study. All had normal or corrected to normal vision, and no one reported haptic impairments.

Ten different types of surfaces (see Figure 16) were glued onto separate thin quadratic tiles of wood with a size of 10 x 10cm. The surfaces were sheets of Teflon, pan liner, smooth and rough foam rubber, cloth, felt (soft and hard), and three different grades of sandpaper.

Two common reference surfaces were picked: human skin and smooth untreated wood. That is, the participants had to estimate the friction of the above ten surfaces with respect to one or the other of the two reference surfaces, skin or wood.

To measure the perceived friction, a ramp was used. Its slope could be adjusted to a steepness corresponding to the setting where the tile was judged to start sliding down. The ramp consisted of two wooden boards connected with a hinge. It was placed in front of the participant and could be continuously adjusted (see Figure

17). A measuring stick was attached to the top of the ramp such that the experimenter could easily record the height of the ramp while the participant saw only the unmarked side of the measuring stick. The height settings were then converted to slope angle, which in turn was used to determine the friction force acting between ramp and probe surface.

Figure 16: The ten materials used in the first experiment. Top row from left to right: Teflon, pan liner, smooth and rough foam rubber, cloth. Bottom row from left: felt (soft and hard), three different grades of sandpaper (320, 180, 40 in that order). All materials were mounted on identical square wooden tiles. The matchstick is shown to provide scale information, it was not there in the experiment.

The slope of the ramp used to estimate the friction of the different surfaces could be varied from 0 to 90 degrees. We computed coefficients of estimated static friction for the subsequent analyses using the following equation:

$$\mu_H = \mathbf{F}_R / \mathbf{F}_N \text{ (friction coefficient = friction force / weight)}$$

A 4 x 2 x 10 design was used, with one four-level between-subjects factor (Condition), and two within-subject factors, Reference Surface (two levels: skin and wood), and Surface Material (ten levels: Teflon, pan liner, smooth and rough foam rubber, cloth, felt (soft and hard), and three different grades of sandpaper).

The factor Condition consisted of different instructions for exploring the surface materials (see Table 1). In the haptic-visual condition, observers were asked to touch the surfaces and to visually inspect them. In the haptic condition, the surfaces were hidden in a box at all times and could only be explored haptically. In the visual condition, observers were not allowed to

touch the surfaces but could inspect them visually. In the photo condition, finally, observers merely viewed photographs of all ten surfaces. The same photographs as depicted in Figure 16 were used, with the exception that the match was not present. The photographs were the same size as the actual tiles (10 x 10 cm).

Figure 17: The ramp used to measure the estimated friction coefficients produced by the participants. The ramp had to be adjusted to the angle at which the respective tile would just about start to slide. In the case of skin as reference surface, observers were told to imagine the ramp to be their torso or to be covered with skin.

Subjects were allowed to look at the respective reference surface (skin or wood) before making a set of judgments based on this reference surface. They were also allowed and encouraged to touch the reference surface regardless of the condition in which they were tested. That is, even the group that could only visually inspect the test surfaces had visual and haptic experience of the generic reference surface. The ramp itself was not to be touched in this phase of the experiment, in order to ensure that the groups did not differ in how they explored the ramp. To envision the friction of skin, subjects were instructed to touch the inner side of their forearm, and to envision the friction of wood, they had a piece of wood (the same wood also used for the ramp) lying in front of them that they could touch. Half of the participants started with wood as reference and then after a short pause used skin as reference. The other half started with skin and then judged wood.

Within each block, the order of the surface tiles was randomized separately for each observer.

Table 1: The four test conditions under which separate groups of subjects were asked to explore the material surfaces.

I. Haptic-visual	The ten test surfaces were visible and could be touched without any restrictions.
II. Haptic	The surfaces were hidden in a box and could only be touched but not seen.
III. Visual	The subjects were only allowed to look at the surfaces.
IV. Photo	Photos of the surfaces were presented on a TFT-display, so only restricted visual information was available.

The procedure consisted of three parts. First, subjects had to estimate the friction of the ten materials, all presented successively and in random order. To do so, they had to adjust the slope of the ramp (see Figure 17). After inspecting the reference surface and the first tile, they had to set the ramp's slope to the point where they expected the particular surface to just start slipping on the ramp. The surface tiles were never physically placed on the ramp. Then the remaining nine tiles had to be judged in the same manner.

Figure 18: Actual and perceived coefficients of friction between **skin** and the respective materials. The solid black line corresponds to the actual angle of the slope at which the tile would indeed start to slide. The other lines represent subjective judgments averaged across all participants of each group respectively. Error bars indicate standard errors of the mean.

In the second part, a short questionnaire was given to the subjects. Finally, the procedure was

repeated with the other reference surface. The order of which reference surface was chosen first was counterbalanced such that half the observers started with wood and the other half started with skin.

2.3.4 Results

Line graphs show the actual and the averaged estimated coefficients of static friction on skin (Figure 18) and on wood (Figure 19). With the exception of Teflon on skin, friction was perceived, albeit underestimated. In some cases, roughness appears to have guided perception. For instance, the different grades of sand paper produce similar friction because roughness and contact area trade off against one another. The coarse paper is rougher but at the same time provides fewer contact points than the fine paper. The resultant friction is in fact comparable. However, the coarse paper was mistakenly thought to produce more friction than the fine paper.

With skin as reference surface, haptic exploration improved performance but estimates remained far from perfect. Teflon in particular was grossly mis-estimated. The overall results showed significant main effects of Material ($F(5.7, 342.4)=22.85, p<.001$, partial $\eta^2 = .27$) and Reference Surface ($F(1.0, 60.0)=17.80, p<.001$, partial $\eta^2 = .23$). In addition, the effects of Condition were more pronounced for the reference surface of skin; the interactions of Material x Condition ($F(17.1, 342.4)=2.92, p<.001$, partial $\eta^2 = .13$) and between Material x Surface ($F(7.9, 475.2)=2.87, p=.004$, partial $\eta^2 = .046$) were significant. The interaction of Material x Surface x Condition was also significant ($F(23.8, 475.2)=1.69, p=.023$, partial $\eta^2 = .078$). Contrasts revealed that performance was poorer in the photo condition compared to the haptic condition ($p=.023$) and the haptic-visual condition ($p=.007$). The latter two did not differ significantly from one another or from vision alone.

The post-experimental questionnaire revealed that most participants attempted to use all available information and that they tried to find out which material they were confronted with. After identifying the material, they estim-

ated the friction on the basis of their experience. Perhaps some erroneous estimates could be ascribed to such cognitive influences upon friction estimation.

Figure 19: Actual and perceived coefficients of friction between **wood** and the respective materials. The solid black line corresponds to the actual angle of the slope at which the tile would start to slide. The other lines represent subjective judgments averaged across all participants of each group respectively. Error bars indicate standard errors of the mean.

In sum, static friction between a number of different materials and the reference surfaces skin and wood were picked up, but only to a limited degree. Vision alone does transport information about the relational property of friction. This ability to see friction is attenuated but still present when photographs are used. Thus, high-resolution detail appears to be crucial. Surprisingly, haptic cues were not superior to visual cues and even in combination only tended to improve performance. Friction is generally underestimated, with the exception of Teflon and wood, which was grossly underestimated. Multisensory information did not help compared to unisensory information. It appears that multiple information sources improve the perception of simple properties such as roughness (Lederman & Abbott 1981; Lederman et al. 1986), but fail to contribute in more complex cases of assessing friction. When visual information was reduced, not surprisingly, this affected friction judgments negatively. The photo condition produced notable judgment errors. It would

be interesting to find out if this degradation could be compensated for by providing haptic cues together with the photographs. Note, however, that the photographs were able to produce estimates that correlated with actual friction. Thus, some information about roughness is preserved in the photo and can be accessed. The relational property of friction appears to be qualitatively different from and not reducible to roughness.

2.3.5 Friction experiment with manipulated visual appearance

The preceding experiment has shown that observers are able to gain some information about friction by visually inspecting the two involved surfaces together exhibiting this complex property. Given this ability, we should be able to isolate some of the relevant visual surface features upon which this ability is based. In a second friction experiment, we limited the reference surface to wood, and manipulated the visual properties of a select number of surfaces, namely Teflon, foam rubber, and sand paper. Among the changes in visual properties were factors that should influence perceived roughness and thereby potentially also friction, such as convolving the picture with a wave pattern, or changing the contrast in the picture.

2.3.6 Method detail

55 volunteer subjects (23 men and 32 women) participated in the study. They were recruited at the campus of the Johannes-Gutenberg University of Mainz and at a nearby supermarket. All participants were naive with respect to the purposes of the experiment. Their average age was 31.8 years ($SD = 12.6$ and a range from age 16 to 59).

We took some of the pictures of the tiles used previously. The pictures were taken on a Fuji Finepix S5500 digital camera (four megapixels) with a resolution of 1420 x 950 pixels. One reference picture each of coarse sandpaper, structured foam rubber, and Teflon were chosen. Then these reference pictures were modified using four special effects provided by

Adobe Photoshop Six. Five visual effect conditions (Filter) were thus created for each of the three materials (see Figure 20 for the case of sand paper):

Figure 20: The reference picture (n) of the sand paper tile, and the four filter effects applied to the reference picture: ocean effect (o), wave effect (w), reduced lightness (d), and enhanced contrast (c). Note that all pictures were of equal size in the experiment.

1. Normal: The reference picture was the original photo of the surface without any special effect.
2. Ocean: The original photo was convolved with the structure of an ocean surface. A photograph showing the ocean from above with its waves was put as a new layer upon the original photograph with an opacity value of 25%. It added a look reminiscent of structured wood to the photograph. We hy-

pothesized that the added structure would increase perceived friction.

3. Wave: This filter introduced a wave pattern into the picture. This distortion effect was used with the parameters Number of Generators (5), Wavelength (Minimum 10 Maximum 120), Amplitude (Minimum 5, Maximum 35), Scale (horizontal 100%, vertical 100%), Repeat Edge Pixels (On), and Type (Sine). This filter distorts the original structure in the pattern of sine waves. We hypothesized that here, the added structure would not change perceived friction because waves are regular and smooth compared to the ocean texture.
4. Dark: The lightness of the surface was reduced uniformly by 50% (parameter setting: 50). We hypothesized that this would reduce detail, which would decrease perceived friction.
5. Contrast: The contrast was uniformly enhanced such that the according parameter was raised to +50. We hypothesized that the added contrast would emphasize roughness and thereby increase perceived friction.

The photos were printed on high-quality photo paper and shown to the volunteers in succession. The “normal” reference version of one material was always shown first, and then four different versions of the same material were presented in changing pseudo-random orders, for each material respectively. All possible sequences of the materials were presented to different observers. They were asked to imagine the surface shown on the photograph as being the surface of the ramp itself. The same ramp as before was used (see Figure 17), but subjects were not allowed to touch its actual wooden surface. Then they were asked to decide how steep the ramp would have to be set for a wooden tile to start sliding down on the shown surface. The tile of wood was shown to them beforehand and they were asked to touch it. Then they had to put the ramp at the angle at which they thought the wooden tile would just start to slide. As before, we measured the height of the ramp setting in centimetres. With this information, we calculated the angle with

$\sin(\alpha) = \text{height} / \text{ramp length} = \text{height} / 44\text{cm}$ and finally the resulting estimated friction coefficient for all surfaces.

2.3.7 Results

Figure 21 shows the estimated friction coefficients for all three materials averaged across all filters and across the respective reference surface. Friction between wood and foam rubber was judged to be highest, friction with sandpaper was judged intermediate, and friction with Teflon was judged to be smallest. Figure 22 depicts the overall averages by Filter (visual effect). Figure 23 shows the interaction between Material and Filter.

A repeated measurement analysis of variance with Material and Filter as within-subject factors and gender as between-subjects factor was conducted on the judged friction coefficients; F-values were corrected by Huynh-Feldt as necessary. Material had a significant effect on estimated friction ($F(2, 106)=9.54$, $p<.001$, partial $\eta^2=.15$). Foam rubber and paper did not differ, but both were judged to produce more friction than Teflon ($p<.001$ and $p<.003$ respectively).

Figure 21: Estimated friction coefficients for the three materials independently averaged across all filters, and the actual coefficients for the three materials on wood. Error bars indicate standard errors of the mean.

The factor Filter also had a significant influence on the estimation of friction ($F(4, 212)=5.351$, $p=.001$, partial $\eta^2=.092$). The unfiltered stimuli were judged to produce the

smallest amount of friction, and all filters appeared to increase the subjective coefficient of friction. Figure 22 shows the estimated friction for all five filters averaged across all three materials. The contrasts between the estimated friction coefficient values for “normal” and “ocean” ($p < .024$), “normal” and “dark” ($p < .001$) and “normal” and “contrast” ($p < .023$) were significant. Because of the sometimes variable judgments, the individual contrasts between “normal” and “wave” as well as “contrast” and “dark” failed to reach significance.

Figure 22: Estimated friction coefficients for the five filters averaged across the three materials. Error bars indicate standard errors of the mean.

We also found a significant interaction between the factors Material and Filter ($F(8, 424) = 3.99$, $p = .002$, partial $\eta^2 = .070$). As visible in Figure 23, this interaction was mainly due to the immunity of Teflon to all filter manipulations and to the special effect of the increased contrast on foam rubber. Now let us have a closer look at the three materials and how they fared with the different filters. Participants could judge the friction between wood and the shown surfaces rather well, with the exception that the friction of sandpaper was underestimated. For some reason some of the grittiness and roughness of sandpaper has been lost in the photos, whereas no such loss occurred for foam rubber and Teflon. To the experimenter, the surface of sandpaper also did not look as rough as it did in real life.

Teflon on wood was clearly judged to be the most slippery surface. Interestingly, the estimated differences between the Teflon reference and its filter-treated variants were very small compared to the other materials (see Figure 23). Presumably, Teflon generally looks so slippery that a ceiling had been approached and the filters could not significantly change the low friction ratings of Teflon. The surfaces that were treated with “ocean” looked like rough wood; the manipulations “contrast” and “dark” seemed to make the structure clearer. The filter “wave” had a smaller influence on the estimations. Participants often said that they found it difficult to classify the wave-treated surface.

Figure 23: Interaction between the two factors Material and Filter. Error bars indicate standard errors of the mean.

The results of this experiment clearly show that irregular additional structure—as introduced into the surface by convolving the picture with the ocean pattern—causes the perception that the surface is less slippery. This was the case for all surfaces that were not extremely slippery to begin with. Other than hypothesized, reducing the lightness of the surface also tended to produce higher ratings of friction. Increased contrast, on the other hand, produced mixed results. Sandpaper with increased contrast was judged to cause more friction. Contrast had a smaller but similar effect on Teflon. However, when applied to foam rubber, increased contrast had no effect. Taken together, these effects demonstrate that visual aspects of

a surface, such as its microstructure, its lightness, and its contrast co-determine how slippery it is judged to be with respect to a given reference surface. Note, however, that the reference surface was always wood, and simple roughness judgments may have guided the friction estimates.

To summarize the friction case study, we conducted two experiments to assess whether observers are able to visually perceive the complex relational property of friction between two surfaces even when not allowed to touch the surfaces. They were able to do so with limitations. Observers generally tended to underestimate the degree of friction. An underestimation of friction as observed in these two studies could be regarded as a conservative approach to judging the grip force required to successfully grasp objects. Using more force than necessary rarely leads to disaster (consider raw eggs), whereas too little grip force causes an object to slip out of our hand and fall.

The first friction experiment compared judgments based upon visual inspection alone, and then after visual and haptic inspection. Vision in and of itself provides valuable information; additional haptic information added surprisingly little. The second experiment explored the particular visual properties that make surfaces look more or less slippery, but note that the reference surface always remained unchanged. Subjects likely differentiated between surfaces of different roughness insofar as roughness (simple property) and friction (relational property) were correlated. Errors were large in particular when the relational property to be judged was variable. Perceiving Teflon as very slippery (with respect to skin) when it is indeed quite the opposite is a grave perceptual error, but it is not very meaningful to call the error an illusion_d. A perceptual miscategorization of the relational property of friction between surfaces might be a more appropriate description.

3 Conclusion

I have attempted to argue that we need to reconceive the notion of what an illusion is. In the context of the traditional line drawings used

over a hundred years ago to illustrate the shortcomings of vision, illusions_m have begun to misguide our thinking about normal perception. Illusions_m do not indicate the error-prone nature of visual perception. On the contrary, they tend to be small compared to the many illusions_d that go unnoticed on a regular basis. To illustrate that this is the case, I have used two examples from the domain of complex relational properties. This choice was based on the conviction that perception of everyday objects always necessarily includes judgment (be it in terms of Helmholtzian unconscious inference, or be it in terms of private models that may or may not become transparent to the perceiver). The notion that illusions_m should be of interest because they reveal the workings of how the visual system derives percepts from simple sensations is not useful. It is not useful because an illusion_m only becomes manifest by a comparison process that is at least as fraught with cognition as is the perception of everyday relational properties. We have used the classical stick in the water and the equally classical Ebbinghaus illusion to illustrate that illusions_m only become manifest if a cognitive operation is performed (i.e., a perception-inference-cycle when moving the stick or comparing the circle to a reference circle known to be of identical size).

It is also impossible to investigate illusions as merely phenomenal problems. And it is ill-conceived to limit the study of visual perception to seemingly simple phenomena that end up requiring cognition after all. Perceiving is to make perceptual judgments, be they explicit (e.g., by saying which of two objects is larger), or be they altogether implicit, or merely amenable to consciousness by an act of attention (e.g., by determining hand-aperture when grasping an object). It is thus impossible to investigate illusions as purely perceptual errors. Instead, illusions always have a cognitive component in the sense that they require an act of comparison or inference. This holds for all illusions_m, even if they may not be amenable to consciousness. To take illusions as a discrepancy between what we see and what there is, is doubly mistaken. First, there is always a discrepancy (illusion_d) between a visual percept and the object in the world to

which it refers, namely the stimulus. And second, only in rare and simple cases do we notice this discrepancy (illusion_m). The discrepancy is owed to the underspecification problem (UP), the qualitative information gap between the two-dimensional retinal image and the richer three-dimensional percept. The UP puts the perceptual system in a position from which it has to draw additional information from memory, from inference, or from internalized structures that have been acquired throughout evolution. Such structures have been suggested to include that objects are three-dimensional, that light comes from above, that gravity acts along the main body axis when standing or walking, or that the brightest patch in the visual field is usually “white”. Internalized structures gain particular weight if the stimulus is poor. This is the case when looking at simple line drawings and it is all the more the case when looking at relational properties. The quality of solutions to the UP differ greatly as the function of the task demands, but not necessarily as a function of the complexity of the stimulus. On the one hand, the perceptual system achieves performance that seemingly approaches perfection where precise motor action is required in personal space. On the other hand, in more remote action or vista space (for a very useful taxonomy of space see e.g., [Grüsser 1983](#)) some blatant errors are made. Our perception often defies the most basic laws of physics. More often than not do these errors go unnoticed. To illustrate how crudely our perceptions approximate reality even in personal space, we have explored errors in balancing objects and judging the slipperiness of surfaces. When it comes to these relational properties, our perception falls far from the truth. It appears that the errors tend to be as large as they can be without interfering with the perception-action cycle required for adequate or acceptable action. The evolutionary fine-tuning would minimize error until it is no longer relevant for survival. In this sense, normal perception (i.e., the illusion_d) is a satisficing solution. The magnitude of the perceptual errors many observers make is in the league of errors associated with probability judgments (see e.g., [Kahneman et](#)

[al. 1982](#)) and syllogistic reasoning, as opposed to the much smaller errors typically associated with perceptual illusions_m.

Our perception, just like our cognition, has developed to find solutions to problems that suffice. When reaching for an object, perception is accurate enough not to knock it over but to grasp it (most of the time). When judging a surface, it is accurate enough that we do not slip (most of the time). These examples are noteworthy because they do not relegate perceptual error to remote vista space, where precision would not matter. Toppling over an object or falling on a slippery slope concern us in personal space.

In essence, the UP is solved with remarkable accuracy for simple properties of objects within our domain of interaction. However, as soon as the perceptual properties become more complex and involve the relation between two or more objects, the perceptual system can no longer solve the UP with any degree sophistication that goes beyond the level of medieval physics. But rather than giving up and seeing astounding illusions everywhere, the system degrades gracefully and builds theories that suffice for the purpose at hand. Their deviation from reality is not experienced. These perceptual theories may be thought of as more or less universal tools for upholding a meaningful world (in the sense of [Shepard 1994](#)); however, it might make more sense to think of them as universal tools with a private touch that accommodates individual perception-action requirements. A hockey player or a juggler will for instance have developed private models, be they unconscious or amenable to introspection, about friction or balancing that are more sophisticated than the layperson’s. Note that these models need not be explicit, in the sense of a perceptual process, of which the cognitive elements cannot be separated out.

Such private adjustments and elaborations when solving the UP need not be made in the case of classical geometric-optical illusions_m. I hope the above examples and case studies have shown that illusions_d, such as the Luther illusion, do not require detection, and illusions_m that become manifest, such as the Ebbinghaus illusion,

can be upheld because their limited magnitude makes them irrelevant for action.

This raises the questions why illusions_m arise at all. Illusions_m might arise as mere epi-phenomena or as meaningful warning signs for the system to signal that a perceptual fine-tuning is needed. The epi-phenomenon interpretation would suggest that the juxtaposition of two contradictory percepts is a fluke and happens per-chance every once in a while. Optical illusions_m are merely collections of such flukes. The warning-sign interpretation would see in them the purpose of fine-tuning the perceptual system. If the perceptual system subserves action, it would ideally minimize error (illusions_d), and one mechanism to do so would be the experience of illusions_m. It is unclear, however, why illusions would have to become conscious for this fine-tuning to work. Would the necessary re-direction of attention require the experience of an illusion_m? Be this as it may, the system does not even notice error—let alone attempt such fine-tuning—when it comes to perceiving relational properties. Even an approximate veridical perception of relational properties is out of reach of the perceptual system. The system merely arrives at the first solution that satisfies our action needs. A flashy epi-phenomenon or a warning system, as indicated by manifest illusions_m, is not useful here, as the discrepancy between percept and reality is too large.

Now, one might ask about cases where the error is exceedingly large and a warning may indeed be in place. These cases are rare; but they do, however, result in manifest illusion_m, and hence are compatible with the purpose of illusion_m that we suggest. Take for instance the perception of pain in a phantom limb. Here the sufferer does notice the illusion_m. How can pain be so vividly felt in a limb that is no longer there? The warning function of this manifest illusion_m is obvious. For instance, learned reflexes involving the absent limb need to be extinguished and reprogrammed. A more interesting case is the infamous rubber-hand illusion (Botvinick & Cohen 1998) or the full-body illusion that can be created in most observers by synchronizing their actions and perceptions with those of an avatar seen in a VR (Virtual

Reality) presentation (see e.g., Blanke & Metzinger 2009; Blanke 2012; Botvinick & Cohen 1998; Lenggenhager et al. 2007). Only in such extreme cases does the error manifest itself in a complex relational case. We feel that we are someone or somewhere else and at the same time feel that we are not. It seems to take such extreme cases before we find a sizable illusion_{d+m} that deserves the name “illusion”.

In most cases, we can adjust perceptions once we notice that they are erroneous, be they ball trajectories or balancing properties. However, this adjustment process is painfully slow and may have to draw on early stages of perceptual and cognitive development. It does not take center stage, and some theoreticians would claim that the adjustment process converges on a veridical understanding of the world (Gibson 1979 calls this “attunement”). Others claim that many perceptions are useful precisely because they do not match or converge on the world (e.g., the multimodal user interface theory of perception, Hoffman 2010). The satisfying nature of private perception may not require a perfect solution of the UP in many cases, as long as the slips and falls remain limited to a tolerable number.

Acknowledgements

Markus Homberg, Cornelius Mülenz, and Mana Saadati helped collect and analyze the balance data; Daniel Oberfeld provided valuable input for the experimental designs; Elsa Krauß, Markus Landgraf, and Laura Längsfeld carried out the friction experiments.

The Illusion of the Given and Its Role in Vision Research

A Commentary on Heiko Hecht

Axel Kohler

Illusions in vision and other modalities are captivating displays of the virtual nature of our subjective world. For this reason, illusions have been an important subject of scientific and artistic endeavors. In his target article, Heiko Hecht discusses the utility of the illusion concept and arrives at the negative conclusion that the traditional understanding of illusions as a discrepancy between world and perception is misguided. In his opinion, the more interesting and revealing cases are when the discrepancy is noticed and accompanies the perceptual state, or when, in the cognitive domain, the discrepancies become exceedingly large, but go unnoticed nonetheless. In this commentary, I argue that Hecht's criticism of the illusion concept is interesting and deserves further study. But at the current stage, I don't see that the model captures the essential features of illusory states. The processes on which Hecht focuses can be considered metacognitive appraisals of the respective sensory events, an interesting topic by itself. In the second part and as an overview, I review how research on the classical apparent-motion illusion has shaped our understanding of the neural underpinnings of motion perception and consciousness in general.

1 Illusions in science and culture

A main staple of research in cognitive science and especially vision science has been, and still is, the investigation of illusions. For one, it is just an amazing fact that although we think that our experience of the world is direct, we live by a subjective model of our environment. We feel that we perceive the world as it is, a naïve realism as we might call it, but we are just not aware that the world is only presented to us as a (re-)construction of our nervous system. In more philosophical terms, this fundamental property of our experience has been re-

ferred to as “phenomenal transparency” ([Metzinger 2003a](#)), the inability to recognize that our mental states are representations. This is probably the reason why we are baffled in cases when the subjective character of our perception becomes evident, although this rarely occurs under natural conditions.

At least in the context of our modern culture, many people will have had the experience that their train is leaving the station when in fact they have just watched the train on the opposite side of the platform taking off. This phe-

nomenon is termedvection, and everybody who has had this experience will remember the moment of insight when a cue destroys the illusion of self-motion and we realize that our train hasn't budged. A more historical example of illusions under natural conditions is the waterfall illusion—, a type of motion aftereffect. After looking at a waterfall or flowing water for a long time, static objects, e.g., the river bank or trees, seem to move in the direction opposite to the previously perceived water flow, probably due to adaptation effects in brain regions processing motion (Anstis et al. 1998). Early descriptions of the effect have been attributed to Aristotle (384–322 BCE) and Lucretius (99–55 BCE; Wade 1998). But apart from these few examples, it's rarely the case that the constructive nature of our perception is noticeable in everyday life.

Illusions have become a part of our popular culture and have had a strong impact on art. A whole art movement in painting, Op Art, is based on using known and discovering new visual illusions. It is a cultural version of vision research, presenting the fascinating nature of illusions to the public in aesthetically appealing ways. Illusions also feature prominently in the work of surrealist painter Salvador Dalí and other modern artists. For such artists, the medium presented a way of expressing the constructive nature of perception and signalled a departure from realism. For painters in general, knowledge about optics and the basis of visual perception has always been important for guiding the construction process of paintings and the refinement of techniques in order to achieve certain effects in the eye of the beholder. The entwinement of science and art is scrutinized in recent work looking at the interaction between fields (Zeki 1999). Two other forms of art that were more or less invented in close interaction with science are photography and film-making. The very basis of TV and movie presentations is rooted in the fact that we are able to fuse a rapid sequence of static images to construct a natural impression of moving objects. TV displays, projectors, and computer screens work with a certain refresh rate at which subsequent images are presented; the rate can be as low as

24 Hz in cinematography. The basic phenomenon that allows us to create a natural perceptual flow from flickering images is referred to as apparent motion, a type of illusory motion.

Because of the fascination with illusions and its influence on culture, illusions have been guiding research on visual perception for a long time—and continue to do so. But this is not the only reason for the utilization of illusions in science. Illusions are a powerful tool for understanding mechanisms of sensory processing in the brain that are unexpected or counterintuitive. Many motion illusions where motion can be seen in static displays (often seen in the entertainment sections of magazines) depend on a specific configuration of color values in directly abutting picture elements. These configurations of picture elements are repeated and cover the entire display, in sum creating a striking motion impression. Psychophysical experiments showed that the key to the illusion is the configuration of neighboring elements, whose effects cannot be predicted by current models of visual processing. Additional neurophysiological measurements in the same study demonstrated that different picture elements were processed with different latencies in certain areas of the visual cortex, mimicking a motion signal (Conway et al. 2005). This suggested a neural explanation for the occurrence of the illusion and led to a revision of existing models of motion selectivity.

Another driving force for the use of illusions in research was a resurgence of interest in understanding conscious perception. At the beginning of the 1990s, Francis Crick and Christof Koch started to publish a sequence of conceptual papers advocating the investigation of consciousness with empirical, and especially neuroscientific methods (Crick & Koch 1990, 1995, 1998). Since then the number of papers on consciousness has grown steadily in the domain of cognitive neuroscience. Certain visual illusions lend themselves specifically to investigating the nature of conscious processing. Some of the most prominent paradigms display the characteristic of bistability or multistability: When presented to observers, conscious perception alternates between two (bistability) or multiple (multistability) interpretations although the

physical characteristics of the display do not change. Rubin's face-vase illusion and the Necker Cube are just the most prominent among a multitude of examples for multistability (Kim & Blake 2005). The promise of using multistability is that it allows for disentangling the neural representation of the physical stimulus characteristics from the processes giving rise to conscious perception. The logic of the approach is that changes in neural activity accompanying switches in subjective experience during constant physical stimulation provide a guide to understanding the neural underpinnings of consciousness.

2 Hecht's criticism of the illusion concept

In his target article "Beyond illusions: On the limitations of perceiving relational properties," Heiko Hecht (this collection) begins with a discussion of the traditional concept of illusion and how it has been employed in the context of research on vision. In its most basic sense, an illusion refers to a difference between our representation of a given scene and its actual physical properties. In an interesting take on the utility of illusions in research, Hecht suggests that the mere discrepancy between our perception and the real world—what he calls *illusion_d* ("d" for "discrepancy")—is less useful than one might think. In simple terms, our perception is off to some degree in many cases. But still, on the other hand it is amazing how on-target it is most of the time: it is sufficiently accurate for an effective interaction with the world. For Hecht, the term "illusion" should be reserved for situations when discrepancies (*illusion_d*) are manifest, i.e., when the error is part of the experience and we become aware of it. This is termed *illusion_m* ("m" for "manifest") and is supposed to be the more interesting case. The moment of insight for the train-ride illusion described above might be a good example. Interpreting relative motion between trains as self-motion is often an adequate interpretation, but the error is manifested in a striking fashion experientially when we spot a part of the platform that indicates unmistakably that we are still in the same place.

In addition to the distinction between *illusion_d* and *illusion_m*, Hecht is concerned with cognitive illusions in comparison to the well-known perceptual illusions. His interesting observation is that when we move away from perception, the discrepancies between the real world and our judgments become even larger, sometimes to an absurd level. Humans are notoriously bad at everyday physics. Hecht mentions that we see nothing wrong with fabricated scenes that glaringly contradict Newtonian physics, and even our spontaneous actions reveal the same degree of error. Nevertheless, they are hardly ever noticed, i.e., *illusion_d* rarely becomes *illusion_m* in the cognitive domain. That this is especially the case for relational properties Hecht demonstrates with a series of his own experiments on physics judgments by university students. Even participants that should at least have some theoretical knowledge about the laws governing the real world (physics students) are surprisingly bad at finding the right answers to quizzes on balancing beams made of different materials with different weight distributions (Experiment 1) and on the slipperiness of surfaces (Experiment 2). In these examples, the students' judgments are in stark contrast to the actual, real-world outcomes, which were also empirically tested in addition to deriving predictions from the laws of physics. So even though the paradigms were chosen to be experientially accessible and ecologically relevant, it seems that our cognitive system does not care about correctness or even rough approximations that would point it in the right direction. Even the mere ordering of solutions without providing quantitative details is seldom correct.

To summarize, Hecht suggests that the small deviations of our perceptual representations are no match for the sometimes extreme discrepancies found in the cognitive domain. *Illusion_d* is the norm rather than the interesting exception in sensory processing because—at least in vision—the full three-dimensional representation of the world has to be derived from a limited array of two-dimensional information on the retinae. Hecht (this collection) refers to this as the "underspecification problem." For an efficient solution to the underspecification prob-

lem, the system employs a range of assumptions and constraints on the makeup of the world to guide the reconstruction process. For Hecht, perception is therefore always fraught with cognitive elements. This is even more so when discrepancy is detected; *illusion_d* becomes *illusion_m*. Then, cognitive judgments are involved, and an explicit comparison process is initiated that allows us to capture the discrepancy and which makes it experientially available.

3 The role of illusions in vision research

Hecht provides compelling evidence for the error-prone nature of everyday judgments, especially when it comes to relational properties. His observation of an antagonism between the size of discrepancies and their detectability is interesting. Moving from the perceptual to the cognitive domain, the size of discrepancies increases, but at the same time we are less likely to notice those errors. But there are a few points of dissent I would like to discuss in what follows. (1) The discussion of the cognitive nature of perception is long-standing and won't be solved in the near future, especially because the term "cognition" is notoriously imprecise. Nevertheless, I am not convinced that the cognitive aspect that is supposed to be part of perceptual as well as cognitive illusions in Hecht's view is a necessary ingredient for a proper concept of illusion. (2) Hecht's arguments are a welcome incentive to reflect upon the concept of illusion and its role for research. Although he does not negate the role of perceptual illusions for vision research, he is rather critical concerning the utility of traditional illusion research, especially with respect to the underspecification problem. Drawing on the vast body of research on apparent motion, I would like to provide an example of a positive research program that has accumulated valuable insights into the mechanisms underlying visual motion processing. This is not necessarily in contradiction to Hecht's stance. The focus of research on illusions has focused more on the neural mechanisms of visual processing and specifically on the neural correlates of conscious perception. In this sense, the research lines can be seen as complementary.

Nevertheless, I would argue in conclusion that the term illusion is well anchored in the perceptual domain and plays an important guiding role for research on visual processing.

There is a long tradition in vision research of considering the influence of cognition on perceptual processes. The basis for the early investigations on vision and, more generally, on sensory processing in the 19th century and early 20th century was the distinction between sensation and perception. One of [Helmholtz's \(1863\)](#) definitions captures the main line of thought:

Empfindungen nennen wir die Eindrücke auf unsere Sinne, insofern sie uns als Zustände unseres Körpers (speciell unserer Nervenapparate) zum Bewusstsein kommen; Wahrnehmungen insofern wir uns aus ihnen die Vorstellung äusserer Objecte bilden.¹

The definition can be seen as a continuation of a philosophical tradition that has the intention of separating pure states of sensory reception from the more cognitive aspects concerned with the reconstruction of the outer world. Already at this time, different authors were aware of the fact that these definitions did not draw a clear dividing line between different types of sensory states. For example, [Sigmund Exner \(1875\)](#) refers to Helmholtz's definition and points to several examples for which the distinction becomes muddled. His observant conclusion is that the philosophical concepts do not fare well in the field of brain physiology and that contradictions have to be resolved in future models of sensory processing ([Exner 1875](#), p. 159). So despite its initial allure, the distinction between sensation and perception produced more problems than solutions.

An interesting recent model of the interaction between perception and cognition has been proposed by [Vetter & Newen \(2014\)](#). They review the current empirical literature on cognitive penetration of perceptual processing and

¹ English:

"We call the impressions on our senses sensations, insofar as we become aware of them as states of our body (especially of our nervous system); we call them perceptions insofar as we create representations of external objects." [My translation]

find compelling evidence that cognitive penetration of perception is ubiquitous. They distinguish four stages of processing in the sensory (visual) hierarchy: (1) basic feature detection, (2) percept estimation, (3) learned visual patterns, and (4) semantic world knowledge. According to their account, almost all possible interactions between processing levels occur under normal conditions and top-down connections can be considered forms of cognitive penetration. They argue that it's not a question of whether cognition influences perception, but rather of what type of interaction takes place in any given case. They advocate a move away from the general conceptual question of the cognition-perception relationship towards an empirically-based consideration of the interactions between different levels of the processing hierarchy.

Importantly, none of the stages characterized by Vetter & Newen (2014) capture the cognitive component Hecht has in mind. The realization that there is a discrepancy between percept and the real world is not something involved in the construction of the perceptual content itself. It seems that this it is more along the lines of a metacognitive appraisal of the current situation. With reference to Metzinger's (2003b) concept of phenomenal transparency (a naïve-realistic stance towards the perceived world) referred to at the beginning of the commentary, it is now the complementary feature of phenomenal opacity—a situation in which the representational character of experience becomes available to the subject—that might play a role here. Metzinger (2003b) refers to cases of lucid dreaming and drug-induced hallucinations as prime examples of phenomenal opacity. Interestingly, it is not sufficient for him that we have accompanying reflexive thoughts on the nature of perceptual representations (the “philosopher's stance”, as one could say), but we must also be attentively engaged with the perceptual content and recognize the illusory nature of the process. Therefore, it seems to be the case that neither the views of Vetter & Newen nor Metzinger's concept of phenomenal opacity seem to capture the cognitive component Hecht has in mind. But in my view, such models of cognitive penet-

ration are much more intimately linked with the illusion concept, because they provide an understanding of how the very nature of the experience is modulated by cognitive processes. Hecht's model doesn't seem to capture that aspect, since it functions more as a cognitive commentary on the impenetrable perceptual process. It is unclear why this metacognitive appraisal should be considered a hallmark of illusory experiences.

When Hecht argues for abandoning the term “illusion” in the perceptual domain, he also refers to Wertheimer's classical work on apparent motion (1912) and contends that the Gestalt psychologists “avoided the term illusion” (Hecht this collection). It is true that, for example, Wertheimer (1912, pp. 167–168) himself mentions in a footnote that “illusion” should not be used to refer to a discrepancy relative to the physical world because his main concern is with mental states. (The German word in the original paper is “Täuschung,” which is indeed best translated as “illusion” in this context.) Nevertheless, the passage is not very clear on the reasons for rejecting the reference to discrepancy. Again, it seems that the distinction between sensation and perception (see above) is lingering in the background. Even assuming a correct sensory reception (sensation) of the apparent-motion inducers, something is added that goes beyond the raw sensory data. In a later section of the paper (Wertheimer 1912, p. 228), this becomes clearer when Wertheimer analyzes another possible meaning of “Täuschung,” i.e., failure of judgment (German: “Urteilstäuschung”). It is important for him that apparent motion is not a result of cognitive processes, of inferences of the type: “If an object was there just before and now is over here, it must have moved between the points.” He is convinced of the perceptual nature of the phenomenon and rejects the idea that cognition plays an important role. Again, there is some ambiguity with respect to the usage of the term “illusion” here. This being said, throughout the article Wertheimer uses the noun-form “Täuschung” thirty-five times and also refers to other motion illusions that were already as well known at the time as “Täuschung.” On my

reading, his main intention was to prove that apparent motion is the result of a low-level perceptual process and that it is indeed illusory in nature.

Wertheimer's 1912 paper, with its detailed psychophysical investigation of the apparent-motion phenomenon is commonly considered to be the founding event of the Gestalt movement (cf. Sekuler 1996; Steinman et al. 2000), although this might not be the complete picture (Wertheimer 2014). We have just passed the centenary of Wertheimer's seminal article, but still there is much work to be done to provide a complete picture of the processes involved in apparent-motion perception at behavioral, computational, and neurophysiological levels of description. In my view, apparent motion is a paradigmatic case of an *illusion_d* that has fertilized the understanding of motion processing and continues to do so. Given the roughly one hundred years of research on apparent motion, it is worthwhile to take stock (briefly) and see where investigations associated with this paradigm have taken us.

Psychophysical investigations of apparent motion are too numerous to review extensively here. Early studies focused on describing the basic features of the phenomenon. Korte's laws (1915) are still part of textbook knowledge in vision research; he described the influence of different stimulus characteristics (stimulus strength, spatial and temporal separation etc.) on the quality of apparent-motion perception. New varieties of apparent motion were described in the following, one of the most important ones being the motion quartet (Neuhaus 1930; von Schiller 1933; see video: <http://www.open-mind.net/videomaterials/kohler-motion-quartet>). This is a bistable version of apparent motion, where two frames with diagonally opposing dots at the corners of a virtual rectangle are flashed in alternation. The identical stimulus sequence can be interpreted as being in vertical or horizontal motion. During longer presentations of the unchanging stimulus, conscious perception will spontaneously switch between the possible alternatives. It is therefore an important example of a multistable display, which allows

various interpretations with the same physical input. Early on, it was noticed that the integration of motion inducers in the motion quartet processed within brain hemispheres is facilitated relative to integration between hemispheres (Gengerelli 1948), a fact we will come back to later on. After a relative hiatus in the 50s and 60s, apparent motion again took center stage in the 70s. It was the basis for the work of Paul Kolars (1972) on configuration effects and for the first investigation of computational principles of motion perception by Shimon Ullman (1979). At the same time, distinctions between different types of apparent motion were introduced (Anstis 1980; Braddick 1974, 1980), later culminating in the three-layered hierarchical system of motion types proposed by Lu & Sperling (1995, 2001).

Currently, in all domains (psychophysical, computational, neurophysiological) there are ongoing research endeavors cross-fertilizing each other in the search for mechanisms underlying illusory perception of motion. After the turn of the millennium, the broad availability of brain-imaging methods spurred the investigation of the neural mechanisms underlying apparent-motion perception. By and large, the same areas that process real motion are involved in the (Muckli et al. 2002; Sterzer et al. 2003; Sterzer et al. 2002; Sterzer & Kleinschmidt 2005), supporting the assumption that results from studies on apparent motion can be transferred to other types of motion processing. Another interesting result from studies using functional magnetic resonance imaging was that traces of the virtual apparent-motion path, the illusory motion between inducers, can already be seen in the primary visual cortex, the earliest stage of visual cortical processing (Larsen et al. 2006; Muckli et al. 2005). This effect is probably mediated through feedback connections from higher areas (Sterzer et al. 2006), explaining the fact that normal visual functioning is disturbed on the path of apparent motion (Yantis & Nakama 1998) and also supporting Wertheimer's (1912) original claim that apparent motion is a perceptual phenomenon that does not depend on cognitive inferences. Animal studies are starting to elucidate the more fine-grained neural

mechanisms subserving apparent-motion processing. Neurophysiological investigations in the animal model demonstrated complex wave patterns of interactions between several cortical areas during the perception of apparent motion (Ahmed et al. 2008). This work also inspired a formal model of these interactions elucidating the computational principles underlying the representation of apparent motion in the brain (Deco & Roland 2010).

In my own recent research, I have specifically looked at interindividual differences in the perception of apparent motion and its anatomical basis. As mentioned above, for the bistable motion quartet there is a difference between perceiving apparent motion in the vertical and horizontal direction. Observers show a bias towards perceiving vertical motion when they fixate on the middle of the motion quartet (Chaudhuri & Glaser 1991). A possible explanation for this is that due to the way the visual field is represented in the visual cortex, vertical motion only requires integration within brain hemispheres, but horizontal motion depends on integration between hemispheres. In fact, we could demonstrate that the individual bias of observers of vertical motion could be partly predicted by the quality of the neural connections between brain halves, suggesting that interhemispheric integration is a relevant factor (Geng et al. 2011).

The very short summary of research on apparent motion demonstrates the various insights this simple paradigm has inspired over the course of the last century and beyond. It led to a detailed description of the involved brain areas, including interindividual differences, and to processing models being developed on the computational and neurophysiological level. As mentioned in the introductory section, one main concern in vision research associated with illusions is the interest in conscious perception and the property of multistability. Both aspects are also dominant in the apparent-motion field. The current state of research is just the starting point for investigations towards a deeper understanding of the exact mechanisms. Often, the results are still descriptive and qualitative in nature and don't allow for very specific predic-

tions with respect to the involved neural machinery and dynamics. Yet the research line is promising and has the potential to lead to broadly applicable results. This might even be the case for the underspecification problem, the problem of reconstructing a full-fledged 3D world from a limited 2D input—one of Hecht's main concerns. Multistability can be seen as one paradigm case in which the nervous system has to resolve ambiguity. For the Necker Cube, the motion quartet, and other multistable displays, the brain settles into a solution for a perceptual problem by resolving competition among alternatives. Therefore, research on multistability might help to elucidate the core mechanisms that give rise to the definitive subjective interpretations with which we represent the world.

4 Conclusion

In conclusion, Hecht's distinction between *illusion_d* and *illusion_m* and his criticism of the naïve illusion concept in vision research is interesting. When we become aware of illusions, when we suddenly recognize the virtual character of our subjective world, certain metacognitive processes are initiated that are a worthwhile subject matter for further investigation. In some sense they become part of the experience, and an important question is whether and how the two aspects of the experience interact. Nevertheless, Hecht also agrees that perceptual representations are relatively immune to top-down control, i.e., even in the rare cases in which the illusory character becomes manifest, the perceptual processes are mostly modular and impenetrable in nature. Therefore, the question of illusory representation can be tackled independently of the question of metacognitive awareness, and continues to be an important guide for research on visual processing. Apart from looking at the more conceptual question of the level at which the term “illusion” should be applied, which is moot to some degree, I have tried to provide examples of relevant *illusion_d* research that has made progress on the question of how the brain processes visual information. Even for the underspecification problem, there is opportunity for valuable insight, which hasn't been exploited to full potential yet in current research.

Manifest Illusions

A Reply to Axel Kohler

Heiko Hecht

The notion of illusion as a discrepancy between physical stimulus and percept (here referred to as illusion_d , as long as merely this “error” is meant) is unable to capture the four very different cases in which illusions can arise. The observer may or may not be aware of the discrepancy, and its magnitude may be large or small. I argue that the special case of small error paired with awareness deserves special attention. Only in this case does the observer readily see the illusion, since it becomes manifest (referred to as illusion_m). Illusion_m is a meaningful category even in cases where illusion_d cannot be determined. Illusions_m of apparent motion and illusions of intuitive physics are solicited.

1 The concept of illusion

Axel Kohler points out that illusions understood as discrepancy between physical stimulus and percept (illusion_d) have inspired progress in the history of experimental psychology. At first glance, this seems to be rather obvious. However, to define a discrepancy, one must have two comparable measures of the same thing. But this is often not the case. Take a given lamp that looks very dim to us during the day but blindingly bright at night. How bright is the stimulus really? We are unable to determine which of the two cases is more illusory_d. The perceiver does not normally notice the illusion_d . Apparent motion, in contrast, which has been a

very influential paradigm, is more than mere illusion_d . By differentiating illusions into illusion_d and illusion_m , I am able to point out a strange inconsistency between the amount of error contained in an illusion and the perceptual conspicuity of this error. I argue that there are four varieties of discrepancy between physical stimulus and the related percept (illusion_d). They can be grouped by the size of the discrepancy and the degree of awareness (see Figure 1). First, there are more or less subtle discrepancies that are ubiquitous and go unnoticed most of the time. In rare occasions, and usually triggered by a revealing piece of contradiction, they are no-

ticed (illusion_m). The second variety consists of very large discrepancies, such as found in many intuitive physics examples. For instance, a water surface may look fine even if it extends impossibly at a large angle from the horizontal. For instance, when asked to draw the surface level that water assumes in a tilted beaker, observers err as if they did not know that water remains parallel to the ground. And the more expert they become at avoiding spills, the larger the error becomes. Experienced bartenders produce the largest errors (see [Hecht & Proffitt 1995](#)). The perception of relational properties discussed in the target article falls into this category. Here the perceptual error can be enormous and still go unnoticed. Typically, we need to consult physics books and learn about a physical stimulus before we are convinced that our perception is erroneous. When conceiving of illusion as mere illusion_d, we fail to honor the special case of illusion_m. Illusions_d are ubiquitous. As a matter of fact, the core discipline of sensory psychology—psychophysics—can be thought of as the formal description of how a physical stimulus differs from its percept. It does so all the time. Illusions_m are a special case. They may warn the organism about where adjustments to the perceptual system are necessary in order to avoid potentially dangerous misjudgments. Or they may just be occasions where the perceptual system fails to suppress the perceptual process that has lost out in the competition to resolve the underspecification problem.

2 Apparent motion (AM)

I thank Axel Kohler for bringing up AM (apparent motion) as an example of how seminal an illusion can be for research. I do concur that it continues to be a fascinating phenomenon. However, I believe that AM did not fascinate [Wertheimer \(1912\)](#) because it is an illusion_d, but rather because it is predominantly an illusion_m. Note that the timing has to be just so (i.e., a particular combination of on-times and ISI, inter-stimuli-intervals) in order to perceive what he called phi-motion: perfectly smooth motion practically indistinguishable from real motion.

Most of his experiments and demonstrations have in fact worked with suboptimal cases in which the perceived motion is bumpy or faint. In all these other cases of AM, the illusory nature of the percept becomes manifest. The bistable quartet is another beautiful case of an illusion_m. The mere fact that the percept can flip at will shows the illusion_m to be manifest.

illusions

		Awareness	
		YES	NO
Magnitude of the discrepancy (stimulus–percept)	SMALL	illusion _m	opaque illusion _d
	LARGE	insight	intuitive physics psychophysics

Figure 1: Varieties of illusions.

As an aside, the Gestalt laws can be understood as an attempt to describe how the percept emerges from the given physical stimulus. But note that while the percept is always different from the physical stimulus, it should not be thought of as illusory just because it is the outcome of a Gestalt process. When I said that Gestalt psychologists have “avoided the term illusion” I was not expecting anyone to count the occurrences of the term in Wertheimer’s 1912 paper. He did use the term. I stand corrected. Note, however, that he put the term “Täuschung” in quotation marks the first time he used it, well aware that the phenomenal experience of motion is what makes the Gestalt, regardless of how it relates to the physical stimulus.

Another revealing aspect of AM is its power to reveal the extent to which world-know-

ledge is factored into our perception, unconsciously and the more so the less well-defined the stimulus. Let us consider a classic AM-display in which two rectangles at two locations and at different orientations are shown in alternation. Whenever the ISI is short (say 100ms), we see one rectangle moving on a straight path and changing its orientation concurrently. If, however, the ISI is lengthened (to, say, 500ms), then the AM-path curves (see [McBeath & Shepard 1989](#); [Hecht & Proffitt 1991](#)). The phenomenal quality of this motion is rather ephemeral. We immediately see that the motion is not distinct but fraught with uncertainty. When choosing intermediate ISI, and forcing observers to make up their minds, some observers will see the rectangle curve and others will see it move along a straight path. And when the display remains unchanged but the area between the rectangles is shaded, then the rectangle appears to move along the shaded path. Thus, one can direct the motion of the rectangle along almost arbitrary paths (e.g., [Shepard & Zare 1983](#)). Such demonstrations reveal that the very notion of error or discrepancy between physical stimulus and percept becomes shaky. It seems rather arbitrary whether the researcher considers only the rectangles to be the relevant stimulus or also considers the background to be part of the stimulus. In these AM displays, the visual system appears to make sense of the entire display, not just the two moving rectangles.

3 The case for illusion_m

Such resolution of the underspecification problem can even annihilate an existing illusion_d. Consider the sophisticated AM display we encounter when going to the movies. And let us take the old-fashioned kind, where the projection screen is black most of the time, only interrupted 24 times a second by a very brief flash of a stationary picture. Smooth motion is perceived. Here, the observer is typically unaware of the illusion_d, but what is perceived is actually closer to the original scene than to the movie that was made from it. We might even entertain the idea that there is no illusion_d, since the percept is very close to the original scene that was

filmed. Now, calling apparent motion illusory_d when dealing with artificial or computer-generated stimuli, but veridical when dealing with a movie, does not seem to make much sense. This is because, in a very deep sense, the visual system has no way of distinguishing between actual motion and snapshot motion. The hardware we use to detect motion is built such that it is unable to differentiate between the two. Basically, the detector for motion is designed such that successive excitations of the receptive fields of two motion-sensitive neurons lead to the impression of motion. These Reichardt/Hassenstein detectors ([Hassenstein & Reichardt 1956](#)) are discrete; they cannot tell the difference between continuous and stroboscopic motion (see e.g., [Hecht 2006](#)). Note that this holds for phi-motion but falls apart when ISI or duty cycle are changed.

Figure 2: Simultaneous color contrast: The orange and the yellow squares are of the same respective color in the panel on the left and on the right.

Let us now look at an example from the color domain to further challenge the notion of illusion_d. The phenomenon of color constancy lets us perceive the same color even if the ambient lighting changes dramatically. We see an object as blue regardless of whether the room is lit by a neon light or by sunlight. It would not make sense to call the percept of “blue” an illusion_d under neon light when the ambient lighting is such that the object mainly reflects wave lengths of say 500 nm and to call it veridical when it is lit by sunlight such that the domin-

ant wavelength is 450 nm. In both cases, the object appears blue. We cannot determine in principle which of the two cases deserves the name *illusion_d*, if any, or if both deserve to be called *illusion_d*. In contrast, when the two cases are juxtaposed, an *illusion_m* becomes manifest. In Figure 2, the center inner square surrounded by red on the left and the outer squares surrounded by yellow on the right are of an identical color, as becomes manifest when occluding the surrounds. Thus, *illusion_m* becomes apparent, but *illusion_d* cannot be defined in any meaningful way.

4 Conclusion

In sum, the role of illusions in vision research has historically been very important. The beginnings of experimental psychology have attempted to measure *illusions_d* in terms of the discrepancy or error between physical stimulus and percept. I have attempted to show that this error is neither substantial enough to serve as a definition of illusion, nor particularly fascinating. Instead, *illusions_d* are as ubiquitous as they are typically unnoticed or indeterminate. In contrast, the cases that engage our imagination usually are manifest *illusions_m*. The latter can be defined even in cases where it is not meaningful to speak of *illusion_d*.

The Neural Organ Explains the Mind

Jakob Hohwy

The free energy principle says that organisms act to maintain themselves in their expected states and that they achieve this by minimizing their free energy. This corresponds to the brain's job of minimizing prediction error, selective sampling of sensory data, optimizing expected precisions, and minimizing complexity of internal models. These in turn map on to perception, action, attention, and model selection, respectively. This means that the free energy principle is extremely ambitious: it aims to explain *everything* about the mind. The principle is bound to be controversial, and hostage to empirical fortune. It may also be thought preposterous: the theory may seem either too ambitious or too trivial to be taken seriously. This chapter introduces the ideas behind the free energy principle and then proceeds to discuss the charge of preposterousness from the perspective of philosophy of science. It is shown that whereas it is ambitious, controversial and needs further evidence in its favour, it is not preposterous. The argument proceeds by appeal to: (i) the notion of inference to the best explanation, (ii) a comparison with the theory of evolution, (iii) the notion of explaining-away, and (iv) a "bio-functionalism" account of Bayesian processing. The heuristic starting point is the simple idea that the brain is just one among our bodily organs, each of which has an overall function. The outcome is not just a defence of the free energy principle against various challenges but also a deeper anchoring of this theory in philosophy of science, yielding an appreciation of the kind of explanation of the mind it offers.

1 The brain and other organs

Many organs in the body have a fairly specific main function, such as cleaning or pumping blood, producing bile, or digesting. Nothing is ever simple, of course, and all the organs of the body have highly complex, interconnected functional roles. The digestive system involves many different steps; the kidneys help regulate blood pressure; while the heart changes the way it pumps in a very complex and context-dependent manner. Experts in different areas of human biology have a wealth of knowledge about the morphology and physiology of organs, at multiple levels of description. For example, much is known about what cellular and molecular processes occur as the kidneys filter blood, or as food is digested. Knowledge about the functions of organs is not yet complete, but there is reasonable agreement about

the overall picture—namely, which organs have what function.

But the brain seems different. There is much less agreement about what is its main function, and much less knowledge about how it fulfills the various functions attributed to it. Of course, everyone agrees that the brain subserves perception, decision-making, and action—and perhaps that it is the seat of consciousness, self and soul. There is a reasonable degree of knowledge about some aspects of the brain, such as the mechanism behind action potentials, and about what happens when neurons fire. But most would agree that it would be controversial or even preposterous to claim that there is one main function of the brain, on a par with the heart's pumping of blood.

Yet there is an emerging view that claims that the brain has one overarching function. There is one thing the brain does, which translates convincingly to the numerous other functions the brain is engaged in. This chapter will introduce this idea and will show that, whereas it may be controversial, the idea is not preposterous. It will help us understand better all the things that the brain does, how it makes us who we are, and what we are.

The main version of the idea is labeled the free energy principle, and was proposed by [Karl Friston \(2010\)](#). It unifies and develops a number of different strands of thinking about the brain, about learning, perception and decision-making, and about basic biology. The principle says that biological organisms on average and over time act to minimize free energy. Free energy is the sum of prediction error, which bounds the surprise of the sensory input to the system. Put one way, it is the idea that brains are hypothesis-testing neural mechanisms, which sample the sensory input from the world to keep themselves within expected states. Generalizing greatly, one might say that, just as the heart pumps blood, the brain minimizes free energy.

Before moving on to introduce and defend this idea, it will be useful to explain why the analogy to the functions of other organs is apt. Once a function is identified it serves as a unifying, organizing principle for understanding what the organ does. For example, even though the heart acts very differently during rest and exercise, it still pumps blood. Similarly, even though the brain acts very differently during the awake state and during sleep it still minimizes free energy. Taking such a general approach therefore helps to provide a unified account of the brain.

Related to this, there is a type of objection that will have little bite on the organ-focused account of the brain. To see this, consider again the heart. The heart pumps blood, and this function is realized in part by the way the contraction of the heart muscle occurs—a process that depends on intricate ion flows across heart cell membranes. One should not object to the notion that the heart pumps blood by referring to the fact that what happens in the heart is an intricate cellular ion flow. This is so even

though one might be able to understand much about the heart just by being told the cellular and molecular story. The story about the function and the story about a level of realization of that function are not in conflict with each other. Similarly, one cannot object to the free energy principle by pointing to facts about what the brain does (e.g., what happens as action potentials are generated, or as long-term potentiation is instantiated). The reason for this is that those low-level processes might be ways of realizing free energy minimization. At best such objections are calls for explanatory work of the sort “how can the generation of action potentials be realizations of free energy minimization?”

These two points together suggest that the functional, organ-based account of the brain is reductionist in two ways (familiar from discussions in philosophy of science). On the one hand it seeks to reduce all the different things the brain does to one principle, namely free energy minimization. This is a kind of theory reduction, or explanatory unification. It says that one theory explains many different things. On the other hand, it is consistent with a kind of metaphysical reduction where the overall function is in the end realized by a set of basic physical processes. Here, mental function is fully physical and fully explained by free energy minimization. It is interesting to note that no one would object to such a two-fold reductionism for the heart and other organs, yet it is controversial or even preposterous to do so for the organ that is the brain. For these reasons, it is useful to keep in mind the simple idea that the brain is also an organ. Much of the discussion in this chapter revolves around these two reductive aspects: how can the free energy principle *explain everything*? And can it provide the *functional* scaffolding that would allow realization by brain activity?

2 Minimizing free energy (or average prediction error minimization)

Consider the following very broad, very simple, but ultimately also very far-reaching claim: the brain’s main job is to maintain the organism within a limited set of possible states. This is a

fairly trivial claim, since it just reflects that there is a high probability of finding a given organism in some and not other states, combined with the obvious point that the organism's brain, when in good working order, helps explain this fact. It is the brain's job to prevent the organism from straying into states where the organism is not expected to be found in the long run. This can be turned around such that, for any given organism, there is a set of states where it is expected to be found, and many states in which it would be surprising to find it. This is surely an entirely uncontroversial observation: we don't find all creatures with equal probability in all possible states (e.g., in and out of water). Indeed, since an organism's phenotype results from the expression of its genes together with the influence of the environment, we might define the phenotype in terms of the states we expect it to be found in, on average and over time: different phenotypes will be defined by different sets of states. This way of putting it then defines the brain's job: it must keep the organism within those expected states. That is, the brain must keep the organism out of states that are surprising given the organism it is—or, in general, the brain must minimize surprise (Friston & Stephan 2007).

Here surprise should not be understood in commonsense terms, in the way that a surprise party, say, is surprising. "Surprise" is technically surprisal or self-information, which is a concept from information theory. It is defined as the negative log probability of a given state, such that the surprise of a state increases the more improbable it is to find the creature in that certain state (in this sense a fish out of water is exposed to a lot of surprise). Surprise is then always relative to a model, or a set of expectations (being out of water is not surprising given a human being's expectations). States in which an organism is found are described in terms of the causal impact from the environment on the organism (for example, the difference to the fish between being in water and being out of water). This, in turn, can be conceptualized as the organism's sensory input, in a very broad sense, including not just visual and auditory input but also important aspects of sensation like ther-

moreception, proprioception, and interoception. Surprising states are then to be understood as surprising sensory input, and the brain's job is to minimize the surprise in its sensory input—to keep the organism within states in which it will receive the kind of sensory input it expects.

To be able to use this basic idea about the brain's overall function in an investigation of all the things minds do we need to ask how the brain accomplishes the minimization of surprise. It cannot assess surprise directly from the sensory input because that would require knowing the relevant probability distribution as such. To do this it would need to, impossibly, average over an infinite number of copies of itself in all sorts of possible states in order to figure how much of a surprise a given sensory input might be. This means that to do its job, the brain needs to do something else; in particular it must harbor and finesse a model of itself in the environment, against which it can assess the surprise of its current sensory input. (The model concerns expected sensory states, it is thus a model of the states of the brain, defined by the sensory boundary in both interoceptive and exteroceptive terms, see Hohwy 2014.)

Assume then that the brain has a model—an informed guess—about what its expected states are, and then uses that model to generate hypotheses that predict what the next sensory input should be (this makes it a generative model). Now the brain has access to two quantities, which it can compare: on the one hand the predicted sensory input, and on the other the actual sensory input. If these match, then the model is a good one (*modulo* statistical optimization). Any difference between them can be conceived as prediction error, because it means that the predictions were erroneous in some way. For example, if a certain frequency in the auditory input is predicted, then any difference from what the actual auditory input turns out to be is that prediction's error.

The occurrence of prediction error means the model is not a good fit to the sensory samples after all, and so, to improve the fit, the overall prediction error should be minimized. In the course of minimizing prediction error, the brain averages out uncertainty about its model,

and hence implicitly approximates the surprise. It is guaranteed to do this by minimizing the divergence between the selected hypothesis and the posterior probability of the hypothesis given the evidence and model. The guarantee stems from the facts that this is a Kullback-Leibler divergence (KL-divergence) which is always zero (when there is no divergence) or positive (when there is prediction error), and which therefore creates an upper bound on the surprise—minimizing this bound will therefore approximate surprise.

The key notion here is that the brain acts to maintain itself within its expected states, which are estimated in prediction error minimization. This is known as the free energy principle, where free energy can be understood as the sum of prediction error (this and the following is based on key papers, such as [Friston & Stephan 2007](#), [Friston 2010](#), as well as introductions in [Clark 2013](#) and [Hohwy 2013](#)). Prediction error minimization itself instantiates probabilistic, Bayesian inference because it entails that the selected hypothesis becomes the true posterior, given evidence and model. On this view, the brain is a model of the world (including itself) and this model can be considered the agent, since it acts to maintain itself in certain states in the world.

3 Varieties of prediction error minimization

The central idea here is that, on average and over the long run, surprising states should be avoided, or, prediction error should be minimized. Prediction error minimization can occur in a number of ways, all familiar from debates on inference to the best explanation and many descriptions of scientific, statistical inference.

First, the model parameters can be revised in the light of prediction error, which will gradually reduce the error and improve the model fit. This is perception, and corresponds to how a scientist seeks to explain away surprising evidence by revising a hypothesis. This perceptual process was alluded to above.

Slightly more formally, this idea can be expressed in terms of the free energy principle in

the following terms. The free energy (or sum of prediction error) equals the negative log probability of the sensory evidence, given the model (the surprise) + a KL-divergence between the selected hypothesis (the hypothesis about the causes of the sensory input, which the system can change to change the free energy), and the true posterior probability of the hypothesis given the input and model. Since the KL-divergence is never negative, this means that the free energy will bound (be larger than) the surprise. Therefore, the system just needs to minimize the divergence to approximate the surprisal.

Second, the model parameters can be kept stable and used to generate predictions—in particular, proprioceptive predictions, which are delivered to the classic reflex arcs and fulfilled there until the expected sensory input is obtained. This is action, and corresponds to how a scientist may retain a hypothesis and control the environment for confounds until the expected evidence obtains. Since action is prediction error minimization with a different direction of fit, it is labeled active inference.

Slightly more formally (and still following Friston), this notion of action arises from another reorganization of the free energy principle. Here, free energy equals complexity minus accuracy. Complexity may be taken as the opposite of simplicity, and is measured as a KL-divergence between the prior probability of the hypothesis (i.e., before the evidence came in) and the hypothesis selected in the light of the evidence. Intuitively, this divergence is large if many changes were made to fit the hypothesis—that is, if the hypothesis has significant complexity compared to the old hypothesis. Accuracy is the surprise about the sensory input given the selected hypothesis—that is, how well each hypothesis fits the input. Free energy is minimized by changing the sensory data, such that accuracy increases. If the selected hypothesis is not changed, then this amounts to sampling the evidence selectively such that it becomes less surprising. This can only happen through action, where the organism re-organizes its sensory organs or whole body, or world, in such a way that it receives the expected sensory data (e.g., holding something closer in order to smell it).

There are further questions one must ask about action: how are goals chosen and how do we work out how to obtain them? The free energy principle can be brought to bear on these questions too. In a very basic way, our goals are determined by our expected interoceptive and proprioceptive states, which form the basis of homeostasis. If we assume that we can approximate these expected states, as described above, what remains is a learning task concerning how we can maintain ourselves in them. This relies on internal models of the world, including, crucially, modeling how we ourselves, through our action, impact on the sensory input that affects our internal states. Further, we need to minimize the divergence between, on the one hand, the states we can reach from a given point and, on the other, the states we expect to be in. Research is in progress to set out the details of this ambitious part of the free energy program.

Third, the model parameters can be simplified (cf. complexity reduction), such that the model is not underfitted or overfitted, both of which will generate prediction error in the long run. This corresponds to Bayesian model selection, where complexity is penalized, and also to how a scientist will prefer simpler models in the long run even though a more complex model may fit the current evidence very well. The rationale for this is quite intuitive: a model that is quite complex is designed to fit a particular situation with particular situation-specific, more or less noisy, interfering factors. This implies that it will generalize poorly to new situations, on the assumption that the world is a fairly noisy place with state-dependent uncertainty. Therefore, to minimize prediction error in the long run it is better to have less complex models. Conversely, when encountering a new situation, one should not make too radical changes to one's prior model. One way to ensure this is to pick the model that makes the least radical changes but still explains the new data within expected levels of noise. This is just what Bayesian model selection amounts to, and this is enshrined in the formulations of the free energy principle. A good example of this is what happens during sleep, when there is no trustworthy sensory input and the brain instead

seems to resort to complexity reduction on synthetic data (Hobson & Friston 2012).

Fourth, the hypotheses can be modulated according to the precision of prediction error, such that prediction error minimization occurs on the basis of trustworthy prediction error; this amounts to gain control, and functionally becomes attention. This corresponds to the necessity for assessment of variance in statistical inference, as well as to how a scientist is guided by, and seeks out, measurements that are expected to be precise more than measurements that are expected to be imprecise.

Precision optimization is attention because it issues in a process of weighting some prediction errors more than others, where the weights need to sum to one in order to be meaningful. Hence, peaks across the prediction error landscape reflect both the magnitude of the prediction error per se and the weight given to that error based on how precise it is expected to be. This moves the prediction error effort around, much like one would expect the searchlight of attention to move around.

Within this framework, there is room for both endogenous and exogenous attention. Endogenous attention is top-down modulation of prediction error gain based on learned patterns of precision. Exogenous attention is an intrinsic gain operation on error units, sparked by the current signal strength in the sensory input; this is based on a very basic learned regularity in nature, namely that strong signals tend to have high signal to noise ratio—that is, high precision.

In all this, there is a very direct link between perception, action, and attention, which will serve to illustrate some of the key characteristics of the framework. In particular, expected precision drives action such that sensory sampling is guided by hypotheses that the system expects will generate precise prediction error. A very simple example of this is hand movement. For hand movement to occur, the system needs to prioritize one of two competing possible hypotheses. The first hypothesis is that the hand is *not* moving, which predicts a particular kind of (unchanging) proprioceptive and kinesthetic input; the second hypothesis is (the

false one) that the hand *is* moving, which predicts a different (changing) flow of proprioceptive and kinesthetic input. Movement will only occur if the second hypothesis is prioritized, which corresponds to the agent harboring the belief that the hand is actually moving. If this belief wins, then proprioceptive predictions are passed to the body, where classic reflex arcs fulfill them. Movement is then conceived as a kind of self-fulfilling prophecy.

A crucial question here is how the actually false hypothesis might be prioritized, given that the actually true hypothesis (that the agent is not moving) has evidence in its favor (since the agent is in fact not moving). Here expected precisions play a role, which means that action essentially turns into an attentional phenomenon: in rather revisionist terms, agency reduces to self-organisation guided by long term prediction error minimization. Hypotheses can be prioritized on the basis of their expected precision: hence if future proprioceptive input is expected to be more precise than current proprioceptive input, the gain on the current input will be turned down, depriving the hypothesis that the agent is not moving of evidence. Now the balance shifts in favor of the actually false hypothesis, which can then begin to pass its predictions to the sensorimotor system. This rather inferential process is then what causes movement to occur. It is an essentially attentional process because acting occurs when attention is withdrawn from the actual input (Brown et al. 2013).

The outstanding issue for this story about what it takes to act in the world is why there is an expectation that future proprioceptive input will be more precise than the current input. One possibility here is that this is based on a prior expectation that exploration (and hence movement) yields greater prediction error minimization gains in the long run than does staying put. Conversely, this is the expectation that the current state will lose its high-precision status over time. Writ large, this is the prior expectation concerning precisions (i.e., a hyperprior), which says that the world is a changing place such that one should not retain the same hypotheses for too long: when the pos-

terior probability of a hypothesis becomes the new prior, it will soon begin to decrease in probability. This is an important point because it shows that the ability to shift attention around in order to cause action is not itself an action performed by a homunculus. Rather, it is just a further element of extracting statistical information (about precisions) from the world.

4 Hierarchical inference and the recapitulating, self-evidencing, slowing brain

A system that obeys the free energy principle minimizes its free energy, or prediction error, on average and over time. It does this through perception, belief updating, action, attention, and model simplification. This gives us the outline of a very powerful explanatory mechanism for the mind. There is reason to think that much of this explanatory promise can be borne out (Clark 2013; Hohwy 2013).

This mechanism shapes and structures our phenomenology—it shapes our lived, experienced world. A good starting point for making good on this idea is the notion of hierarchical inference, which is a cornerstone of prediction error minimization.

Conceive of prediction error minimization as being played out between overlapping pairs of interacting levels of processing in the brain. A pair has a lower level receives input, and a higher level that generates predictions about the input at the lower level. Predictions are sent down (or “backwards”) where they attenuate as well as possible the input. Parts of the input it cannot attenuate are allowed to progress upwards, as prediction error. The prediction error serves as input to a new pair of levels, consisting of the old upper level, which is now functioning as lower input level, and a new upper level. This new pair of levels is then concerned with predicting the input that wasn’t predicted lower down. This layering can then go on, creating in the end a deep hierarchy in our brains (and perhaps a more shallow hierarchy in some other creatures). The messages that are passed around in the hierarchy are the sufficient statistics: predictions and prediction errors concern-

ing (1) the means of probability distributions (or probability density functions) associated with various sensory attributes or causes of sensory input out there in the world, and (2) the precisions (the inverse of variance) of those distributions, which mediate the expected precisions mentioned above.

The hierarchy gives a deep and varied empirical Bayes or prediction error landscape, where prior probabilities are “empirical” in that they are learned and pulled down from higher levels, so they do not have to be extracted *de novo* from the current input. This reliance on higher levels means that processing at one level depends on processing at higher levels. Such priors higher up are called hyperparameters, for expectations of means, and hyperpriors for expectations of precisions.

The key characteristics of the hierarchy are *time and space*. Low levels of the hierarchy deal with expectations at fast timescales and relatively small receptive fields, while higher levels deal with expectations at progressively slower timescales and wider receptive fields. That is, different levels of the hierarchy deal with regularities in nature that unfold over different spatiotemporal scales. This gives a trade-off between detail and time horizon such that low down in the hierarchy, sensory attributes can be predicted in great detail but not very far into the future, and higher in the hierarchy things can be predicted further into the future but in less detail. This is essential to inference because different causal regularities in nature, working at different time scales, influence each other and thereby create non-linearities in the sensory input. Without such interactions, sensory input would be linear and fairly easy to predict both in detail and far into the future. So the temporal organization of the hierarchy reflects the causal order of the environment as well as the way the causes in the world interact with each other to produce the flow of sensory input that brains try to predict.

The structure of the hierarchy in the brain, and thereby the shape of the inferences performed in the course of minimizing prediction error, must therefore mimic the causal order of the world. This is one reason why hier-

archical inference determines the shape and structure of phenomenology, at least to the extent that phenomenology is representational. The way inference is put together in the brain recapitulates the causes we represent in perception. Moreover, this is done in an integrated fashion, where different sensory attributes are bound together under longer-term regularities (for example, the voice and the mouth are bound together under a longer-term expectation about the spatial trajectories of people). This immediately speaks to long-standing debates in cognitive science, concerning for example the binding problem and cognitive penetrability (for which see Chs. 5-6 in Hohwy 2013). Though there is, of course, much more to say about how prediction error minimization relates to phenomenology, so far this suggests that there is some reason to think the austere prediction error minimization machine can bear out its explanatory promise in this regard.

Goals and actions are also embodied in the cortical hierarchy. Goals are expectations of which states to occupy. Actions ensue, as described above, when those expected states, which may be represented at relatively long timescales, can confidently be translated into policies for concrete actions fulfilled by the body. There are some thorny questions about what these goals might be and how they are shaped. One very fundamental story says that our expected states are determined by what it takes to maintain homeostasis. We are creatures who are able to harness vast and deep aspects of the environment in order to avoid surprising departures from homeostasis; though this opportunity comes with the requirement to harbor an internal model of the environment. Reward, here, is then the absence of prediction error, which is controlled by using action to move around in the environment, so as to maintain homeostasis on average and in the long run.

Taking a very general perspective, the brain is then engaged in maintaining homeostasis, and it does so by minimizing its free energy, or prediction error. Minimization of prediction error entails building up and shaping a model of the environment. The idea here is very simple. The better the model is at minimizing

prediction error the more information it must be carrying about the true causes of its sensory input. This means that the brain does its job by recapitulating the causal structure of the world—by explaining away prediction error, the brain is essentially becomes a deeply structured mirror of the world. This representational perspective is entailed by the brain's efforts to maintain itself in a low entropy or free energy state. This means that we should not understand the brain as first and foremost in the business of representing the world, such that it can act upon it—which may be an orthodox way of thinking about what the brain does. Put differently, the brain is not selected for its prowess in representation per se but rather for its ability to minimize free energy. Even though this means representation is not foundational in our explanation of the brain, it doesn't mean that representation is sidelined. This is because we don't understand what free energy minimization is unless we understand that it entails representation of the world. (This formulation raises the issue of the possibility of misrepresentation in prediction error minimization, for discussion see [Hohwy 2013](#), Chs. 7-8.)

The brain can be seen, then, as an organ that minimizes its free energy or prediction error relative to a model of the world and its own expected states. It actively changes itself and actively seeks out expected sensory input in an attempt to minimize prediction error. This means the brain seeks to expose itself to input that it can explain away. If it encounters a change in sensory input that it cannot explain away, then this is evidence that it is straying from its expected states. Of course, the more it strays from its expected states, the more we should expect it to cease to exist. Put differently, the brain should enslave action to seek out evidence it can explain away because the more it does so, the more it will have found evidence for its own existence. The very occurrence of sensory input that its model can explain away becomes an essential part of the evidential basis for the model. This means the brain is self-evidencing ([Hohwy 2014](#)), in that the more input it can explain away, the more it gains evidence for the

correctness of the model and thereby for its own existence.

The notions of recapitulation of the world and of self-evidencing can be captured in an exceedingly simple idea. The brain maintains its own integrity in the onslaught of sensory input by *slowing down* and controlling the causal transition of the input through itself. If it had no means to slow down the input its states would be at the mercy of the world and would disperse quickly. To illustrate, a good dam-builder must slow down the inflow of water by slowing down and controlling it with a good system of dams, channels, and locks. This dam system must in some sense anticipate the flows of water in a way that makes sense in the long run and that manages flows well on average. The system will do this by minimizing “flow errors”, and it and its dynamics will thereby carry information about—recapitulate—the states of water flow in the world on the other side of the dam. In general, it seems any system that is able to slow the flow of causes acting upon it must be minimizing its own free energy and thereby be both recapitulating the causes and self-evidencing ([Friston 2013](#)).

With these extremely challenging and abstract ideas, the brain is cast as an organ that does one thing only: minimize free energy and thereby provide evidence for its own existence. Just as the heart can change its beat in response to internal and external changes, the brain can change its own states to manage self-evidencing according to circumstances: perceive, act, attend, simplify. The weighting between these ways of minimizing prediction error is determined by the context. For example, it may be that learning is required before action is predicted to be efficient, so perception produces a narrow prediction error bound on surprise before action sets in, conditional on expected precisions; or perhaps reliable action is not possible (which may happen at night when sensory input is so uncertain that it cannot be trusted) and therefore the brain simplifies its own model parameters, which may be what happens during sleep ([Hobson & Friston 2012](#)).

This is all extremely reductionist, in the unificatory sense, since it leaves no other job for

the brain to do than minimize free energy—so that everything mental must come down to this principle. It is also reductionist in the metaphysical sense, since it means that other types of descriptions of mental processes must all come down to the way neurons manage to slow sensory input.

The next sections turn to the question of whether this extreme explanatory and reductionist theory is not only controversial and ambitious but also preposterous.

5 A preposterous principle? Comparing the free energy principle with evolution

One way to curtail the free energy principle is to allow that the idea of a hypothesis-testing mechanism in the brain may be useful for some but *not all* purposes. Thus the idea could explain, say, visual illusions, but not action. Indeed, versions of the idea in this curtailed form have surfaced many times in the history of philosophy of mind, vision science, and psychology (see [Hohwy 2013](#), Introduction). One view would be that evolution very likely has recruited something like hypothesis-testing, such that the brain can represent the world, but that this likely co-exists with many other types of mechanism that the brain makes use of, for good evolutionary reasons. From this perspective, the universal ambition of the free energy principle is preposterous because it goes against the evolutionary perspective of a tinkering, cobbled-together mechanism.

It is possible of course that a limited-use, Bayesian neural mechanism has evolved in this way. There is no strong evidence that there is in fact something like a circumscribed, modular mechanism. For example, Bayes optimal integration seems to work across modalities and types of sensory attributes ([Trommershäuser et al. 2011](#)). On the other hand, there is not yet strong empirical evidence for the ubiquitousness of free energy minimization, though there is emerging evidence of its usefulness for explaining a very surprising range of mental phenomena, from visual perception, illusion, movement, decision, and action.

Speaking more conceptually, the free energy principle is not a theory that lends itself

particularly well to piecemeal, curtailed application. Recall that the principle concerns the very shape and structure of the brain, mirroring as it does the causal structure of the world. The very hierarchical morphology of the organ is shaped by free energy minimization. This means that other neural mechanisms, that are not involved in prediction error minimization, would have to have evolved in a way parasitic on the free energy principle rather than alongside it. In this sense, the free energy principle would, at the very least, lay the foundation for everything else. Against this, it could be said that perhaps parts of the brain are not, strictly speaking, part of hierarchical inference. Perhaps subcortical nuclei have evolved independently of free energy. This is therefore an argument for which empirical evidence would be important: are there areas of the brain that are not best described in terms of prediction error message passing?

Continuing the very general approach, the free energy principle has such generality that it tends to monopolize explanation. To demonstrate this, consider the theory of evolution, which is also an extremely ambitious theory in the sense that it aims to explain all parts of biology with just a few very basic tools. It is conceptually possible to curtail this theory: perhaps it explains only 70% of life, leaving some other mechanism to explain the rest, or perhaps it explains only non-human life, leaving some deity to fully explain us. This kind of curtailed view would of course ignore the mountain of evidence there is for evolution in absolutely all parts of life (a point we will revisit in a moment), but it would also miss something about the kind of theory that the theory of evolution is. It seems that, as an explanation, evolution is so powerful that it would be incredible that something else would be equally able to explain life.

Whereas it cannot be stipulated that the theory of evolution is true universally, it can be argued that if it is true, it is true everywhere. To see this, consider that if incontrovertible evidence was found that evolution does not explain, say, the eight eyes of most spiders, then for most people that would cast aspersions on the theory of evolution in all other areas—even

where it is backed up with overwhelmingly strong evidence. This is not simply to say that some recalcitrant evidence lowers the posterior probability of the theory somewhat, but rather that it would begin to completely undermine the theory. It seems the theory of evolution posits such a fundamental mechanism that anything short of universal quantification would invalidate it.

Perhaps we can describe what goes on in terms of “explaining away” (Pearl 1988). Imagine, for example, that one night the electricity in your house cuts out. You consider two hypotheses: that a possum has torn down the power line to your house, or that the whole neighbourhood has blacked out due to the recent heat wave. Out in the street you see other people checking their fuse boxes and this evidence favours the second hypothesis. Importantly, this evidence considerably lowers the probability of the possum hypothesis even though the two hypotheses could be true together. There is debate about what explaining away really is, but agreement that it exists. Part of what grounds this notion is that our background knowledge of the frequency of events tells us that it would be rather an unusual coincidence if, just as the overall power goes out due to the heat wave, a possum caused the line to go down (unless possums are known to take to power lines during heat waves). In the case of the deity hypothesis and the evolutionary hypothesis, it seems that explaining away is particularly strong. It would be an utterly astounding coincidence if something as fundamental as speciation and adaptation had two coinciding explanations.

After this excursion into philosophy of science, we can return to the free energy principle. Though it still has nothing like the amount of evidence in its favour that evolution has, it seems that if it is true then it too must apply everywhere, and if not then it must be false. There is no middle way. This again seems to relate to explaining away. It would be too much of a coincidence if two explanations both accounted for something as fundamental as the organism’s ability to sustain itself in its expected states. If the principle was directed at only fairly superficial aspects of mentality, such as

the nature of visual illusions, then it would not strongly explain away other theories. But this misrepresents how deep the explanatory target actually is.

The issue was whether the explanatory ambition of the free energy principle can be curtailed, in order to make it seem less preposterous. If it is assumed that explaining away is particularly strong for fundamental rather than superficial explanations, then it appears that a principle as fundamental as the free energy principle cannot be curtailed. If it is believed, then it is believed with maximal scope. It is therefore misguided to think that one can take a divide and conquer approach to the free energy principle.

Of course, this can be taken to cement its preposterousness. If it is a hypothesis designed to be universal, then how can it be anything but preposterous? The immediate answer to this lies in comparing it again to the theory of evolution. This venerable theory must be preposterous in just the same way, but of course it isn’t—it is true. This means that the issue whether the free energy principle is preposterous cannot be decided just by pointing to its explanatory ambition, since this would also invalidate the theory of evolution. Not surprisingly, it must be resolved by considering the evidence in favour of the free energy principle. As mentioned, this does not yet compare to that of the theory of evolution, though it is noteworthy that evidence is coming in, and that it is coming in from research on a comfortably large suite of mental phenomena.

Consider next the question of what happens with existing, competing theories once something like the free energy principle or the theory of evolution begins to gain explanatory force. Existing theories may have considerable evidence in their favour (this may be a theory about a cognitive or perceptual domain, such as attention or illusion); and they may explain away the existing evidence relatively well and therefore have that evidence in their favour (this contrasts with the comparison with the deity hypothesis, which strictly speaking has no evidence in its favour). Nevertheless, once additional, relevant evidence becomes available, ex-

isting theories may begin to lose ground to a new theory, like the free energy principle, even if it as yet has less evidence in its favour. For example, once it is noted that the brain is characterized by plentiful backwards connections, it becomes clear that these must be relevant to phenomena like attention and illusion (for example, disrupting them disrupts attention and illusion). However, if existing theories cannot explain this new evidence, then a new theory can begin to usurp their explanatory job. This means the evidence in their favour begins to wane, even if the new theory is still only enjoying spotty support. Compare again to the electricity blackout example. There might be a very impressive theory of the whereabouts and heat wave-related behavior of possums that very snugly explains the blackout in the house and perhaps other things besides. But the moment we become aware that the whole neighborhood is without electricity, even a poor theory of the blackout that can also address this new evidence (“perhaps it is some central distributor thingamajig that has broken down”) becomes much more attractive than the existing possum theory. New evidence and new theories can very quickly wreak havoc on old, cherished theories. The free energy principle should therefore be expected to usurp the explanatory jobs of existing theories, and thereby challenge them, even if it is still a fairly fledgling theory. Of course, explanatory usurpation depends on acknowledging the occurrence of new evidence, such as the presence of backwards connections in the brain. Perhaps it is no surprise that the free energy principle is beginning to gain ground just as imaging brain science is maturing beyond the phase in which it was concerned mainly with collecting new evidence, and on to a new phase in which researchers consider the theoretical significance of the evidence in terms of both functional specificity and effective connectivity.

6 Predictions, distinctness, fecundity

It will be useful to discuss a concrete example of explanatory contest for the free energy principle. A good example comes from [Ned Block & Susanna Siegel \(2013\)](#) who argue against [Andy](#)

[Clark’s \(2013\)](#) version of the predictive processing framework in a way that pertains to the preceding remarks about explanatory prowess and ambition. In a comparison with an existing theory of attentional effects (proposed by [Marisa Carrasco](#)), they argue first that the predictive framework makes false predictions, and second that it offers no distinctive explanations.

As to the first point, Block and Siegel consider the effect where covert attention to a weak contrast grating enhances its perceived contrast. They argue that this increased contrast should be unexpected and therefore should elicit a prediction error that in turn should be extinguished, thereby annihilating the perceptual effect that the account was meant to explain in the first place. However, their argument does not rely on the correct version of the free energy account of attention. Block and Siegel overlook the fact that attention is itself predictive, in virtue of the prediction of precision. This means that attention enhances the prediction error from the weak grating, which in turn is explained away under the hypothesis that a strong contrast grating was present in that location of visual space. This conception of attention thus does yield a satisfactory account of the phenomenon that they claim cannot be explained (attentional enhancing), and it does not generate the false predictions they suggest ([Hohwy 2013](#)).

Block and Siegel’s second point is more difficult to get straight. They argue that the predictive account offers no explanation of attentional findings, in particular relating to receptive field distortions; they then suggest that the account could adopt the existing theory, which asserts that “representation nodes” have shrinking receptive fields. They continue to argue that since the purported prediction error gain relates to error units in the brain rather than representation nodes, the prediction error account cannot itself generate this explanation. The argument is then that if the prediction processing account simply *borrow*s that explanation (namely the existing explanation in terms of representation nodes), it hasn’t offered anything distinctive. Again, this rests on an incorrect reading of the free energy account: error units

are not insulated from representation units. Error units receive the bottom-up signal and this leads to revision of the predictions generated from the representation units. The outstanding question is how the distortions of receptive fields can be explained within the prediction error account.

This question has been addressed within the predictive coding literature. Thus [Spratling \(2008\)](#), who is a proponent of predictive coding accounts of attention, says (referring to the literature on changing receptive fields to which Block and Siegel themselves appeal) “the [predictive processing] model proposes, as have others before, that the apparent receptive field distortion arises from a change in the pattern of feedforward stimulation received by the cell”. That is, increased gain explains the distortion of the receptive field.

In fact, one might speculate that the predictive processing story makes perfect sense of the existence of modulable receptive fields. The receptive field of a given representational unit would, that is, be a function of the prediction error received from below, where—as described earlier—lower levels operate at smaller spatiotemporal scales. To give a toy illustration, assume that a broad receptive field would receive an equal amount of error signal from ten lower units each with smaller receptive fields, whereas a narrow receptive field receives error only from two such units. For the broad receptive field, if the gain on error from lower unit numbers one and two increases due to attention, then the gain on the other eight units decreases (since weights sum to one). Now, the hitherto broad receptive field mainly receives error from two lower units, so its receptive field has automatically shrunk. Attentional effects thus track the effects of expected precisions.

Here a more specific point can be made about Block and Siegel’s argument. The predictive processing account of attention can potentially offer a distinctive explanation of rather finegrained attentional findings. There is also reason to think that this explanation has more promise than existing theories. This is because the existing theories help themselves to the notion of ‘representational nodes’ whereas the free

energy principle explains what these are, what they do, and how they connect with other nodes. Moreover, the prediction error account can deal very elegantly for key receptive field properties ([Rao & Ballard 1999](#); [Harrison et al. 2007](#)).

This seems to be a good example of the situation outlined earlier with respect to the contest between the free energy principle and existing theories. The free energy principle can explain more types of evidence, under a more unificatory framework, and this immediately begins to undermine existing theories. Specifically, the theory that has no role for prediction error in receptive field modulation and activation only in representation nodes is explained away, even if it has significant evidence in its favour.

Underlying this story, there are some larger issues in the philosophy of science. One issue concerns the role of unification in explanation ([Kitcher 1989](#)). This is the idea that there are explanatory dividends in explanations that unify a variety of different phenomena under one theory. Obviously the free energy principle is a strong, ambitious unifier (perception, action, and attention all fall under the principle). Whereas there is discussion about whether this in itself adds to its explanatory ability as such, the ability to unify with other areas of evidence is part of what makes an explanation *better* than others. Noting this aspect of the free energy principle therefore supports it, in an inference to the best explanation ([Lipton 2004, 2007](#)). Confronted with a piecemeal explanation of a phenomenon and a unificatory explanation of the same phenomenon, the inference to the latter is stronger. There may be some difficult assessments concerning which explanation best deals with the available evidence. In the case discussed above, the free energy principle can explain less of the attention-specific evidence than the piecemeal explanation, but on the other hand it can explain more kinds of evidence, it provides explanatory tools that are better motivated (roles of representation and error 725 units), and it offers a more unifying account overall.

A second issue from the philosophy of science, in particular concerning inference to the

best explanation, is the fecundity of an explanation, which is regarded as a best-maker. The better an explanation is at generating new predictions and ways of asking research questions, the stronger is the inference in its favour. Whereas this is not on its own a decider, it is an important contributor to the comparison of explanatory frameworks. Block and Siegel also seem to suggest that the predictive framework has nothing new to offer, or at least very little compared to existing (piecemeal) theories. Their example of a piecemeal theory is Carrasco's impressive work on attention, which has proven extraordinarily fecund, leading to a series of discoveries about attention. Assessing which theory is the more fecund is difficult, however, and involves considerations of unification. The free energy principle, as described above, does not posit any fundamental difference between perception and action. Both fall out of different re-organisations of the principle and come about mainly as different directions of fit for prediction error minimization (Hohwy 2013, 2014). This means that optimization of expected precisions, and thereby attention, must be central to action as well as to perception. This provides a whole new (and thus fecund) source of research questions for the area of action, brought about by viewing it as an attentional phenomenon. Important modeling work has been done in this regard (Feldman & Friston 2010), age-old questions (such as our inability to tickle ourselves) have been re-assessed (Brown et al. 2013), and new evidence concerning self-tickle has been amassed (Van Doorn et al. 2014). Theoretically, this has led to the intriguing idea that action occurs when attention is withdrawn from current proprioceptive input (described above). This idea points to a fully integrated view of attention, where attention is ubiquitous in brain function (with deep connections to consciousness, Hohwy 2012).

There is thus fecundity on both sides of this debate. It is difficult to conclusively adjudicate which side is more fecund, in part because the new research questions are in different areas and with different theoretical impact. It is surprising to be told that too much attention can undermine acuity—which is an example

from Block and Siegel—but it is also surprising to be told that action is an attentional phenomenon.

The third issue from the philosophy of science concerns theory subsumption. It would be very odd if the explanations associated with the free energy principle (e.g., that attention is optimization of expected precision) completely contradicted all existing, more piecemeal explanations of attention. It should be expected that explanations of attention have some overlap with each other, as they are explaining away overlapping bodies of evidence. Indeed, the free energy explanation seems to subsume elements of biased competition theories of attention, as well as elements of Carrasco's theory, as seen above. This raises the question of to what extent a new theory, like the free energy principle's account of attention, really contributes a new and better understanding, especially if it carries within it elements of older theories. One way to go about this question again appeals to inference to the best explanation. The new and the old theories overlap in some respects, but they differ in respect of further elements of unification, theoretical motivation, broadness, fecundity, and so on. It can be difficult to come up with a scheme for precise assessment of these features, but it seems not unreasonable to say that the free energy principle performs best on at least those further elements of what makes explanations best.

At this stage it is tempting to apply the free energy principle to itself. This is an apt move since the idea of the hypothesis-testing brain arose in comparison with scientific practice (Helmholtz 1867; Gregory 1980). On this view, the point of a good scientific theory is to minimize prediction error as well as possible, on average and in the long run. This imputes an overall weighting of all the very same elements to science as we have ascribed to the brain above: revise theories in the light of evidence, control for confounds by making experimental manipulations, be guided by where highly precise evidence is expected to be found, adopt simple theories that diverge minimally from old theories, and let theories have a hierarchical structure such that they can persist in the face

of non-linearities (due to causal interactions) in the evidence. All of these considerations speak in favour of the free energy principle over piecemeal, existing theories. By absorbing and revising older theories under the hierarchically imposed scientific “hyperparameter” of the free energy principle, it seems a very reasonable weighting of all these aspects can be achieved. For example, aspects of Carrasco’s theory are subsumed, but under revised accounts of its notions of the functional role of representation nodes; due to the hierarchical aspect it is able to account for evidence arising under attentional approaches to action; in addition, this subsumption may be fecund, since we could expect it to lead to new findings in action (for example, a prediction that there will be attentional enhancement in the sensorimotor domain, leading to “illusory action”).

7 The triviality worry

There is a different worry about preposterousness, also related to the issue of evidence. This worry is that the free energy principle is so general that anything the brain does can be construed as minimizing its prediction error. This is most clearly seen once the idea is cast in Bayesian terms. The brain harbours priors about the causes in the environment, and it calculates likelihoods that it combines with the priors to arrive at posterior probabilities for the hypotheses in question. One way to make this story apply to a particular case is to ascertain what is believed and then in a retrodictive fashion, posit priors and likelihoods accordingly unto the brain in question. If this can always be done, then the theory is trivialised by “just-so” stories and explains nothing. It is then preposterous because it pretends to be fundamental but is just trivial.

This triviality worry alerts the defender of the free energy principle to some pitfalls, but it is not a critical worry. To see this, an appeal can again be made to the theory of evolution. It is clear that when described in very general terms, anything can be described as enhancing fitness. For example, in an infamous hoax, Ramachandran gave a ridiculous, just-so adapt-

ationist account of why gentlemen prefer blondes (Ramachandran & Blakeslee 1998), which some reportedly took seriously. Yet, no one serious thinks this invalidates the theory of evolution. The reason is, to repeat, that there is abundant solid, non-trivial evidence in favour of evolution. In other words, the presence of just-so triviality at some level of description can co-exist with non-trivial explanations at the level of detailed, quantifiable evidence. Therefore the free energy principle cannot be invalidated just because it invites just-so stories. Of course, it is then hostage to translation into more precise, constricted applications to various domains, where predictions can be quantified and just-so stories avoided. Though there is nowhere near the same evidence that we have for the theory of evolution, evidence of this sort is becoming available (some is reviewed in Hohwy 2013).

Whereas the triviality worry does not invalidate the free energy principle, it does alert to some pitfalls. In particular, when forming hypotheses and when explaining phenomena in Bayesian terms, priors should not be stipulated independently of other evidence. If there is independent reason for asserting a prior with an explanatory role, then it is less likely that this prior is part of a just-so story. Similarly, discovery and manipulation of priors has a particularly important role in the defence of the free energy principle as applied to perception. For example, there is independent evidence that we expect light to come more or less from above (Adams et al. 2004), that objects move fairly slowly (Sotiropoulos et al. 2011), and that we expect others to look at us (Mareschal et al. 2013). Once established on independent grounds, researchers are better able to appeal to such priors in other explanations. This then helps avoid the just-so pitfall.

The triviality worry was that *everything* we do can be made to fit with the free energy principle. A different worry is that almost *nothing* we do fits with the free energy principle. If the free energy principle basically says the brain is an organ that tries to slow down the causal impact upon it from the world, then why don’t organisms with brains just seek out sensory deprivation such as dark, silent rooms (Friston

et al. 2012)? This dark room problem is aired very often and is natural on first thought when considering prediction error minimization. However, it also rests on a fundamental misreading of the free energy principle. The principle is essentially about maintaining the organism in its expected states, homeostatically defined, on average and in the long run. Locking oneself up in a dark silent room will only produce transitory free-energy minimization, as the demands of the world and the body will not be avoided for long. Soon, action is required to seek food, and soon the local council will come round to switch off the gas. It is much better for the brain to harness the deep model of the world in order to control its movement through the environment and thereby maintain itself more efficiently in its expected states.

Notice that this point harks back to a very basic hyperprior mentioned above—namely that the world is a changing place so that occupying the same state for too long will incur increasing free energy costs. This means that even if you currently have the prior that sensory deprivation is the right strategy for minimizing free energy, and even if this strategy works initially (as it does after a long and stressful day), that prior will decrease in strength as time goes by—leading to action and thus escape from sensory deprivation.

This response to the dark room problem in fact has a parallel in evolutionary theory. It has been argued that the free energy principle is false, essentially because not every action contributes directly to instantaneous prediction-error minimization and, analogously, it could be objected that evolutionary theory is false because not every trait directly contributes to instantaneous fitness. But of course this is a poor objection because fitness is measured over longer timescales and some traits, such as spandrels, contribute indirectly to fitness.

This and the preceding two sections have considered whether the explanatory ambition of the free energy principle is preposterous. By comparing the principle with the theory of evolution, and casting the worry in terms of philosophy of science, it can be seen that the explanatory ambition is not preposterous in and of it-

self. The verdict on the principle must come down to the quality of the explanations it offers and the amount of evidence in its favour. The principle is bound to be controversial, however, because it strongly explains away competing theories.

Of course, there are further issues to explore regarding the analogy between the free energy principle and the theory of evolution, and no doubt the analogy will have its limits. One interesting issue concerns the possibility of theory revision and thereby the possibility that the original statement of a theory is strictly speaking, false, even if it is one of those theories with extreme explanatory scope. The notion of natural selection as the only mechanism behind evolution is, for example, put under pressure by the discovery of genetic drift. This has led to revision of the theory of evolution, to encompass drift. Could something similar happen to the free energy principle, or is it in effect so ambitious that it is unrevisable? Conversely, is there any conceivable evidence that could falsify the current version of the theory in a wholesale fashion, rather than the piecemeal, detailed fashion discussed above? There are various answers available here, all of which reflect the peculiar theory emerging from the free energy principle.

First, the current form of the principle itself results from a long series of revisions of the basic idea that the brain engages in some kind of inference. Helmholtz' and Ibn Al Haytham's original ideas (reviewed briefly in Hohwy 2013) have been greatly revised, particularly in response to the mathematical realisation that the inversion of generative models presents an intractable problem, thus calling for variational Bayesian approaches to approximate inference. These developments occurred partly in concert with the empirical discovery that the brain, as mentioned above, is characterized by massive backwards connectivity. It is then not unreasonable to say that older feed-forward versions of computational, information theoretical (e.g., infomax) theories of cognition constitute earlier versions of the free energy principle and that the latter is a revision in the light of formal and empirical discovery. The analogy with theory of

evolution can thus be maintained in at least this backwards-looking respect.

Second, a more forward-looking example concerns the nature of the backwards connectivity in the brain. The free energy principle deems these descending signals *predictions*, but crucially it needs them to be of two kinds, namely predictions of the means of the underlying level's representations, and, as mentioned briefly above, predictions of the precisions of the underlying representations (thus encompassing sufficient statistics). There is some direct and some circumstantial evidence in favour of this dual role for descending signals, but the empirical jury is still out. Should it be found that descending signals do not mediate expected precisions, this would falsify the free energy principle. Notice that this falsification would be specific to the free energy principle, since the element of expected precisions is not found in some of the much broader theories in the academic marketplace that seem to countenance a predictive element in cognition. Notice also that a failure to identify top-down expectations of precision would amount to a wholesale falsification of the principle, since these “second-order” expectations are crucial not only for perception but also for action and action initiation (as explained above).

Third, and speaking much more generally, the principle would be falsified if a creature was found that did not act at all to maintain itself in a limited set of states (in our changing world). Such a creature should not on average and over time change its model parameters or active states and yet it would be able to prevent itself from being dispersed with equal probability among all possible states. This is a clear notion of a strong falsifier, and it speaks to the beauty of the free energy principle since it showcases its deep link between life and mind. However, it is not a very feasible falsifier because there is significant doubt that we would classify such a ‘creature’ as being alive or being a creature at all. Consider, for example, that a simple rock would serve as a falsifier in this sense since it is maintained on average and over the long run (that is, its states do not immediately disperse). One possibility here ([Friston](#)

[2013](#)) is to require that the scope is restricted to creatures that are space-filling, that is, who visits the individual states making up their overall set of expected states. A falsifier would then be a creature that manages to be space-filling but who does not manage this by changing its internal and active states via variational Bayes.

One nice question, in all of this, is whether the theory of evolution and the free energy principle can co-exist—and if so, how. This is a substantial issue, and a pertinent one, since both theories are fundamental and pertain to some of the same aspects—such as morphology, phenotypes, and life. Here is not the place to try to answer this interesting question, though inevitably some initial moves are made that might start to integrate them.

8 How literally is the brain Bayesian?

Bayes' rule is difficult to learn and takes considerable conscious effort to master. Moreover, we seem to flout it with disturbing regularity ([Kahneman et al. 1982](#)). So it is somewhat hard to believe that the brain unconsciously follows Bayes' rule. This raises questions about how literally we should think of the brain as a Bayesian hypothesis-tester. In blog correspondence, Lisa Bortolotti put the question succinctly:

Acknowledging that prior beliefs have a role in perceptual inference, do we need to endorse the view that the way in which they constrain inference is dictated by Bayes' rule? Isn't it serendipitous that something we came up with to account for the rationality of updating beliefs is actually the way in which our brain unconsciously works?

Part of the beauty of the free energy principle is that even though it begins with the simple idea of an organism that acts to stay within expected states, its mathematical formulation forces Bayesian inference into the picture. Expected states are those with low surprisal or self-information. That is they have high probability given the model (low negative log probability).

These states cannot be estimated directly because that would require already knowing the distribution of states one can be in. Instead it is estimated indirectly, which is where the free energy comes in. Free energy, as mentioned above, is equal to the surprisal plus the divergence between the probability of the hypothesis currently entertained by the brain's states and the true posterior of the hypothesis given the model and the state. This much follows from Bayes' rule itself. This means that if the brain is able to minimize the divergence, then the chosen hypothesis becomes the posterior. This is the crucial step, because a process that takes in evidence, given a prior, and ends up with the posterior probability, as dictated by Bayes, must at least implicitly be performing inference (Friston 2010).

Hence, if the free energy principle is correct, then the brain must be Bayesian. How should this be understood? Consider what happens as the divergence is minimized. Formally this is a Kullback-Leibler divergence (or cross entropy), which measures the dissimilarity between two probability distributions. The KL-divergence can be minimized with various minimization schemes, such as variational Bayes. This plays an important role in machine learning and is used in simulations of cognitive phenomena using the free energy principle. Given the detail and breadth of such simulations, it is not unreasonable to say that brain activity and behavior are describable using such formal methods.

The brain itself does not, of course, know the complex differential equations that implement variational Bayes. Instead its own activity is brought to match (and thereby slow down) the occurrence of its sensory input. This is sufficient to bring the two probability distributions closer because it can only do this if it is in fact minimizing prediction error. This gives a mechanistic realization of the hierarchical, variational Bayes. The brain is Bayesian, then, in the sense that its machinery implements Bayes not serendipitously but necessarily, if it is able to maintain itself in its expected states. (There is discussion within the philosophy of neuroscience about what it means for explanations to be

computational. See papers by Piccinini 2006, Kaplan 2011, Piccinini & Scarantino 2011, Chirimuuta 2014.)

The notion of realization (or implementation, or constitution) is itself subject to considerable philosophical debate. A paradigmatic reading describes it in terms of what plays functional roles. Thus a smoke alarm can be described in terms of its functional role (*i.e.*, what it, given its internal states, does, given a certain input). The alarm has certain kinds of mechanisms, which realize this role. This mechanism may comprise radioactive ions that react to smoke and causes the alarm to sound. The analogy between the smoke alarm and the brain seems accurate enough to warrant the paradigmatic functionalist reading of the way neuronal circuitry implements free energy minimization and therefore Bayes. Perhaps it is in some sense a moot point whether the ions in the smoke alarm “detect smoke” or whether they should merely be described in terms of the physical reactions that happen when they come into contact with the smoke particles. Rather than enter this debate it seems better to return to the point made at the start, when the brain was compared to other organs such as the heart. Here the point was that it is wrong to retract the description of the heart as a blood pump when we are told that no part of the cardiac cells are themselves pumps. The brain is literally Bayesian in much the same sense as the heart is literally a pump.

Behind this conceptual point is a deeper point about what kind of theory the free energy principle gives rise to (the following discussion will be based on Hohwy 2014). As described above, the Bayesian brain is entailed by the free energy principle. Denying the Bayesian brain then requires denying the free energy principle and the very idea of the predictive mind. This is, of course, a possible position that one could hold. One way of holding it is to “go down a level” such that instead of unifying everything under the free energy principle, theories just describe the dynamical causal interactions between brain and world. This would correspond to focusing more on systematic elements in the realization than in the function (looking

at causal interaction between the heart and other parts of the body, and the individual dynamics of the cells making up the heart, rather than understanding these in the light of the heart being a pump). Call this the “causal commerce” position on the brain. Given the extensive and crucial nature of causal commerce between the brain and the world, this is in many ways a reasonable strategy. It seems fair to characterize parts of the enactive cognition position on cognitive science as informed primarily by the causal commerce position (for a comprehensive account of this position, see [Thompson 2007](#); for an account that brings the debate closer to the free energy principle, see [Orlandi 2013](#)).

From this perspective, the choice between purely enactive approaches and inferential, Bayesian approaches becomes methodological and explanatory. One key question is what is accomplished by re-describing the causal commerce position from the more unified perspective of the free energy principle. It seems that more principled, integrated accounts of perception, action, and attention then become available. The more unified position also seems to pull away from many of the lessons of the enactive approach to cognition, because the free energy principle operates with a strict inferential veil between mind and world—namely the sensory evidence behind which hidden causes lurk, which must be inferred by the brain. Traditionally, this picture is anathema to the enactive, embodied approaches, as it lends itself to various forms of Cartesian skepticism, which signals an internalist, secluded conception of mind. A major challenge in cognitive science is therefore to square these two approaches: the dynamical nature of causal commerce between world, body, and brain and the inferential free energy principle that allows their unification in one account. On the approach advocated here, modulo enough empirical evidence, denying that the free energy principle describes the brain is on a par with denying that the heart is a pump. This means that it is not really an option to deny that the brain is inferential. This leaves open only the question of *how* it is inferential.

One line of resistance to subsuming everything under the free energy principle has to do with intellectualist connotations of Bayes. Somehow the idea of the Bayesian brain seems to deliver a too regularized, sequential, mathematical desert landscape—it is like a picture of a serene, computational mechanism silently taking in data, passing messages up and down the hierarchy, and spitting out posterior probabilities. This seems to be rather far from the somewhat tangled mess observed when neuroscientists look at how the brain is in fact wired up. In one sense this desert landscape is of course the true picture that comes with the free energy principle, but there need be nothing serene or regularized about the way it is realized. The reason for this goes to the very heart of what the free energy principle is. The principle entails that the brain recapitulates the causal structure of the world. So what we should expect to find in the brain will have to be approximating the far-from-serene and regularized interactions that occur between worldly causes. Just as there are non-linearly interacting causes in the world there will be convolving of causes in the brain; and just as there are localized, relatively insulated causal “eddies” in the world there will be modularized parameter spaces in the brain.

Moreover, there is reason to think the brain utilizes the fact that the same causes are associated with multiple effects on our senses and therefore builds up partial models of the sensorium. This corresponds to cognitive modules and sensory modalities allowing processing in conditionally independent processing streams, which greatly enhances the certainty of probabilistic inference. In this sense the brain is not only like a scientist testing hypotheses, but is also like a courtroom calling different, independent witnesses. The courtroom analogy is worth pursuing in its own right ([Hohwy 2013](#)), but for present purposes it supports the suggestion that when we look at the actual processing of the brain we should expect a fairly messy tangle of processing streams. ([Clark 2013](#) does much to characterize and avoid this desert landscape but seems to do so by softening the grip of the free energy principle.)

9 Functionalism and biology

So far the free energy principle has been given a functionalist reading. It describes a functional role, which the machinery in the brain realizes. One of the defining features of functionalism is that it allows multiple realization. This is the simple idea that the same function can be realized in different ways, at least in principle. For example, a smoke alarm is defined by its functional role but can be realized in different ways. There is on-going debate about whether something with the same causal profile as the human brain could realize a mind. Philosophers have been fond of imaging, for example, a situation in which the population of Earth is each given a mobile phone and a set of instructions about whom to call and when, which mimics the “instructions” followed by an individual neuron (Block 1976). The question then is whether this mobile phone network would be a mind. Though this is not the place to enter fully this debate, it seems hard for the defender of the free energy principle to deny that, if these mobile phone-carrying individuals are really linked up in the hierarchical message-passing manner described by the equations of the free energy principle, if they receive input from hidden causes, and if they have appropriate active members, then they do constitute a mind.

However, a different issue here is to what extent the free energy principle allows for the kind of multiple realization that normally goes with functionalism. The mathematical formulations and key concepts of the free energy principle arose in statistical physics and machine learning, and hierarchical inference has been implemented in computer learning (Hinton 2007). So there is reason to think that prediction error minimization can be realized by computer hardware as well as brainware. There is also reason to think that within the human brain the same overall prediction error minimization function can be realized by different hierarchical models. Slightly different optimizations of expected precisions would determine the top-down vs. bottom-up dynamics differently, but may show a similar ability to minimize prediction error over some timeframes. Different weightings of low

and high levels in the hierarchy can lead to the same ability to minimize prediction error in the short and medium term. This is similar to how a dam can be controlled with many small plugs close to the dam wall, or by fewer connected dam locks operating at longer timescales further back from the dam wall. In some cases, such different realizations may have implications for the organism over the long run, however (for example, building locks in a dam may take time, and thus allow flows in the interim; whereas many small plugs prevent flows in the short run but may be impractical in the long run). Such differences may show up in our individual differences in perceptual and active inference (for an example, see Palmer et al. 2013), and may also be apparent in mental illness (Hohwy 2013, Ch. 7).

Functionalist accounts of the mind are widely discussed in the philosophical literature, and there are various versions of it. A key question for any functionalism is how the functional roles are defined in the first instance (for an overview see Braddon-Mitchell & Jackson 2006). Some theories—psychofunctionalism or empirical functionalism—posit that functional roles should be informed by best empirical science (“pain is caused by nociceptor activation... etc.”). The consequence is that their domain is restricted to those creatures for whom that empirical science holds. Other theories—commonsense functionalism—begin with conceptual analysis and use that to define the functional roles (“pain is the state such that it is caused by bodily damage, gives rise to pain-avoidance behavior, and relates thus and so to internal states...”). The consequence of taking the commonsense approach is that such functionalisms apply widely, including to creatures science has never reached, in so far as they have something realizing that functional role.

There are some nice questions here about what we should really say about creatures with very different realizations of the same functions (e.g., “Martian pain”), and creatures with very similar realizations but different functions (e.g., “mad pain”; see Lewis 1983). Setting those issues aside for the moment, one question is which kind of functionalism goes with the free

energy principle. There is no straightforward answer here, but one possibility is that it is a kind of “biofunctionalism”, where the basic functional role is that of creatures who manage to maintain themselves within a subset of possible states (in a space-filling or active manner) for a length of time. Any such creature must be minimizing its free energy and hence engaging in inference and action. It is biological functionalism because it begins by asking for the biological form—the phenotype—of the candidate creature.

This is an extremely abstract type of functionalism, which allows considerable variation amongst phenotypes and hence minds. For example, it has no problem incorporating both Martians and madmen in so far as they maintain themselves in their expected states. It will however specify the mental states of the organism when it becomes known in which states it maintains itself. This follows from the causal characterization of sensory input, internal states, and active output that fully specify a prediction error minimizing mechanism. Once these states are observed, the states of the system can be known too, and the external causes rendered uninformative (i.e., the sensory and active states form a Markov blanket; [Friston 2013](#)).

What drives biofunctionalism is not species-specific empirical evidence, as in psychofunctionalism. And it does not seem to be commonsense conceptual analysis either. Rather, it begins with a biological, statistical observation that is as basic as one can possibly imagine—namely that creatures manage to maintain themselves within a limited set of states. As seen at the very start of this paper, this defines a probability density for a given creature, which it must approximate to do what it does. For an unsupervised system, it seems this can only happen if the organism minimizes its free energy and thereby infers the hidden causes of its sensory input, and then acts so as to minimize its own errors. This is an empirical starting point at least in so far as one needs to know many empirical facts to specify which states a creature occupies. But it is, arguably, also a conceptual point in so far as one hasn’t under-

stood what a biological creature is if one does not associate it at least implicitly with filling some specified subset of possible states.

The upshot is that the free energy principle sits well with a distinct kind of functionalism, which is here called biofunctionalism. It remains an open question how this would relate to some versions of functionalism and related views, such as teleosemantics ([Neander 2012](#)), which relies on ideas of proper function, and information theoretical views ([Dretske 1983](#)). The biofunctionalism of the free energy principle seems to have something in common with those other kinds of positions though it has no easy room for the notion of proper function and it doesn’t rely on, but rather entails, information theoretical (infomax) accounts.

Setting aside these theoretical issues, note that biofunctionalism has a rather extreme range because it entails that there is Bayesian inference even in very simple biological organisms in so far as they minimize free energy. This includes for example *E. coli* that with its characteristic swimming-tumbling behavior, maintains itself in its expected states. And it includes us, who with our deeper hierarchical models maintain ourselves in our expected states (with more space-filling and for longer than *E. coli*). Of course, one might ask where, within such a wide range of creatures, we encounter systems that we are comfortable describing as minds—that is, as having thought, as engaging in decision-making and imagery, and not least as being conscious. This remains a challenge for the free energy principle, just as it is a challenge for any naturalist theory of the mind to specify where, why, and how these distinctions between creatures arise.

10 The neural organ can explain the mind

The brain is an organ with a function, namely to enable the organism to maintain itself in its expected states. According to the free energy principle, this is to say that it minimizes prediction error on average and over the long run. This is a controversial idea, with extreme explanatory ambition. It might be considered not only controversial but also preposterous. But

the philosophy of science-based discussions above have sought to show that it is not in fact preposterous. The different ways in which it might be preposterous either do not apply, misunderstand the principle, or would also apply to the paradigmatically non-preposterous theory of evolution. The free energy principle yields a theory that should, indeed, strongly explain away competing theories. The free energy principle is an account that displays a number of explanatory virtues such as unification and fecundity. It is therefore not reasonable to detract from the principle by claiming it is preposterous or too ambitious. Scientifically speaking, what remains is to assess the evidence for and against the free energy principle and consider how, more specifically, it explains our mental lives (a task I undertake in Hohwy 2013). Speaking in terms of philosophy of mind, there remain questions about what type of functionalist theory the free energy principle is, how it performs vis-à-vis traditional questions about functionalism and the realizers of functional roles, and, finally, some more metaphysical questions about what it says about the nature of the mind in nature. None of these philosophical issues are apparently more damning for the free energy principle than they are for other, previously proposed accounts of the nature of the mind, and there is reason to think that with the free energy principle a new suite of answers may become available.

From Explanatory Ambition to Explanatory Power

A Commentary on Jakob Hohwy

[Dominic L. Harkness](#)

The free energy principle is based on Bayesian theory and generally makes use of functional concepts. However, functional concepts explain phenomena in terms of how they should work, not how they in fact do work. As a result one may ask whether the free energy principle, taken as such, can provide genuine explanations of cognitive phenomena. This commentary will argue that (i) the free energy principle offers a stronger unification than Bayesian theory alone (strong unification thesis) and that (ii) the free energy principle can act as a heuristic guide to finding multilevel mechanistic explanations.

1 Introduction

The free energy principle has far-reaching implications for cognitive science. In fact, the free energy principle seeks to explain everything related to the mind. Due to this explanatory ambition, it has been deemed preposterous by researchers. Jakob Hohwy challenges the opponents of the free energy principle and its applications by demonstrating that this framework is everything but preposterous. Rather, he compares the free energy principle with the theory of evolution in biology. The theory of evolution is not discarded due to its unifying power; and

the free energy principle shouldn't be either. In this paper I will present a negative as well as two positive theses: first, the free energy principle will be contrasted to Bayesian theory with regard to the degree of unification they offer. I will argue that the unification resulting from the free energy principle can be regarded as stronger since it attempts to empirically ground its conclusions in the brain via neuroscience and psychology. The negative thesis consists in the suggestion that one major flaw of the free energy principle, taken as such, lies within its ex-

planatory *power*. As a result of being a functional theory, the concepts it employs are also functional. Yet functional concepts, at least when it comes to explaining the brain and cognitive phenomena, do not explain how a certain phenomenon actually works, but rather how it should work. To improve this situation, the second positive thesis of this paper makes use of a suggestion by [Piccinini & Craver \(2011\)](#), namely that functional analyses are mechanism sketches, i.e., incomplete descriptions of mechanisms. In other words, functional concepts (such as precision) must be enriched with mechanistic concepts that include known structural properties (such as “dopamine”) in order to count as a full explanation of a given phenomenon. The upshot of this criticism lies within the free energy principle’s potential to act as a heuristic guide for finding multilevel mechanistic explanations. Furthermore, this paper will not advocate that functional concepts should be fully replaced or eliminated, but that functional and mechanistic descriptions complement each other.

2 The free energy principle

In his article “The Neural Organ Explains the Mind”, [Jakob Hohwy \(this collection\)](#) proposes that the brain, as every other organ in the human body, serves one basic function. Just as one might say that the basic function of the heart is to pump blood through the body or that of the lungs is to provide oxygen, the basic function of the brain is to minimise free energy ([Friston 2010](#)). However, this is a very general claim that does not yet establish how the minimisation of free energy is realised in humans. How is this done?

Very generally, the brain stores statistical regularities from the outer environment or, in other words, it forms an internal model about the causal structure of the world. This model is then used to predict the next sensory input. Consequently, we have two values that can be compared with each other: the predicted sensory feedback and the actual sensory feedback. When perceiving, the brain predicts what its own next state will be. Depending on the accu-

acy of the prediction, a divergence will be present between the predicted and the actual sensory feedback. This divergence is measured in terms of prediction errors. The larger the amount of prediction error, the less accurately the model fits the actual sensory feedback and thus the causal structure of the world. Crucially, the model that fits best, i.e., that which brings forth the smallest amount of prediction error, also determines consciousness. In this framework, free energy amounts to the sum of prediction errors. Thus, minimizing prediction errors always entails the minimisation of free energy.

The minimization of prediction error can generally be achieved in two ways: either the brain can change its models according to the sensory input or, vice versa, it can change the sensory input according to its models. In this scheme the former mode can be seen as veridical perception, whereas the latter can be seen as action, or more formally active inference—the fulfillment of predictions via classic reflex arcs ([Friston et al. 2009](#); [Friston et al. 2011](#)). Furthermore, two other factors play a large role in the minimization of prediction error: first, the precision, or “second-order statistics” ([Hesselmann et al. 2012](#)), which ultimately encodes how “trustworthy” the actual sensory input is. Precision is realised by synaptic gain, and it has been established that the modulation of precision corresponds to attention ([Hohwy 2012](#)). Second, model optimization ensures that models are reduced in complexity in order to account for the largest number of possible states in the long run, i.e., under expected levels of fluctuating noise. For example, sleep has been associated with this type of model optimization ([Hobson & Friston 2012](#)). More detailed descriptions of these four factors, i.e., perception, active inference, precision, and model optimization can be found in Hohwy’s article.

Additionally, models are arranged in a cortical hierarchy ([Mumford 1992](#)). This hierarchy is characterised, as [Hohwy](#) points out ([this collection](#), p. 7), by time and space: models higher up in the hierarchy have a larger temporal scale and involve larger receptive fields than models lower down in the hierarchy, which concern pre-

dictions at fast time scales and involve small receptive fields (p. 7). This hierarchy implies a constant message-passing amongst different levels. Once a sensory signal arrives at the lowest level it is compared to the predictions coming from the next higher level (in this case level two).¹ If prediction errors ensue they are sent to the higher level (still level two). Here they are predicted by the next higher level (now level three). This process goes on until prediction errors are minimised to expected levels of noise.

Now the general scheme of prediction error minimization can be presented: the brain builds models that represent the causal structure of the world. These models are, in turn, used to generate predictions about what the next sensory input might be. The two resulting values, i.e., the predicted and the actual sensory feedback, are continuously compared. The divergence between these two values is the prediction error, or free energy. Since it is the brain's main function to minimise the amount of free energy and therefore prediction error, it will either change its models or engage in active inference. Decisions about which path will be taken depend on the precision of the incoming sensory signal (or prediction error). Signals with high precision are taken to be "trustworthy", and therefore model changes can follow. Low precision signals, however, require further investigation since noise could be the principal factor in an ambiguous input. In addition, models during wakefulness are changed "on-the-fly", thus leading to highly idiosyncratic and complex models. This complexity is reduced, for example during sleep (Hobson & Friston 2012), to increase the generalizability of models, since noise is always present.

3 Bayesian theory and unification

As mentioned above, all this serves the basic function of the brain: the minimization of free energy. This strategy is employed in every aspect of cognition; thus the free energy principle (Friston 2010) is a grand unifying theory. But

from where does the free energy principle derive its unifying power?²

The free energy principle makes use of Bayesian theory, which can be regarded as its foundation. For some years now, Bayesian theory has been applied to many cognitive phenomena, since it may "offer a new interpretation of the goals of cognitive systems, in terms of inductive probabilistic inference [...] can make the assumptions of Bayesian models more transparent than in mechanistically oriented models [...] and may have the potential to explain some of the most complex aspects of human cognition [...]" (Jones & Love 2011, p. 170). Yet Jones & Love (2011) also address the fact that Bayesian theories, although aiming at researching and investigating the human brain and its workings, remain unconstrained by psychology and neuroscience "and are generally not grounded in empirical measurement" (*ibid.*, p. 169). They term this approach "Bayesian Fundamentalism", since it entails that all that is necessary to explain human behaviour is rational analysis. Supporters of this position rely on the mathematical framework of Bayesian theory as the origin of its explanatory power and unification. The positive thesis of Jones & Love (2011) consists in arguing for "Bayesian Enlightenment" that tries to include mechanistic explanation in Bayesian theory. To give more detail, they propose that, rather than following Bayesian Fundamentalism and thus being "logically unable to account for mechanistic constraints on behavior [...] one could treat various elements of Bayesian models as psychological assumptions subject to empirical test" (Jones & Love 2011, p. 184). Similarly, Colombo & Hartmann (2014) argue that although "the Bayesian framework [...] does not necessarily reveal aspects of a mechanism[,] Bayesian unification [...] can place fruitful constraints on causal-mechanical explanation" (Colombo & Hartmann 2014, p. 1).

According to Colombo & Hartmann (2014), many Bayesian theorists falsely equate unification with explanatory power. But Bayesian theories derive their unificatory power

¹ The numerical values for the levels have no scientific relevance. They are used only for illustrative purposes.

² At this point I would like to thank one of the reviewers for her or his substantial advice and constructive comments.

from their mathematical framework. However, just because different cognitive phenomena can be mathematically unified does not entail a causal relationship between them, and nor does the mathematical unification tell us anything about the causal history of these phenomena. However, as will be presented in the next section, explanatory power, at least from a mechanistic point of view, results from investigating structural components and their causal interactions that give rise to a certain phenomenon. For example [Kaplan & Craver \(2011\)](#) write that “[...] the line that demarcates explanations from merely empirically adequate models seems to correspond to whether the model describes the relevant causal structures that produce, underlie, or maintain the explanandum phenomenon” (p. 602). Yet in the case of Bayesian theory—and Bayesian Fundamentalism in particular—, this cannot be achieved, since they “say nothing about the spatio-temporally organized components and causal activities that may produce particular cognitive phenomena [...]” ([Colombo & Hartmann 2014](#), p. 5). But not everything is lost concerning the explanatory role of Bayesian theories. Even if Bayesian theory cannot provide mechanistic explanations, it may nonetheless be beneficial to cognitive science by offering constraints on causal-mechanical explanation ([Colombo & Hartmann 2014](#)).

This brings us to the free energy principle. As noted, the free energy principle is, at its core, a theory that makes use of Bayesian theory; consequently it inherits all of Bayesian theory’s pros and cons. Thus, since unification in the free energy principle is also grounded in its mathematical foundations “[...] the real challenge is to understand how [the free energy principle] manifests in the brain” ([Friston 2010](#), p. 10). With regard to [Jones & Love’s \(2011\)](#) distinction, the free energy principle can be considered to belong to Bayesian Enlightenment, since it attempts to ground its findings in neurobiology and psychology rather than remaining unconstrained by these sciences. Furthermore, due to the fact that the free energy principle integrates neuroscientific findings into its conclusions, it can offer more precise constraints on causal-mechanical explanations than

Bayesian theory alone. For example, the free energy principle tries to incorporate neuroscientific facts about brain structure and its hierarchical organization, or tries to link concepts such as “precision” to neurophysiological phenomena such as “dopaminergic gating” ([Friston et al. 2012](#)).³ The latter example will be presented in greater detail in section 5.

In sum, the free energy principle offers a form of unification that exceeds that offered by Bayesian theory alone. It makes statements about how the free energy principle could be realised in the brain and does not solely rely on its mathematical framework. Thus, one could term the former a “strong unification thesis” (SUT) and the latter a “weak unification thesis” (WUT).

If the free energy principle is true it creates a backdrop against which other theories must be evaluated. This also implies a kind of explanatory monopolization, since “the free energy principle is not a theory that lends itself particularly well to piecemeal” ([Hohwy this collection](#), p. 9). In other words, as Hohwy highlights on many occasions, the free energy principle is an all-or-nothing theory. He compares it to the theory of evolution in biology and states that, just like the free energy principle, “evolution posits such a fundamental mechanism that anything short of universal quantification would invalidate it” (p. 10). Due to this large explanatory ambition, some researchers have described the free energy principle as preposterous. Yet “the issue whether the free energy principle is preposterous cannot be decided just by pointing to its explanatory ambition [...] [but] by considering the evidence in favour of the free energy principle” (p. 11). This is a very important transition, i.e., the switch from explanatory ambition to explanatory power, since, from a mechanistic viewpoint, the former gives no statement about the veridicality of its assumptions, whereas the latter does.

³ However, I’d like to point out that the free energy principle does not make any commitments to one single neuroscientific theory. Rather, it tries to find entities that may realize the free energy principle in the brain; what these entities are remains to be inquired.

In the remainder of this paper, I will argue that one major shortcoming of the free energy principle lies in its explanatory *power*. The main issue to be discussed consists in the fact that most concepts employed in the free energy principle, or in its applications such as predictive coding (Friston 2005; Rao & Ballard 1999) or predictive processing (Clark 2013; Hohwy 2013), are principally functional concepts. Yet, at least in the case of the free energy principle, functional concepts do not hold much explanatory power, since they “describe how things ought to work rather than how they in fact work” (Craver 2013, p. 18). For example, the concept of “precision” represents the amount of uncertainty in the incoming sensory signal that may arise due to noise. Thus the precision of the incoming sensory inputs determines how an agent interacts with its environment next: it can either change its models or its sensory input. Yet, this description holds no commitments as to how precision is realised in the brain; it only describes what effect precision *should* have on a given cognitive system. Therefore the free energy principle seems to be of a normative, rather than descriptive, nature.⁴ On the other hand, there are mechanistic explanations that, according to Craver (2007), can also count as such, since they don’t describe how things should work but how they in fact *do* work.

Yet these two types of epistemic strategies don’t necessarily exclude each other. Here I want to introduce Piccinini & Craver’s (2011) claim that functional analyses can serve as “mechanism sketches”. The upshot lies within the free energy-principle’s unifying power: it can act as a kind of conceptual guide for revealing mechanistic explanations. Once physiological concepts are mapped onto the functional concepts derived from the free energy-principle, multilevel mechanistic explanations follow. But before this is elaborated the next section will give a short introduction to mechanistic explanation (Craver 2007).

4 Mechanistic explanation

Mechanistic explanation claims that in order “[t]o explain a phenomenon, [...] one has to

know what its components are, what they do and how they are organized [...]” (Craver & Kaplan 2011, p. 269). It does not suffice to merely be able, e.g. to accurately predict a phenomenon. Craver & Kaplan (2011, p. 271) show this by referring to the example of a heat gauge on a car. Despite the fact that the gauge represents engine heat and that one can also predict when the engine will overheat by looking at the gauge, it doesn’t explain why the engine is overheating. It only states that it is—not how it came about. Thus, mechanists introduced the “model-to-mechanism-mapping” (3M) requirement for explanatory models:

(3M) A model of a target phenomenon explains that phenomenon when (a) the variables in the model correspond to identifiable components and organizational features of the target mechanism that produces, maintains, or underlies the phenomenon, and (b) the causal relations posited among these variables in the model correspond to the activities or operations among the components of the target mechanism. (Kaplan 2011, p. 272)

This requirement can serve as a demarcation criterion as to when a model can actually be seen as explanatory. But how does mechanistic explanation progress? Two principal approaches are described by Craver & Kaplan (2011): reductionism and integrationism. The former tries to reduce mental phenomena into ever-smaller entities. Its most radical form, “ruthless reductionism”, is advocated by John Bickle (2003), who states that neuroscience should reduce “[...] psychological concepts and kinds to molecular-biological mechanisms and pathways” (Bickle 2006, p. 412). In other words, mental phenomena should be explained with low-level concepts. The integrationist approach, on the other hand, claims that explanations can be found across a hierarchy of mechanisms (Craver 2007), since every mechanism is itself embedded into a higher-level mechanism. Consequently, reductionism isn’t the only option, since “[...] mechanistic explanation requires consideration not just of the parts and operations in the mechanism but also of the organization

⁴ This does not mean that the free energy principle is false. On the contrary, this paper will present an attempt to increase its explanatory potential.

within the mechanism and the environment in which the mechanism is situated” (Bechtel 2009, p. 544). In particular, multilevel mechanistic explanations consider three viewpoints on any given mechanism: the etiological, constitutive, and contextual aspects (Craver 2013). At the etiological level, the causal history of a given mechanism is investigated at the same level of the hierarchy. Yet mechanisms can also be broken down into smaller, more specialised mechanisms. When investigating the internal mechanisms that give rise to a mechanism at a higher level, one can speak of the constitutive aspect of mechanistic explanation. This strategy resembles reductionism most. But, as mentioned before, every mechanism is also embedded in a higher-level mechanism. Thus, one must also investigate how a given mechanism contributes to the next higher-level mechanism. This has been termed the contextual aspect, because it situates a mechanism into a higher-order context. After this short introduction into mechanistic explanation, the next section will show how this relates to the problem above, i.e., that applications of the free energy principle operate with functional concepts and thus can’t serve as full explanations.

5 The free energy principle as heuristic guide

Here I will follow Piccinini & Craver’s (2011) proposal that functional descriptions are nothing other than mechanism sketches that derive their “[...] explanatory legitimacy from the idea that [they][...] capture something of the causal structure of the system” (Piccinini & Craver 2011, p. 306). Mechanism sketches are simply outlines of mechanisms that haven’t been fully investigated with regard to their structural properties. Thus, functional descriptions serve as placeholders until a mechanistic explanation can fully account for a given phenomenon by enriching functional concepts with concepts related to its structural properties.⁵ The explanatory gaps⁶ resulting from the functional nature of

the free energy principle could then be closed, leading to a shift from explanatory ambition to explanatory power. This also directly relates to the alleged preposterousness of the free energy principle, since the process of “filling-in” will diminish any residual doubts about the theory’s truthfulness. This can be applied to the free energy principle, which works with functional concepts such as “precision”, “prediction error”, “model optimization” or “attention”: “[o]nce the missing aspects are filled in, a functional analysis turns into a full-blown mechanistic explanation” (Piccinini & Craver 2011, p. 284). Take the concept of precision in the free energy principle as an example. As described above, precision gives an estimate concerning the “trustworthiness” of a given sensory signal and its ensuing prediction errors. Taken as such, precision is clearly a functional concept since it is “[...] specified in terms of effects on some medium or component under certain conditions” (Piccinini & Craver 2011, p. 291) without committing to any structural entities that could realise these functional properties. However, according to Friston et al. (2012), “[...] dopaminergic gating may represent a Bayes-optimal encoding of precision that enhances the processing of particular sensory representations by selectively biasing bottom-up sensory information (prediction errors)” (p. 2). In turn, “dopaminergic gating” involves the neurotransmitter dopamine, a molecule that can be structurally described. Crucially, now that the functional concept of precision, derived from the free energy principle, has been linked with dopaminergic gating, one can make further inferences as to how this entity is situated in a multilevel mechanism. For example, the modulation of precision has been associated with attention (Feldman & Friston 2010; Hohwy 2012), and since precision is realised via dopamine mediation, one can investigate the effects of dopamine on attentional mechanisms.⁷ On the other hand, if empirical evidence regarding precision or in particular predictions of precisions (hyperpriors) find “[...] that

⁵ However, as a preliminary note, both functional and structural properties are needed for a full mechanistic explanation (cf. Piccinini & Craver 2011, p. 290).

⁶ In this paper, the term “explanatory gap” is not used in the sense of “an explanatory gap [...] between the functions and experience”

(Chalmers 1995, p. 205; see Levine 1983 for the classical reference), as we see in the philosophy of mind. Rather, it describes the lack of neurobiological details in functional concepts.

⁷ Of course, to do so one would also have to know all the components involved in the mechanism responsible for attention.

descending signals do not mediate expected precisions, this would falsify the free energy principle” (p. 16). This further accentuates the need for mechanistic explanations.

As a more elaborate example, the phenomenon of biased competition will shortly be introduced. In biased competition, two stimuli are presented at a topographically identical location. However, only one of these stimuli is actually perceived. Thus the principal question: by which means does the brain “select” any given stimuli? In the free energy principle, the most obvious answer would be the stimulus that best minimises free energy or prediction error. However, in these cases, the stimuli are equally accurate, i.e., they both represent the causal structure of the world equally well. As a consequence, the stimuli will “[...] compete for the responses of cells in visual cortex” (Desimone 1998, p. 1245). Crucially, Desimone (1998) brings up a preliminary study by Reynolds et al. (1994) that states “[...] that attention serves to modulate the suppressive interaction between two or more stimuli within the receptive field [...]” (Desimone 1998, p. 1250). Thus, attention could be the determining factor as to which stimulus is perceived at a given moment. From the perspective of the free energy principle and in accordance with these findings, Feldman & Friston (2010) propose that “[...] attention is the process of optimizing synaptic gain to represent the precision of sensory information (prediction error) during hierarchical inference” (p. 2). These two views agree, since synaptic gain also entails a suppressive effect upon the other competing stimuli. Also, as just mentioned, Friston et al. (2012) identify precision weighting with dopaminergic gating, i.e., they argue that dopamine mediation realises the precision of incoming stimuli or prediction errors.

Now a fuller picture can be presented. This much more complete picture allows us to see how the free energy principle or prediction error minimization framework can prove to be beneficial with regard to mechanistic explanation. The phenomenon to be explained is biased competition. The mechanism that realises, or resolves, biased competition, i.e., the competition between two identically accurate and topo-

graphically identical stimuli, is precision weighting. This represents the etiological level of description since it describes how biased competition is resolved at a level of description that doesn’t refer to lower-level processes nor to how they are embedded into a higher order mechanism. It remains at the same level in the hierarchy of mechanisms. At the constitutive level we have the fact presented by Friston et al. (2012), that precision weighting is neurophysiologically realised by dopaminergic gating. This *constitutes* precision weighting and is located at a lower level. Last, precision weighting is embedded into the higher-order mechanism of attention. Precision weighting contributes to this higher order mechanism, or, from the other perspective, attention is constituted by precision weighting. This represents the contextual description.

The upshot is that, just as “[e]volutionary thinking can be heuristically useful as a guide to creative thinking about what an organism or organ is doing [...]” (Craver 2013, p. 20), the free energy principle can be a useful guide in finding multilevel mechanistic explanations concerning how the mind works. Due to its unifying power, the free energy principle offers a grand framework that seeks to explain every aspect of human cognition. Thus, filling increasingly more mechanistic concepts into functional placeholders will enable an understanding of the mind in terms of how it does work instead of how it ought to work. The explanatory worth of the free energy principle would then be preserved, since “[i]f these heuristics contribute to revealing some relevant aspects of the mechanisms that produce phenomena of interest, then Bayesian unification has genuine explanatory traction” (Colombo & Hartmann 2014, p. 3).

However, this should not be seen as an attempt to eliminate functional concepts by reducing them to mechanistic ones. Instead, as mentioned above, the integrationist account emphasises that functional and mechanistic concepts are both necessary for mechanistic explanations, since “structural descriptions constrain the space of plausible functional descriptions, and functional descriptions are elliptical mechanistic descriptions” (Piccinini & Craver 2011,

p. 307). Furthermore, once every functional term has a mechanistic counterpart, the 3M requirement posed by mechanists can be fulfilled in the case of the free energy principle.

Last, as a general remark, searching for structural properties seems important if researchers want to ground the free energy principle in the human brain. Functional theories are subject to multiple realizability. This means that not only humans or mammals could be bound to the free energy principle, but also Martians or bacteria or anything that could possess the “hardware” to do so. Hohwy suggests that the free energy principle can be seen as a biofunctionalist theory (this collection p. 20). In principle this means that the free energy principle can be multiply realised as long as that creature acts in such a way as to maintain itself in a certain set of expected states. These expected states then determine the creature’s phenotype. In seeking to explain human cognition, functional theories have to be enriched with mechanistic concepts relating to structural properties, since otherwise we could also be investigating Martians.

6 Conclusion

The negative thesis of this paper states that the free energy principle’s explanatory power, unlike its unificatory power, can be regarded as weak, since it does not fulfil the 3M requirement posited by mechanists. This follows from the fact that the free energy principle is a functional theory, thus also employing functional concepts. Yet these do not explain how a given phenomenon in fact does work but only how it should work. However, Piccinini & Craver (2011) propose that functional analyses, ultimately, are nothing else but mechanism sketches, i.e., incomplete mechanistic explanations.

In this paper I have tried to make a positive contribution to the discussion by arguing for two claims: first, since the free energy principle incorporates empirical results from psychology and neuroscience it provides a stronger case of unification (SUT) than the unification provided by Bayesian theory alone. By not solely relying

on its mathematical foundation, the free energy principle can try to ground its findings empirically in the brain. As a result, both the free energy principle and theories from psychology and neuroscience can constrain each other, thus being beneficiary to one another. Second, I argue that the free energy principle can act as a guide to finding multilevel mechanistic explanations. By linking mechanistic concepts with functional concepts from the free energy principle, the 3M requirement posited by mechanists can be fulfilled, consequently leading to actual explanations. This relates to the accused preposterousness of the free energy principle: with increasing explanatory power it becomes more and more difficult to deny that the free energy principle itself is, in fact, true.

The Diversity of Bayesian Explanation

A Reply to Dominic L. Harkness

Jakob Hohwy

My claim is that, if we understand the function of the brain in terms of the free energy principle, then the brain can explain the mind. Harkness discusses some objections to this claim, and proposes a cautious way of solidifying the explanatory potential of the free energy principle. In this response, I sketch a wide, diverse, and yet pleasingly Bayesian conception of scientific explanation. According to this conception, the free energy principle is already richly explanatory.

1 Introduction

The free energy principle (FEP) is ambitiously touted as a unified theory of the mind, which should be able to explain everything about our mental states and processes. Dominic L. Harkness discusses the route from the principle to actual explanations. He reasonably argues that it is not immediately obvious how explanations of actual phenomena can be extracted from the free energy principle, and then offers positive suggestions for understanding FEP's potential for fostering explanations. The argument I focus on in [Hohwy \(this collection\)](#) is that FEP is not so preposterous that it cannot explain at all; Harkness's com-

mentary thus raises the important point that there may be other obstacles to explanatoriness than being preposterous.

A further aspect of Harkness' approach is to make contact between the discussion of FEP's explanatory prowess and discussions in philosophy of neuroscience about computational and mechanistic explanation. This matters, since, if FEP is really set to dominate the sciences of the mind and the brain, then we need to understand it from the point of view of philosophy of science.

In this response, I will attempt to blur some distinctions between notions currently dis-

cussed in the philosophy of science. This serves to show that there is a diversity of ways in which a theory, such as FEP, can be explanatory. I am not, however, advocating explanatory pluralism; rather, I am roughly sketching a unitary Bayesian account of explanation according to which good explanation requires balancing the diverse ways in which evidence is explained away. This seems to me an attractive approach to scientific explanation—not least because it involves applying FEP to itself. The upshot is that even though FEP is not yet a full explanation of the mind, there are several ways in which it already now has impressive explanatory prowess.

2 Explanations, functions and mechanisms

Harkness employs existing views in the philosophy of science to create a divide between functions and mechanisms: functions specify what some phenomenon of interest ought to be doing, they don't specify how it actually does it. For that, a mechanism is needed which, in addition to specifying a functional role, also names the parts of the mechanism that perform this role (i.e., the realisers of the function), for example in the brain. This is thought to limit the explanatory power of FEP, which at its mathematical heart is just functionalist.

Whilst I accept the divide between functions and realisers, I don't think there is much explanatory mileage in naming realisers. If I already know what functional role is being realized, I don't come to understand a phenomenon better by being given the names of the realizing properties. This can be seen by imagining any mechanistic explanation (encompassing both functional role and realisers) where the names of the realizing properties are exchanged for other names. Such a move might deprive us of knowledge of which parts of the world realize this function, but this is not in itself explanatory knowledge. For example, I get to understand the heart by being told the functional role realized by atria and ventricles; I don't lose understanding if we rename the atria "As" and ventricles "Bs".

This is not to deny that we can gain understanding from learning about mechanisms. In particular, if I don't know about a phenomenon of interest, then I might explore the realizer of a particular case, and thereby get clues about the functional role. For example, in the 17th century William Harvey was able to finally comprehensively explain the functional role of the heart by performing vivisection on animals. Indeed, the point of such an exercise is to arrive at a clear and detailed description of a functional role (recall the difference between behaviourism and functionalism is that for the latter, the functional role is not just an input-output profile but also a description of the internal states and transitions between states).

Importantly, exploration (e.g., via vivisection, or via functional magnetic resonance imaging) of a mechanism is not the only way to eventually arrive at explanations. There can be multiple contexts of discovery. In particular, there can be very broad empirical observations as well as conceptual arguments. In the case of FEP, a key observation is that living organisms exist in this changing world. That is, organisms like us are able to maintain themselves in a limited number of states. This immediately puts constraints on any mechanistic explanation, which must cohere with this basic observation. Further, since an organism cannot know a priori what its expected states are, there must be an element of uncertainty reduction going on within the organism in order to estimate its expected states, or model. In a world with state-dependent uncertainty, this must happen through hierarchical inference. With these simple notions, FEP itself is well on its way to being established.

So I don't think it is explanatory power that is limited by being confined, as FEP fundamentally is, to functional roles. This mainly seems to impose a limit on our knowledge of *which* objects realize a given functional role, or it might curb our *progress* in finessing the functional role in question. Whereas it is right to say that FEP is limited because it is merely functional, this limit does not apply to its explanatory prowess.

3 Explanations and mechanism sketches

In assessing the explanatoriness of a functional theory like FEP it is useful, as Harkness proposes, to consider it as a mechanism sketch. Sketchiness, however, comes in degrees, and it is hard to think of any extant scientific account that is not sketchy in some respects—no matter how abundantly mechanistic it is. There doesn't seem to be any principled point at which a sketchy functional account passes over into being a non-sketchy mechanistic account. Rather, an account may become less and less sketchy as the full functional role and its realisers are increasingly revealed. This would be one respect in which the explanation in question would expand: more types and ranges of evidence would be explained, accompanied by a richer understanding of the functional workings of the mechanism.

The idea here is that mechanistic explanation comes in degrees, which makes it hard to say clearly when something is a mechanism sketch. Speaking of organs, consider again the case of the heart. Harvey is often said to have provided the first full account of pulmonary circulation, and it might be true that his account is less sketchy than that of his precursors, such as the much earlier Ibn al-Nafis. Yet even Harvey had areas of ignorance about the heart, and had to deduce some parts of his theory from his hypothesis about the overall function of the heart. Indeed, he readily acknowledges the difficulty of his project:

When I first gave my mind to vivisections, as a means of discovering the motions and uses of the heart, and sought to discover these from actual inspection, and not from the writings of others, I found the task so truly arduous, so full of difficulties, that I was almost tempted to think, with Fracastorius, that the motion of the heart was only to be comprehended by God. (Harvey 1889, p. 20)

A key question then is how sketchy FEP is—is it more like Harvey's rather comprehensive sketch of the heart, or is it like that of al-

Nafis? (If it is not completely misguided, like Galen's claim that there are invisible channels between the ventricles.) Harkness suggests that part of the attraction of FEP is that it comes with more empirical specification than mere Bayesian theory. It is true that much of the literature on FEP tries to map mathematical detail onto aspects of neurobiology. However, the mathematical detail of FEP itself is devoid of particular empirical fact—it is purely functionalist. (We might even say FEP is more fundamental than the Bayesian brain hypothesis, since the latter seems to be derivable from the former.)

However, this austerity with respect to specification of particular types of fact does not make FEP inherently sketchy. The starting point for FEP is the trivial but contingent fact that the world is a changing place and yet organisms exist—that is, that they can maintain themselves in a limited set of fluctuating states. This very quickly leads to the idea that organisms must be recapitulating (modelling) the structure of the world, and that they must be approximating Bayesian inference in their attempt to figure out what their expected states are.

This starting point for FEP gives us a lot of structure to look for in the brains of particular creatures. It calls for hierarchical structures the levels of which can encode sufficient statistics (means and variances) of probability distributions, pass these as messages throughout the system, and engage in explaining away and updating distributions over various time-scales. This has a much more mechanistic flavour than a more pure appeal to Bayes' rule, which leaves many more questions about the inferential mechanistics of the brain unanswered. (Part of the difference here is that FEP suggests that the brain implements approximate Bayesian inference, described in terms of variational Bayes.)

It is reasonable, then, to say that, even when stripped of extraneous neurobiological scaffolding, FEP is not inherently sketchy. It might not have the wealth of particular fact that would make it analogous to Harvey's theory of the heart. But it gives a surprisingly very

rich description of the functional role implemented by the brain of living organisms.

4 Explanation and types of functionalism

One might still insist on the point that Harkness raises, namely that, even if FEP is not particularly sketchy when stripped of empirical content, it is really only an account of what the system *should* do, rather than what it *actually* does. There is of course some truth to this, since the mathematical formulation of FEP is an idealization of a system engaged in variational Bayes.

However, perhaps FEP is in a peculiar functionalist category. Its starting point, as I mentioned earlier, is the trivial truth that organisms exist, from which it follows that they must be acting to maintain themselves in a limited set of states, from which it in turn follows that they must be reducing uncertainty about their model. Thus the function described by FEP is not about what the system should or ought to be doing but about what it *must* be doing, given the contingent fact that it exists.

This starting point differs from common-sense functionalism because it is not based on conceptual analysis but is instead based on a basic observation, plus statistical notions. It also differs from empirical functionalisms (cf. psychofunctionalism) because it does not specify functional roles in terms of proximal input–output profiles for particular creatures. Neither are the functional roles it sets out defined in terms of teleologically-defined proper functions (cf. teleosemantics), except in so far as it could be said that the proper function of an organism is to exist.

This category of functionalism, which I dubbed “biofunctionalism”, seems intriguingly different from other kinds of functionalism. It provides a foundational functional role, which *must* be realized in living organisms, and from which more specific processes can be derived (for perception, action, attention etc.). This differs from austere functionalisms, which only say how things ought to be working, and it differs from fully mechanistic functionalisms, which specify how particular types of things actually work.

5 Explanation by unification, and by mechanism revelation

Explanation in science is not just a matter of revealing the full detail of the parts and processes of mechanisms. Explanation is many things, as evidenced by the literature on the topic in philosophy of science. Most commonly, explanation is sought to reveal causes, and the contemporary discussion of mechanisms contributes substantially to this discussion. A different idea is that *unification* is explanatory—and yet explanation by unification is a multifaceted and disputed notion.

I think FEP explains by unification because it is a principle that increases our understanding of many very different phenomena, such as illusions, social cognition, the self, decision, movement, and so on (see *The Predictive Mind*, Hohwy 2013, for examples and discussion). FEP teaches us something new and unexpected about these phenomena, namely that they are all *related* as different *instances* of prediction-error minimization. For example, we are surprised to learn that visual attention and bodily movement are not only both engaged in prediction error minimization, they are essentially identical phenomena. FEP thus explains by providing a new, unified and coherent view of the mind.

In this manner, FEP is explanatory partly in ways that are separate from mechanistic explanation, and also from the discussion of how the functionalist and mechanistic approaches relate to each other.

6 Explanation is itself Bayesian

The comments I have provided so far appear to pull somewhat in different directions. I have argued that there is no sharp delineation between functional and mechanistic accounts, and yet I acknowledged that the functional aspects of FEP do set it apart from fully mechanistic accounts. I have argued that merely naming realisers is not explanatory, yet I have acknowledged that mechanistic accounts are explanatory. I have argued (with Harkness) that FEP explains by guiding particular mechanistic ac-

counts, but also by unification. In each of these cases, there seems to be much diversity, or even tension, in how FEP is said to be explanatory.

This diversity and tension, however, is by design. Explanation is not a one-dimensional affair; rather, a hypothesis, h , can be explanatory in a number of different ways. This can be seen by applying the overall Bayesian framework to scientific explanation itself. The strength of the case for h is consummate with how much of the evidence, e , h can explain away. As we know from the discussion of FEP, explaining away can happen in diverse ways: by changing the accuracy, the precision, or the complexity of h , or by intervening to obtain expected, high precision e . As discussed for FEP in Hohwy (this collection), we can also consider h 's ability to explain away e over shorter or longer time scales: if h has much fine-grained detail it will be able to explain away much of the short term variability in e but may not be useful in the longer term, whereas a more abstract h is unable to deal with fine-grained detail but can better accommodate longer prediction horizons.

Sometimes these diverse aspects of Bayesian explaining-away pull in different directions. For example, an attempt at unification via de-complexifying h may come at the loss of explaining some particular mechanistic instantiations. Conversely, an overly complex h may be overfitted and thereby explain away occurrent particular detail extremely well but be at a loss in terms of explaining many other parts of e .

In constructing a scientific explanation, how should one balance these different aspects of Bayesian explanation? Again we can appeal to FEP itself for inspiration: a good explanation minimizes prediction error on average and in the long run. That is, a good explanation should not generate excessively large prediction errors, and should be robust enough to persist successfully for a long time. This is intuitive, since we don't trust explanations that tend to generate large prediction errors, nor explanations that cease to apply once circumstances change slightly.

Formulating the goal of scientific explanation in this way immediately raises the question of what it means for prediction error to be

"large" or for a hypothesis to survive a "long time". The answer lies in expected precisions and context dependence. In building a theory, the scientist also needs to build up expectations for the precision (i.e., size) of prediction errors, and for the spatiotemporal structure of the phenomenon of interest. Not surprisingly, these aspects are also found in the conception of hierarchical Bayesian inference.

Achieving this balanced goal requires a golden-mean-type strategy: explanations should not be excessively general nor excessively particular, given context and expectations. That is, h should be able to explain away e in the long term without generating excessive prediction errors in the short term, as guided by expectations of precision and domain.

I think FEP is useful for attaining this golden mean, and that this is what makes FEP so attractive and promising. As a scientific hypothesis, it does not prioritise one type of explanatory aspect over another, but instead balances explanatory aspects against each other such that prediction error concerning the workings of the mind is very satisfyingly minimized on average and in the long run (and this indeed is the message of *The Predictive Mind*). Rather poetically, in my view, this means that we should evaluate FEP's explanatory prowess by applying it to itself.

7 Conclusion

I have agreed, to a large extent, with the points Harkness makes in his commentary. I have however also sought to suggest a more pluralistic perspective on scientific explanation. This ensures that the free energy principle, as it applies to the neural organ, has great potential to explain many aspects of the mind. I went one step further, however, and suggested that behind this explanatory pluralism lies a unified, Bayesian account of explanation, which perfectly mimics the unifying aspects of the free energy principle itself.

Millikan's Teleosemantics and Communicative Agency

Pierre Jacob

Millikan's teleosemantic approach constitutes a powerful framework for explaining the continued reproduction and proliferation of intentional conventional linguistic signs, and thereby the stability of human verbal intentional communication. While this approach needs to be complemented by particular proximate psychological mechanisms, Millikan rejects the mentalistic psychological mechanisms, which are part of the Gricean tradition in pragmatics. The goal of this paper is to assess the balance between Millikan's teleosemantic framework and the particular proximate psychological mechanisms that she favors.

1 Introduction

In this paper, I wish to revisit a topic that I addressed many years ago (cf. [Jacob 1997](#)) from a novel perspective. Much philosophy of mind of the latter part of the twentieth century has been devoted to naturalizing intentionality or the contents of mental representations. One of the landmarks of naturalistic philosophy of mind of the past thirty years is unquestionably Ruth Millikan's teleosemantic framework. Teleosemantic theories are teleological theories that seek to explain content by appealing to the *functions* of representations. Like most teleosemantic approaches, [Millikan \(1984, 2004\)](#) embraces an *etiological* conception of function, ac-

cording to which functions are *selected effects* ([Millikan 1984, 1989b; Neander 1991, 1995, 2004; Wright 1973](#)): the function of a trait is the effect caused by the trait that explains the continued reproduction (survival or proliferation) of past tokens of this trait.

Millikan's teleosemantic approach is particularly impressive for two related reasons. First, it applies in a single stroke to the contents of intentional *mental* representations, whose function is to mediate between pairs of cognitive mechanisms located within single brains, and also to the meanings of intentional *conventional* linguistic signs, whose function is

to mediate between pairs of cognitive mechanisms located in the brains of distinct individuals. Second, her overall teleological (or teleo-functional) approach, based on the etiological theory of functions, is meant to offer an account of the proliferation or continued reproduction of both biological entities and non-biological cultural things, such as linguistic and non-linguistic conventions.

Following Mayr (1961), evolutionary biologists and philosophers have long argued that the distinction between so-called *ultimate* and *proximate* explanations of biological traits (e.g., behaviors) is central to evolutionary theorizing. Roughly speaking, ultimate explanations address *why*-questions: for example, why do birds sing? Why does singing confer a selectional advantage (or greater fitness) to birds? Proximate explanations address *how*-questions: for example, what are the particular external circumstances which trigger singing in birds? What are the internal brain mechanisms that allow birds to sing?

The distinction between ultimate and proximate biological explanations raises some deep scientific and philosophical questions. One such question is whether ultimate explanations should be construed as non-causal answers to why-questions. Some philosophers have argued that ultimate explanations are *selectional* explanations based on natural selection. Natural selection can account for the prevalence of some trait in a population of individuals, but it cannot track the causal process whereby the trait is generated in each individual in the first place (Sober 1984, pp. 147–152; Dretske 1988, pp. 92–93; Dretske 1990, pp. 827–830). Other philosophers have replied that selectional explanations are causal explanations, on the grounds that no token of a trait whose type has been selected for fulfilling its (etiological) function could proliferate unless it was linked by a causal chain to the earlier production of the selected effect by ancestor tokens of the same type of trait (Millikan 1990, p. 808).¹

In this paper, I will not address such perplexing issues. I will simply accept the validity

of the distinction and assume that (whether ultimate explanations are causal explanations or not) ultimate and proximate explanations are complementary, not competing, explanations. Given that why-questions are fundamentally different from how-questions, it is likely that ultimate explanations offer few (if any) constraints on proximate explanations, and vice versa. I will further assume that the distinction carries over from biological to cultural evolution and applies to the evolution of human communication (cf. Scott-Philipps et al. 2011). In particular, Millikan's basic teleosemantic account of the proliferation of intentional conventional linguistic signs can usefully be construed as a kind of ultimate explanation of human (verbal and non-verbal) communication. Its main task is to address questions such as: what is the evolutionary or cultural function of human communication? Why do humans engage in communication at all? As with other kinds of ultimate explanations, it needs to be supplemented by specific proximate explanations whose role is to disclose the particular human cognitive capacities and mental processes whereby humans produce and understand intentional conventional signs.

The goal of this paper is to assess the balance between Millikan's broad teleosemantic approach to the cooperative function of human communication and the choice of particular proximate psychological mechanisms that she endorses. In particular, I will focus on her anti-mentalistic view, namely that verbal understanding of another's utterance is a kind of direct *perception* of whatever the utterance is about, and her correlative rejection of the basic Gricean pragmatic assumption that verbal understanding is an exercise in *mindreading*. One of the distinctive features of the human mindreading capacity is that it enables individuals to make sense of two kinds of agency: instrumental and communicative agency. In order to make sense of an agent's instrumental action, one must represent the contents of both her motivations and epistemic states. In order to make sense of an agent's communicative action, as Grice has basically argued, the addressee must infer what the agent is trying to convey, i.e., her communicative intention, whose very fulfilment

¹ For further discussion cf. Jacob 1997, pp. 256–269.

requires that it is recognized by the addressee. What is distinctive of human intentional communication is that it enables the communicative agent to cause her addressee to acquire new psychological states, and thereby to manipulate his mind.

Thus, I shall examine the contrast between the particular proximate mechanisms favored by Millikan and the Gricean pragmatic tradition. In the first section, I shall spell out the basic Gricean mentalistic framework. In the second section, I will spell out Millikan's teleosemantic machinery. In the third section, I will examine Millikan's view that verbal understanding is an extended form of perception. In the fourth section, I will examine the extent to which Millikan's account of conventions can support her rejection of the Gricean assumption that verbal understanding is an exercise in mindreading. Finally, in the last section, I will show that recent developmental findings in the investigation of early human social cognition are relevant to the controversy between Millikan and the Gricean tradition over the choice of proximate mechanisms underlying human communication.

2 The Gricean mentalistic picture of communicative agency

The Gricean mentalistic tradition rests on three basic related assumptions.²

- The first is the assumption that the complete process whereby an addressee contributes to the full success of a speaker's communicative act should be decomposed into two separable psychological sub-processes: a process of *understanding* (or *comprehension*) of the speaker's utterance and a process of *acceptance*, which in turn can be construed as the addressee's acquiring either a new belief or a new desire for action (depending on the direction of fit of the speaker's utterance). I'll call this the *separability* thesis.

² Although the relevance-based approach advocated by Sperber & Wilson (1986) and Wilson & Sperber (2004) departs in some interesting respects from Grice's (1969, 1989) own approach, I will nonetheless call their approach "Gricean" because, in the context of the present paper, the continuities between the two frameworks are far more important than the discontinuities.

- The Gricean mentalistic tradition also rests on the assumption that verbal understanding is an exercise in mindreading, whereby the addressee recognizes the complex psychological state that underlies the speaker's communicative act. I'll call this the *mindreading* thesis. (Clearly, the mindreading thesis is presupposed or entailed by the separability thesis.)
- Third, the Gricean mentalistic tradition further rests on a fundamental hypothesized asymmetry between what is required for understanding *instrumental* non-communicative agency and *communicative* agency. An agent intends her instrumental action to satisfy her desire in light of her belief, and the desirable outcome of her instrumental action can be recognized even if the agent fails to fulfil her goal or intention. But the intended effect of a speaker's communicative action, which is the addressee's understanding of what she means, cannot be achieved unless the speaker's intention to achieve this effect is recognized (cf. Sperber 2000, p. 130). Unlike purely instrumental agency, communicative agency is *ostensive* in the following sense. A speaker's communicative act is ostensive because its desirable outcome cannot be identified unless the addressee recognizes what the speaker intends to make manifest to him, i.e., what Sperber & Wilson (1986) call the speaker's *informative* intention. Thus, the Gricean tradition rests on the thesis of the *ostensive* nature of communicative agency (Sperber & Wilson 1986).

2.1 The mindreading thesis

On the picture of pragmatics which is part of the Gricean tradition of the past forty years broadly conceived, a human agent could not achieve a verbal or non-verbal act of intentional communication unless she had a complex psychological state, which Grice (1957) called the "speaker's meaning" and which he construed as a set of three interrelated intentions.³ First of all, by producing an utterance (or any other piece of ostens-

³ For brevity, I'll use "speaker" instead of "communicative agent". But of course not all communicative actions are verbal.

ive communicative behavior), the speaker must have the basic intention (i) to act on her addressee's mind, i.e., to cause him to acquire a new belief or a new desire (or intention) to perform some action. Second, the speaker must intend (ii) her addressee to recognize the content of her basic intention. Third, she must further intend (iii) her addressee's recognition of her basic intention (in accordance with (ii)) to play a major role in his fulfilling her basic intention (i).

In the following, I will adopt (Sperber & Wilson's (1986) simplified two-tiered account, according to which a communicative agent who produces an utterance has *two* (not three) inter-related intentions: an *informative* and a *communicative* intention, the first of which is nested within the other. She has the informative intention to make some state of affairs manifest to her addressee and also the further communicative intention to make her informative intention manifest to her addressee. So in this framework, the speaker's communicative intention is fulfilled by the addressee as soon as the latter recognizes (or understands) which state of affairs it is the speaker's informative intention to make manifest. But more is required for the speaker's informative intention to be fulfilled: the addressee must further accept the speaker's epistemic or practical authority. Depending on the direction of fit of the speaker's utterance, the addressee must either believe the fact which it is the speaker's informative intention to make manifest to him, or he must acquire the desire to act so as to turn into a fact the possible state of affairs which it is the speaker's informative intention to make manifest to him.

In a nutshell, much of (Sperber & Wilson's (1986) relevance-based framework rests on their insightful recognition that, on the broad Gricean picture of the speaker's meaning, the task of the addressee can be usefully divided into two basic psychological processes: one is the process whereby the addressee *understands* (or recognizes) the speaker's informative intention and the other is the process whereby he *fulfils* the speaker's informative intention. The first process involves the addressee's recognition of the speaker's informative intention, whereby the addressee fulfils the speaker's communicat-

ive intention that he recognize the speaker's informative intention. By recognizing the speaker's informative intention, the addressee comes automatically to both fulfil the speaker's communicative intention and to understand (or comprehend) the speaker's utterance. But for the addressee to *recognize* the speaker's informative intention is not *ipso facto* to *fulfil* it. So the second process needed for the success of the speaker's communicative act involves the addressee's fulfilment of the speaker's informative intention, whereby the addressee either accepts a new belief (in accordance with the content of the speaker's assertion) or forms a new desire to act (in accordance with the content of the speaker's request; cf. Jacob 2011).

2.2 The separability thesis

While the relevance-based account of communication clearly presupposes the mindreading thesis, Sperber (2001) has offered further support in favor of the separability thesis. Following Krebs & Dawkins (1984), Sperber (2001) has argued that for cooperative communication to stabilize in human evolution, it must be advantageous to both senders and receivers. Since the interests of speakers and hearers are not identical, the cooperation required for the stabilization of communication is vulnerable to deception. When her utterance is descriptive, the speaker can speak either *truthfully* or *untruthfully*. The addressee can either *trust* the speaker or not. The speaker is better off if her addressee trusts her and worse off if he distrusts her, whether or not the speaker is truthful. If the addressee trusts the speaker, then he is better off if the speaker is truthful and worse off if the speaker is not truthful, while the addressee remains unaffected if he distrusts the speaker.

Clearly, not every speaker is (or should be) granted equal epistemic or practical authority on any topic by every addressee. As Sperber et al. (2010) have further argued, given the risks of deception, it is likely that human cooperative communication would not have stabilized in human evolution unless humans had evolved mechanisms of *epistemic vigilance*, whereby they filter the reliability of descriptive utter-

ances. Focusing on a speaker's assertions at the expense of her requests, a speaker's epistemic authority depends to a large extent on the addressee's evaluation of her reliability (or trustworthiness), which in turn depends jointly on the addressee's evaluation of the speaker's competence on the topic at hand and on the addressee's representation of how benevolent are the speaker's intentions towards him. According to [Sperber et al. \(2010\)](#), an addressee's epistemic vigilance can apply to either or both the *source* of the information being communicated and its *content*.

3 Millikan's teleosemantic machinery

3.1 Teleosemantics and informational semantics

One of the first attempts at a naturalistic account of content (or intentionality) in the philosophy of mind was [Dretske's \(1981\)](#) informational semantics, according to which a sign or signal s carries information about property F iff there is a nomic (or lawful) covariation between instances of F and tokenings of s . As [Millikan \(1984, 2004\)](#) emphasized shortly after, informational semantics faces the puzzle of accounting for the possibility of *misrepresentation*. If the conditional probability that F is instantiated given s is 1, then how could s ever misrepresent instances of F ? This puzzle is neatly solved by teleological approaches: if a representation has a *function*, then it can fail to fulfil its function and thereby misrepresent what it is designed to represent ([Millikan 2004](#), Ch. 5). According to [Dretske's \(1988, 1995\)](#) own later attempt at preserving informational semantics as part of teleosemantics, a sign or signal s could not represent some property F unless s had the function of carrying information about (or indicating) instances of F .

[Millikan's \(1984, 2004\)](#) teleosemantic approach sharply departs from [Dretske's \(1988, 1995\)](#) information-based framework in at least two fundamental respects. First of all, in [Millikan's](#) earliest (1984) teleosemantic framework, there was no room for information-theoretic notions at all. In her later (1989a, 2004) work, she

argued that carrying information could not be a teleological function of a sign on the following grounds. Whether a sign carries information about some property depends on how the sign was *caused* or *produced*. But according to the etiological theory of functions, the function of a sign is one of its own *effects*, i.e., the selected effect that explains the continued reproduction of tokens of signs of this kind. How a sign was caused cannot be one of its effects, let alone its selected effect. If and when a sign happens to carry information about something, carrying information cannot be its selected effect, i.e., its etiological function.⁴

Second, [Dretske's \(1981\)](#) informational semantics could only be suitably naturalistic in the required sense if information is construed as the converse of nomological covariation (or necessity), i.e., as an entirely non-intentional and/or non-epistemic commodity. But as [Millikan \(2004, pp. 32–34\)](#) argues, if signal s could not carry information about F unless the probability that F is instantiated when s is tokened were 1 (in accordance with some natural law), then no animal could ever learn about F from perceiving tokens of s .

In her 2004 book, [Millikan](#) elaborates a notion of natural sign that is more “user-friendly” precisely because “it is at root an epistemic notion” ([Millikan 2004](#), p. 37). On [Millikan's \(2004\)](#) account, natural signs (e.g., tracks made by quail) are locally recurrent signs within highly restricted spatial and temporal domains: relative to one local domain, such tracks are natural signs of quail. Relative to a neighboring domain, the very same tracks are made by pheasants and are therefore natural signs of pheasants, not quail. Locally recurrent signs afford knowledge of the world for animals who can learn how to track the circumscribed domains relative to which they carry reliable information. Furthermore, locally recurrent natural signs can form transitive chains (or be productively embedded) within circumscribed do-

⁴ For significant discussion and defense of the view that it is the etiological function of mental representations to carry information, in response to Millikan's criticisms, cf. [Neander \(1995, 2007\)](#), [Godfrey-Smith \(2006\)](#) and [Shea \(2007\)](#). Cf. the recent exchange between [Neander \(2011\)](#) and [Millikan \(2011\)](#) For a criticism of Millikan's view, cf. [Pietroski \(1992\)](#) and see [Millikan's \(2000\)](#) reply.

mains. For example, retinal patterns can be a natural sign of tracks in the ground, which in turn may be a natural sign of quail within a circumscribed local domain. Perception is what enables non-human animals and humans alike to track the meanings of locally recurrent natural signs in their circumscribed domain of validity and thereby to acquire knowledge of the world (Millikan 2004, Ch. 4).

The application of Millikan's (1984, 2004) teleosemantic framework to the meanings of intentional *conventional* signs results from the combination of three related ingredients: (i) the etiological view of functions; (ii) acceptance of the sender-receiver structure as a necessary condition on the contents of intentional representations; and (iii) a naturalistic account of the reproduction of conventions.

3.2 The etiological conception of functions

As I said above, on the etiological view, the function of some trait is its selected effect that explains the continued reproduction of past tokens of this trait. This is what Millikan (1984) calls a device's *direct* proper function. But a device may also have what she calls a *derived* proper function. For example, it is the direct proper function of the mechanism of color change in the skin of chameleons to make them undetectable from the local background by predators. It is a derived proper function of this mechanism in a particular chameleon, Sam, at a particular place and time, to make the color of its skin match the color of its particular local background at that time so as to make it undetectable by predators there and then.

While Millikan's teleofunctional framework based on the etiological approach to functions primarily fits biological traits, it applies equally to non-biological items such as non-bodily tools—including public-language forms. For example, screwdrivers have the direct proper function of turning (driving or removing) screws. This is the effect of screwdrivers that explains their continued reproduction. Clearly, a screwdriver may also be intentionally used for the purpose of driving a screw with a particular metallic

structure, length, and diameter into a particular wooden material at a particular time and place. If so, then driving this particular screw into this particular wooden material at a particular time and place will be the derived proper function that this particular screwdriver inherits from the agent's intention.

3.3 The sender-receiver framework

According to the sender-receiver framework, a sign or signal *R* can be an *intentional* representation (as opposed to a *natural* sign) only if it is a *relatum* in a three-place relation involving two systems (or mechanisms), one of which is the sender (who produces *R*), the other of which is the receiver (who uses *R*). By application of the etiological view of functions, the sender (or producer) and the receiver (or consumer) have co-evolved so that what Millikan (1984, 2004) calls the *Normal* conditions for the performance of the function of one depends on the performance of the other's function and vice versa. In a nutshell, the producer and the consumer are *co-operative* devices, whose interests overlap and whose activities are beneficial to both. Thus, the cooperative ternary sender-receiver structure naturally applies to the contents of intentional mental representations that mediate between cognitive mechanisms located within a single organism.⁵

In virtue of the fact that intentional mental representations can have two basic directions of fit, the evolved cooperation between the producer and the consumer can take two basic forms. If and when the representation is *descriptive* or has a mind-to-world direction of fit, the producer's function is to make a sign *R*, whose content matches some state of affairs *S*, for the purpose of enabling (or helping) the consumer to perform its own task when and only when *S* obtains. If and when the representation is *directive* (or prescriptive) or has a world-to-mind direction of fit, the producer's function is to produce a representation whose content will guide the consumer's action, and it is the con-

⁵ Cf. Godfrey-Smith (2013) and Artiga (forthcoming) for further elaborate discussion of the requirement of cooperation as a condition on application of the sender-receiver structure.

sumer's function to make the world match the content of the sign by its own activities. Furthermore, Millikan (1995, 2004) has argued that the most primitive kinds of intentional mental representations (shared by humans and non-human animals) are what she calls *pushmi-pullyu* representations, which are at once descriptive and prescriptive, with both a mind-to-world and a world-to-mind direction of fit.

3.4 Conventional patterns

The third component of Millikan's teleosemantic approach to the meanings of intentional conventional signs involves her (1998) naturalistic account of *conventions*. On her account, so-called *natural conventionality* rests on two elementary characteristics: first, natural conventions are patterns that are *reproduced* (or that proliferate). Second, they are reproduced (or "handed down") "owing to precedent determined by historical accident, rather than owing to properties that make them more intrinsically serviceable than other forms would have been" (Millikan 2005, p. 188). The fact that conventions rest on historical precedent to a large extent accounts for their arbitrariness.⁶ On the basis of her naturalistic account of the continued reproduction of natural conventions, Millikan further offers a purportedly naturalistic account of the continued reproduction of conventional public-language signs, whose function is to coordinate the transfer of information between speakers and hearers. She thereby extends the cooperative ternary sender–receiver structure to the meanings of intentional conventional signs (or public-language forms) that mediate cognitive mechanisms located within pairs of distinct organisms.

Conventional public-language forms are tools or *memes* in Dawkins's (1976) sense: they have been selected and have accordingly been reproduced because they serve *coordinating* functions between a sender (the speaker) and a receiver (the addressee), whose interests overlap. But like any other tool, in addition to its direct *memetic* (or "stabilizing") function (which ex-

plains its continued reproduction), a particular token of some public-language form may also have a derived function or purpose, derived from the purpose of the speaker who produced it at a particular place and time. Thus, a token of a public-language form has two kinds of purposes: a memetic purpose and the speaker's purpose, which may or not coincide (cf. Millikan 1984, 2004, 2005).

4 Is verbal understanding an extended form of perception?

4.1 Perceiving the world through language

One basic problem raised by Millikan's account of the proliferation of intentional conventional signs is that one and the same linguistic form detached from its context of use may belong to different *memetic* families (or chains of reproductive events). In the reproductive process, what gets copied from one pair of sender-receivers to the next is not merely a linguistic form (e.g., "clear"), but the *use* of a linguistic form embedded in a particular *context*. This is why on Millikan's (2005, Ch. 10, section 3) view, the boundary between semantics and pragmatics is *blurry* and the process whereby a hearer tracks the memetic lineage of a conventional sign is a pragmatic process. On the teleosemantic approach, the hearer's task is to retrieve the appropriate context necessary for recognizing the correct memetic family (or lineage) to which a particular conventional sign belongs. In a nutshell, the hearers' task is to track the *domains* of intentional *conventional* signs.

Thus, it would appear that the hearer's task is quite similar to what is involved in tracking the restricted domain over which the information carried by a locally recurrent *natural* sign (e.g., tracks made either by quail or by pheasants) is valid. Since tracking the local domains over which the information carried by locally recurrent natural signs is a *perceptual* task, it is not surprising that Millikan has persistently urged that "in the most usual cases understanding speech is a form of direct perception of whatever speech is *about*. Interpreting

⁶ Including the arbitrariness of the relation between particular word-types and what they mean (sense and/or reference).

speech does not require making any inferences or having any beliefs about words, let alone about speaker intentions” (Millikan 1984, p. 62).⁷ Millikan (2004, p. 122) nicely illustrates her view that verbal understanding is an extended form of perception:

rain does not sound the same when heard falling on the roof, on earth, on snow, and on the water, even though it may be directly perceived as rain through any of these media. Exactly similarly, rain has a different sound when the medium of transmission is the English language (“It’s raining!”). And it sounds different again when the medium of transmission is French or German.

In a nutshell, “during Normal conversation, it is not language that is most directly perceived by the hearer but rather the world that is most directly perceived *through* language” (Millikan 2005, p. 207).

Furthermore, both ordinary and extended perception rest on *translation*, not inference: “the first steps in perception involve reacting to natural signs of features of the outer world by translating them into inner intentional representations of these outer features, for example, of edges, lines, angles of light sources in relation to the eye” (Millikan 2004, p. 118). In *normal* verbal communication, translation plays a two-fold role in mediating transfer from the speaker’s belief to the addressee’s belief. First, the speaker of a descriptive utterance translates her belief into a sentential conventional sign. Secondly, the addressee translates the content of the speaker’s utterance into his own new belief (Millikan 1984, 2004, 2005).

4.2 Ordinary and extended perception

Clearly, Millikan’s thesis that verbal understanding is an extended form of perception is not consistent with the Gricean thesis that verbal understanding is an exercise in *mindreading*. But on the face of it, the thesis

that verbal understanding is an extended form of perception (of whatever speech is *about*) itself is puzzling for at least three related reasons.⁸ First of all, as Millikan (2004, Ch. 9) herself recognizes, there is a major difference between the content of a perceptual representation of some state affairs and the verbal understanding of the content of another’s testimony about the very same state of affairs. At an appropriate distance and in good lighting conditions, one could not perceive a cup resting on a table without also perceiving its shape, size, color, texture, content, orientation, and spatial location with respect to the table, to any other object resting on the table, and especially to oneself. As Millikan (2004, p. 122) recognizes, unlike the content of testimony, the content of ordinary perception can be put at the service of action precisely because it provides information about the agent’s spatial relation to an object that is potentially relevant for action. But if an addressee located in a room next to the speaker’s room understands the content of the latter’s utterance of the sentence “There is a cup on the table”, he may endorse the belief that there is a cup on the table without having any definite expectation about the shape, size, color, texture, content, orientation, and spatial location of the cup with respect to himself, the table, or anything else.

Second, the thesis that verbal understanding is an extended form of perception ought to be restricted to the hearer’s verbal understanding of the meanings of *descriptive* utterances of indicative sentences with a mind-to-world direction-of-fit, which describe *facts* (or *actual* states of affairs). It cannot without further modifications be directly applied to the hearer’s verbal understanding of the meanings of *prescriptive* utterances of *imperative* sentences whereby a speaker *requests* an addressee to *act* so as to turn a *possible* (non-actual) state of affairs into a fact (or an actual state of affairs). Prescriptive utterances, which have a world-to-mind direction of fit, fail to describe any fact that could be directly perceived at all. So the question arises whether Millikan would be willing to en-

⁷ Cf. Millikan (2000, Ch. 6), Millikan (2004, Ch. 9), Millikan (2005, Ch. 10).

⁸ Cf. Recanati (2002) for a defense of Millikan’s thesis.

dorse the revised two-tiered thesis that (i) a verbal understanding of a speaker's descriptive utterance is the perception of whatever the utterance is about and (ii) a verbal understanding of a speaker's prescriptive utterance is to intend to perform whatever action is most likely to comply with the speaker's request.

Finally, testimony enables a speaker to convey beliefs whose contents far outstrip the perceptual capacities of either the speaker or her addressee. For example, an addressee may understand that the speaker intends to verbally convey to him her belief that there is no greatest integer, that democracy is the worst form of government except all those other forms that have been tried from time to time, or that religion is the opium of the people. But it does not make much sense to assume that either the speaker or her addressee could perceive what the speaker's utterance is about.

4.3 Tracking the domains of intentional conventional signs

Furthermore, the thesis that verbal understanding is an extended form of perception clearly rests on the assumption that the process whereby the hearer of a speaker's utterance tracks the memetic family of the intentional conventional sign used by the speaker is basically the same as the process whereby human and non-human animals track the meanings of locally recurrent natural signs in their circumscribed domain of validity. As I mentioned above, Millikan (2004) argues that perception is the basic process whereby animals track the meanings of locally recurrent natural signs in their circumscribed domain of validity. Crucially, one can track the meanings of locally recurrent natural signs within their circumscribed domain of validity *without* representing an agent's psychological state. So the question arises whether a hearer of a speaker's utterance could *always* track the memetic family of the intentional conventional signs used by a speaker *without* representing any of the speaker's psychological states.

In particular, as Recanati (2007) has argued, the question arises for descriptive utter-

ances containing at least four kinds of conventional expressions considered by Millikan (2004, Chs. 10–12): so-called unarticulated constituents in Perry's (1986) sense, incomplete definite descriptions, quantifiers, and possessives. Consider first an utterance of (1):

(1) It is raining.

It is unlikely that by an utterance of (1) a speaker means to assert that it is raining somewhere or other at the time of utterance. Instead, she is likely to mean that it is raining at the time of utterance and at the place of utterance (which remains unarticulated in the sentence). If by an utterance of (1), the speaker could *only* mean that it is raining at the place of utterance, then Millikan's claim that a hearer need not represent any of the speaker's psychological states for the purpose of tracking the local domains of intentional conventional signs might be vindicated. However, by an utterance of (1) on the phone, a speaker located in Paris may mean that it is raining in Chicago, not in Paris. Similarly, a French speaker located in Paris may use the incomplete description "the President" to refer, not to the French President, but instead to the President of the US.

For the purpose of understanding an utterance of a sentence containing a universal quantifier, as shown by example (2), the hearer must be able to properly restrict the domain of the quantifier:

(2) Everyone is asleep.

By an utterance of (2), the speaker presumably means to assert, not that everyone in the universe is asleep, but that everyone in some restricted domain (e.g., a relevant household) is asleep.⁹ The relevant restricted domain is the domain the speaker has in mind. Finally, by using the possessive construction "John's book", the speaker may have in mind many different relations between John and the book: she may mean the book written by John, the book

⁹ A nice example suggested by a referee is "There is no beer left", where the audience does not take the speaker to mean that there is no beer left in the universe, but instead in some properly restricted domain (e.g., some relevant fridge).

read by John, the book bought by John, the book sold by John, the book John likes, the book John dislikes, the book John just referred to in the conversation, the book John lost, the book John gave to the speaker, the book the speaker gave to John, the book the hearer gave to John, and so on. Unless the hearer hypothesizes what relation the speaker has in mind, he will fail to understand what the speaker means by her utterance of “John’s book”. In none of these four cases does it seem as if the hearer could recognize the memetic family of intentional *conventional* signs, i.e., track their relevant domains—unless he could represent the contents of some of the speaker’s *beliefs* or *assumptions*.

5 Conventions and belief-desire psychology

5.1 Teleosemantics and the separability thesis

Millikan’s thesis that verbal understanding is an extended form of perception is meant as an alternative to the Gricean thesis that verbal understanding is an exercise in mindreading. The further question arises to what extent Millikan’s teleosemantic account of the proliferation of public language conventions is consistent with the Gricean separability thesis, i.e., the distinction between verbal understanding and either acceptance (belief) or compliance. I will first argue that there is a restricted sense in which Millikan’s teleosemantics seems to be consistent with the separability thesis. But I will further argue that in a broader sense Millikan’s rejection of the mindreading thesis undermines the separability thesis.

On Millikan’s teleosemantic account, for a speaker’s descriptive utterance of an indicative sentence to meet the requirement of cooperation (and mutual interest) between the sender (or producer) and the receiver (or consumer), its direct proper function must be to cause the addressee to form a (true) belief. For a speaker’s *prescriptive* utterance of an imperative sentence to meet the requirement of cooperation, its direct proper function must be to cause the ad-

dresser to act in compliance with the content of the speaker’s request.

In the terminology of the relevance-based framework, a speaker who utters a descriptive utterance makes manifest to her addressee her communicative intention to make manifest her informative intention to make some fact manifest to him. The addressee may fulfil the speaker’s communicative intention by recognizing her informative intention and yet fail to fulfil her informative intention by resisting endorsing the relevant belief. A speaker who utters a prescriptive utterance makes manifest to her addressee her communicative intention to make manifest her informative intention to make manifest to him the desirability of turning some possible state of affairs into a fact by his own action. The addressee may fulfil the speaker’s communicative intention by recognizing her informative intention and yet fail to fulfil the speaker’s informative intention by resisting endorsing the intention to act in accordance with the speaker’s request.

Origgi & Sperber (2000, pp. 160–161), who subscribe to the Gricean thesis of the separability between verbal understanding and acceptance or compliance, have argued that the direct proper function of either a descriptive utterance or a prescriptive utterance could not be to reliably elicit the addressee’s response “at the level of belief or desire formation” (i.e., “the cognitive outputs of comprehension”), but instead “at an intermediate level in the process of comprehension”. Millikan might reply that according to her teleosemantic framework, an utterance may have a direct proper *function* and yet remain *unfulfilled*. If so, then the fact that an addressee may fulfil the speaker’s communicative intention (by recognizing her informative intention) and yet fail to fulfil the speaker’s informative intention seems entirely compatible with the teleosemantic framework.

However, to the extent that Millikan explicitly rejects the mindreading thesis, which is presupposed by the separability thesis, it is unlikely that she would find the separability thesis itself acceptable. On the relevance-based approach, it is a sufficient condition for securing what Austin (1975) called the “up-

take” (or success) of a communicative act (or speech act) that the speaker causes the addressee to fulfil the speaker’s communicative intention by recognizing her informative intention. It is not necessary that the addressee further fulfil the speaker’s informative intention. Successful communication does not require the addressee to accept either a new belief or a new desire, in accordance with the speaker’s informative intention. But on Millikan’s teleosemantic framework, failure of the addressee to comply with the speaker’s goal of causing the addressee to accept either a new belief or a new desire looks like a failure of the addressee to cooperate with the speaker’s conventional action, and therefore like a breakdown of the speaker’s communicative action. In fact, Millikan (2000, 2004, 2005) has offered two broad grounds for rejecting the mindreading thesis, both of which make it unlikely that she would support the separability thesis; the second of which is based on developmental evidence. I start with the non-developmental argument.

5.2 Cooperation and social conformity

First, Millikan (2004) rejects the mindreading thesis as part of her criticism of the reasoning that leads to the separability thesis: she rejects the joint assumptions that human predictions of others’ behavior are based on mindreading and that cooperation in human verbal communication is vulnerable to the risks of deception. On the one hand, she argues that “most aspects of social living involve cooperation in ways that benefit to everyone [...] for the most part, social cooperation benefits both or all parties. There is nothing mysterious about its evolution in this respect” (Millikan 2004, pp. 21–22). In a nutshell, Millikan argues that the urge to explain how the benefits of human communication are not offset by the risks of deception is misplaced on the grounds that the interests of speakers and hearers are sufficiently similar, if not identical.¹⁰

On the other hand, she argues that we use belief-desire psychology, not for prediction, but “for explanation after the fact” (Millikan 2004, p. 22). This is consonant with her (1984, pp. 67–69) earlier claim that while human adults have the ability to *reflect* on a speaker’s communicative intention if the automatic flow of conversation is interrupted for one reason or another, *normal* verbal understanding does *not* require representing the speaker’s communicative intention. Instead, *normal* verbal understanding should be construed as a *conventional* transfer of information whereby the speaker *translates* her belief into an utterance, whose meaning is in turn *translated* back by the addressee into a newly acquired belief.

Thus, Millikan rejects two of the major assumptions on which the separability thesis rests. She underestimates the gap between the interests of speakers and hearers in human communication and she minimizes the role of belief-desire psychology in the prediction of others’ behavior. Interestingly, her rejection of both assumptions rests in turn on her own competing account of communicative acts. As she puts it, “a surprise of this analysis of the conventional nature of the information-transferring function of the indicative is that believing what you hear said in the indicative turns out to be a conventional act, something one does in accordance with convention” (Millikan 2005, p. 46).¹¹ First of all, Millikan (2004, p. 23) argues that humans expect others to behave in conformity with social conventions, not on the basis of others’ beliefs and desires. Second, she further speculates that the conventional behaviors that are caused by a disposition to social conformity may derive from natural selection the memetic function of serving a coordinating function (*ibid.*).

Clearly, being disposed to social conformity and expecting others to be similarly disposed may help solve coordination problems (as shown by driving on one side of the road). However, being disposed towards social conformity is not sufficient to comply with social conventions. Compliance requires *learning*, i.e., the ac-

¹⁰ As Godfrey-Smith (2013, p. 45) observes, sameness of interests in human cooperation can be safely assumed in small contemporary communities, but not on a large scale, and nor in an evolutionary context.

¹¹ Note that this quote seems to presuppose the negation of the separability thesis.

quisition of relevant true *beliefs* about the contents of social conventions. Thus, the basic challenge for Millikan's claim that humans expect others to behave, not so much in accordance with the contents of their beliefs and desires, but in conformity with social conventions, is to offer an account of how humans come to learn and thereby know what it takes to act in conformity with social conventions.

5.3 Counterpart reproduction

This issue has been highlighted by the exchange between Tomasello's (2006) comments on Millikan's (2005) book and Millikan's (2006) response, which focuses on Millikan's (1998) thesis that many conventions, whose function it is to solve *coordination* problems, are reproduced by what she calls *counterpart* reproduction (or nuts and bolt reproduction). Typical coordination problems involve at least two partners, who share a common purpose that can be achieved only if each partner plays its assigned role, where both partners can be required to perform either the same act or two distinct complementary acts. In counterpart reproduction, when the respective roles of each partner require them to perform two different complementary acts, one typically adjusts her behavior to the other's and vice-versa. Counterpart reproduction is exemplified by, e.g., handshake reproduction, the reproduction of the respective postures assumed by men and women in traditional dancing, the reproduction of social distances appropriate for conversation, or the reproduction of the use of chopsticks for eating. Similarly, Millikan (2005, 2006) argues that counterpart reproduction also underlies the continued reproduction of conventional public-language signs.

Millikan (2005) further mentions open, partially or completely blind, conventional *leader-follower* co-ordinations involved in joint actions based on shared goals, whereby one agent (the leader) introduces a component of a pattern whose completion requires her partner (the follower) to perform a complementary component (*ibid.*, pp. 12–14). One example of open conventional leader-follower coordination is the

pattern whereby one agent selects her seat at an arbitrary table in a restaurant and her partner follows suit and selects his accordingly. One example of a partially blind conventional leader-follower coordination is the couch-moving pattern whereby the leader affords the follower anticipatory cues of her next move by ostensibly exaggerating her own movements, where the follower's familiarity with the pattern enables him to recognize the leader's ostensive cues and thereby to reproduce the complementary portion of the joint action. Another of Millikan's examples of a partially blind conventional leader-follower coordination is the US mailbox-flag convention, whereby the leader puts up a flag after she has placed mail in the mailbox and the postman picks up the mail after perceiving the flag.

Much comparative work by Tomasello and colleagues (reported by Tomasello et al. 2005 and summarized by Tomasello 2006, 2008) shows that while most communicative gestures in chimpanzees are learnt by ontogenetic ritualization, most communicative behaviors in human infants are acquired by imitative learning. As Tomasello (2006) argues, Millikan's own requirement that the reproduction of a conventional pattern depends on "the weight of precedent", not on its perceived intrinsic superior ability to produce a desired result, seems better fulfilled by a process of imitative learning than by a process of trial and error whereby one individual adjusts her behavior to another's. There seems to be nothing arbitrary (as there should if it were conventional) about an individual's adjusting her behavior to another's. While Tomasello (2006) does not deny that counterpart reproduction plays a significant role in cultural transmission, he disputes the claim that the output of counterpart reproduction qualifies as conventional.

Part of the gap between Millikan and Tomasello lies in what they take to be the proper unit for the analysis of the mechanism underlying the continued reproduction of conventional patterns involved in solving problems of coordination. While Tomasello focuses on the learning capacities of single individual minds, Millikan focuses on what can be achieved by the

reciprocal adjustments of pairs of cooperative partners. For example, when [Millikan \(2005, 2006\)](#) argues that counterpart reproduction underlies the continued proliferation of the custom of using chopsticks for eating in some cultures, she construes the convention of using chopsticks as a solution to the problem of coordination between pairs of partners, some of whom buy chopsticks and use them for eating and others who manufacture chopsticks. The latter would not manufacture chopsticks unless the former bought them and used them for eating. Conversely, the former would not buy them and use them for eating unless the latter manufactured them.

But of course, as Millikan is aware, this leaves open the question of how young children learn to use chopsticks for eating. As [Millikan \(2006, pp. 45–46\)](#) rightly observes, young human children understand their native language long before they can speak it. Nor can they learn to understand by imitating mature speakers: as she puts it, “they don’t watch how other people understand and then copy”. She further argues that young children would never understand their native tongue unless “their teachers” spoke to them, but “their teachers” would never speak to young children unless “they had had some reasonably successful experience” with previous listeners. This makes the continued reproduction of conventional public-language signs fit the pattern of counterpart reproduction. But still the question arises: how do young children learn to produce words of their native tongue? Vocal imitative learning may well play an important role (cf. [Hauser et al. 2002](#)). In a nutshell, according to Millikan the function of conventions is to solve coordination problems. She offers an elegant account of the proliferation of conventions based on counterpart reproduction. Her account must make room for the role of imitative learning in the way young human children learn either to use chopsticks for eating or to produce (and not just understand) words of their native tongues. As I shall argue in section 6.2, evidence shows that imitative learning in young children rests on their ability to construe the model’s demonstration as an ostensive communicative action. If so, then Mil-

likan’s view that counterpart reproduction underlies the proliferation of conventions must make room for the role of children’s ability to recognize the model’s communicative intention.

6 Teleosemantics and the puzzles of early human social cognition

6.1 Millikan’s developmental puzzle

To further undermine the mindreading thesis, [Millikan \(1984, 2000, 2004, 2005\)](#) has also appealed to findings from the developmental psychological investigation of early human social cognition, showing that “children younger than about four, although fairly proficient in the use of language, don’t yet have concepts of such things as beliefs, desires, and intentions” ([Millikan 2005, p. 204](#)). If such children do not have such concepts, then, unlike adults, they cannot reflectively engage in tasks of mindreading, i.e., in tracking the contents of others’ intentions, beliefs, and desires. To the extent that they can engage in verbal understanding, this further shows that verbal understanding cannot rest on mindreading (or belief–desire psychology).

As Millikan emphasizes, much developmental evidence shows that before they are at least four years old the majority of human children systematically *fail* elicited-response false-belief tasks. (In the terminology of developmental psychologists [Baillargeon et al. 2010](#), *elicited-response* tasks are tasks in which a participant is requested to generate an explicit answer in response to an explicit question.) For example, in the Sally-Anne test, after Sally places her toy in the basket, she leaves. While Sally is away, Anne moves Sally’s toy from the basket to the box. When Sally returns, participants, who know the toy’s actual location, are explicitly asked to predict where Sally (who falsely believes her toy to be in the basket) will look for her toy. The evidence shows that the majority of three-year-olds, “although quite proficient in the use of language” (in Millikan’s terms, [Millikan 2005, p. 204](#)), typically point to the box (i.e., the toy’s actual location), not to the basket where the agent falsely believes her toy to be (cf. [Wimmer & Perner 1983](#), [Baron-](#)

Cohen et al. 1985 and Wellman et al. 2001 for a meta-analysis).

Millikan assumes that the failure of most three-year-olds in such elicited-response false-belief tasks demonstrates that they lack what she calls a “representational theory of mind”. In a nutshell, she assumes that success at elicited-response false-belief tasks is a necessary condition for crediting an individual with a representational theory of mind (i.e., the ability to track the contents of others’ false beliefs). Acceptance of this assumption gives rise to Millikan’s developmental puzzle, which is “to understand how very young children can be aware of the intentions and of the focus of attention of those from whom they learn language without yet having this sort of sophisticated theory of mind” (Millikan 2005, p. 205). Before explaining why Millikan’s assumption is contentious, I shall briefly examine Millikan’s solution to her own puzzle.

Millikan’s solution involves three related ingredients, the most important of which is her thesis that normal verbal understanding is an extended form of perception (which does not require thinking about a speaker’s intention at all). Second, she argues that young children can understand the goal-directedness of a speaker’s communicative action without tracking the content of her communicative intention. Third, she argues that young children can understand the referential focus of a speaker’s attention without having a sophisticated theory of mind. As I understand it, much of the argument for the possibility of understanding the referential focus of a speaker’s attention without having a sophisticated theory of mind rests on the thesis that verbal understanding is an extended form of perception. As I have already expressed doubts about the thesis that verbal understanding is an extended form of perception, I shall now briefly examine the second thesis: that young children could understand the goal-directedness of a speaker’s communicative without tracking the content of her communicative intention.

Millikan (2005, pp. 206–207) offers two main reasons for granting young children the ability to recognize the goal-directedness of a speaker’s communicative action without grant-

ing them a full representational theory of mind. First, she argues that the evidence shows that mammals (dogs and cats and non-human primates, presumably, as well) lack a representational theory of mind but have the ability to recognize the goal-directedness of each other’s behavior. So by parity, very young children should also be granted the ability to recognize the goal-directedness of others’ actions, including speakers’ communicative actions. Second, she argues that communicative actions are cooperative actions. When young children are engaged in some cooperative action (including a communicative action) with a caretaker, they can easily keep track of the shared goal of the cooperative action, while tracking the focus of the speaker’s visual attention, without having a full representational theory of mind.

On the one hand, there is evidence that non-human primates recognize the goals of *instrumental* actions (Call & Tomasello 2008). On the other hand, there is also evidence that non-human primates—and birds as well—can discriminate *knowledgeable* agents (who know about, e.g., food from visual perception) from *ignorant* agents (who don’t know about food because their line of vision is obstructed) in *competitive* situations (Bugnyar 2011; Call & Tomasello 2008; Dally et al. 2006; Hare et al. 2001; Tomasello et al. 2003). But the question raised by Millikan’s puzzle is to understand what enables very young human children to make sense jointly of a speaker’s goal and the focus of her visual attention, when the speaker is performing a *communicative* action, not an *instrumental* action, in a *cooperative*, not a *competitive*, context. The fact that non-human primates can represent the goal of an agent’s *instrumental* action and discriminate a *knowledgeable* from an *ignorant* agent in a *competitive* context falls short of providing the required explanation.

Furthermore, two of Millikan’s assumptions are contentious in light of recent findings from developmental psychology. One is her assumption that young children could recognize the goal-directedness of speakers’ *communicative* actions without a representational theory of mind. The other is her assumption that success

at elicited-response false-belief tasks should be taken as a criterion for having the ability to track the contents of others' false beliefs (and therefore having a representational theory of mind). I shall start with the former, which amounts to denying the asymmetry between instrumental and communicative agency—which I earlier dubbed the thesis of the *ostensive* nature of human communicative agency.

6.2 The puzzle of imitative learning

The first relevant developmental finding, reported by [Gergely et al. \(2002\)](#), shows that approximately one-year-old human children (fourteen-month-olds) selectively imitate an agent's odd action. First, infants were provided with ostensive cues whereby an agent made manifest her intention to convey some valuable information by looking into the infants' eyes and addressing them in motherese. She then told the infants that she felt cold and covered her shoulders with a blanket. She finally performed an odd head-action whereby she turned a light box in front of her by applying her head, in two slightly different conditions. In the hands-occupied condition, she used her hands in order to hold the blanket around her shoulder while she executed the head-action. In the hands-free condition, she ostensibly placed her free hands on the table while she executed the head-action. [Gergely et al. \(2002\)](#) found that while 69% of the children replicated the head-action in the hands-free condition, only 21% did in the hands-occupied condition. In the hands-occupied condition, the majority of children used their own hands to turn the light box on. [Csibra & Gergely \(2005, 2006\)](#) further report that the asymmetry between infants' replication of the model's odd head-action in the hands-free and hands-occupied conditions vanishes if the model fails to provide infants with ostensive cues.

[Gergely & Csibra \(2003\)](#) have reported evidence that twelve-month-olds expect agents engaged in the execution of *instrumental* actions to select the most efficient action as a means towards achieving their goal (or goal-state), in the context of relevant situational constraints. So

the findings on imitation reported by [Gergely et al. \(2002\)](#) raise the following puzzle. Many more infants replicated the agent's head-action when the teleological relation between the agent's means and the agent's goal was opaque (in the hands-free condition) than when it was transparent (in the hands-occupied condition). Why did infants reproduce the agent's head-action more when it was a *less* efficient means of achieving the agent's goal of switching the light box on?

The Gricean thesis about the *ostensive* nature of communicative agency and the asymmetry between instrumental and communicative agency is relevant to answering this puzzle. Arguably, reception of ostensive signals prepared the infants to interpret the agent's action as a communicative, not an instrumental, action. It made manifest to the infants that the agent intended to make something novel and relevant manifest to them by her subsequent non-verbal communicative action. In the hands-occupied condition, the infants learnt how contact was necessary in order to turn on the light bulb, which was part of an unfamiliar device. Since the model's hands were occupied, the infants whose own hands were free assumed that that they were free to select the most efficient means at their disposal to achieve the same goal as the model. In the hands-free condition, the model could have used her hands, but she did not. So the infants learnt from the model's non-verbal demonstration that they could turn the light on by applying their own heads.

On the one hand, the evidence shows that infants construe imitative learning as a response to an agent's communicative action and that they selectively imitate a model's action as a function of what they take to be relevantly highlighted by the model's communicative act (cf. [Southgate et al. 2009](#)). On the other hand, further evidence shows that newborns prefer to look at faces with direct gaze over faces with averted gaze. Right after birth, they display sensitivity to eye-contact, infant-directed speech or motherese, and infant-contingent distal responsiveness. If preceded by ostensive signals, an agent's gaze shift has been shown to generate in preverbal human infants a referential expecta-

tion, i.e., the expectation that the agent will refer to some object (Csibra & Volein 2008, cf. Csibra & Gergely 2009, and Gergely & Jacob 2013, for review).

One further intriguing piece of evidence for the early sensitivity of human toddlers to the ostensive nature of human communicative agency is offered by experiments that shed new light on the classical A-not-B perseveration error phenomenon first reported by Piaget (1954). Infants between eight and twelve months are engaged in an episodic hide-and-seek game in which an adult repeatedly hides a toy under one (A) of two opaque containers (A and B) in full view of the infant. After each hiding event, the infant is allowed to retrieve the object. During test trials where the demonstrator places the object repeatedly under container B, infants continue to perseveratively search for it under container A where it had been previously hidden. Experimental findings reported by Topal et al. (2008) show that minimizing the presence of ostensive cues results in significant decreases of the perseverative bias in ten-month-olds. This finding is consistent with the assumption that infants do not interpret the hide-and-seek game as a game, but instead as a teaching session about the proper location of a toy.

All this evidence strongly suggests that human infants are prepared from the start to recognize nonverbal ostensive referential signals and action-demonstrations addressed to them as encoding an agent's communicative intention to make manifest her informative intention to make some relevant state affairs manifest to the addressee. But of course this raises a puzzle: how could preverbal infants recognize an agent's communicative intention to make manifest her informative intention? A novel approach to this puzzle has been insightfully suggested by Csibra (2010). According to Csibra, very young infants might well be in a position similar to that of a foreign addressee of a verbal communicative act, who is unable to retrieve a speaker's informative intention for lack of understanding of the meaning of the speaker's utterance. Nonetheless, the foreign addressee may well recognize being the target of the speaker's communicative intention on the basis of the speaker's ostensive

behavior. Furthermore, ostensive signals to which preverbal human infants have been shown to be uniquely sensitive can plausibly be said to *code* the presence of an agent's communicative intention. If this is correct, then little (if any) further work would be left for preverbal infants to infer the presence of a speaker's communicative intention after receiving ostensive signals.

6.3 The puzzle about early false-belief understanding

As Millikan has emphasized, much developmental psychology has shown that the majority of three-year-olds fail *elicited-response* false-belief tasks. For example, when asked to predict where an agent with a false belief will look for her toy, most three-year-olds who know the toy's location point to the toy's actual location, and not to the empty location where the mistaken agent believes her toy to be. However, in the past ten years or so, developmental psychologists have further designed various *spontaneous-response* false-belief tasks, in which participants are *not* asked any question and therefore *not* requested to produce any answer. Typical spontaneous-response tasks involve the use of the violation-of-expectation and anticipatory-looking paradigms, which involve two steps. In habituation or familiarization trials, participants are first experimentally induced to form expectations by being repeatedly exposed to one and the same event. Second, in test trials of violation-of-expectation experiments, participants are presented with either an expected or an unexpected event. By measuring the time during which participants respectively look at the expected vs. the unexpected event, psychologists get evidence about the nature and content of the infants' expectations formed during the habituation or familiarization trials. Psychologists can also use the anticipatory-looking paradigm and experimentally determine where participants first look in anticipation of the agent's action, thereby revealing their expectation about the content of the agent's belief.

Thus, in a seminal study based on the violation-of-expectation paradigm by Onishi & Baillargeon (2005), fifteen-month-olds saw an

agent reach for her toy either in a green box or in a yellow box when she had either a true or a false belief about her toy's location. Onishi and Baillargeon report that fifteen-month-olds looked reliably longer when the agent's action was incongruent rather than congruent with the content of either her true or false belief. In a study based on the anticipatory looking paradigm, twenty-five-month-olds were shown to look correctly towards the empty location where a mistaken agent believed her toy to be, in anticipation of her action (Southgate et al. 2007). Many further subsequent studies show that toddlers and even preverbal human infants are able to track the contents of others' false beliefs and expect others to act in accordance with the contents of their true and false beliefs.

In a classical experiment by Woodward (1998), six-month-olds were familiarized with an agent's action, who repeatedly chose one of two toys. In the test trials, the spatial locations of the toys were switched and the infants either saw the agent select the same toy as before at a new location or a new toy at the old location. six-month-olds looked reliably longer at the former than at the latter condition. Luo & Baillargeon (2005) further showed that infants do not look reliably longer at a change of target if, in the familiarization trials, the agent repeatedly reached for the same object, but there was no competing object (for further discussion cf. Jacob 2012). This result has been widely interpreted as showing that six-month-olds are able to ascribe a preference to an agent. Luo (2011) further found that ten-month-olds who know that an agent is in fact confronted with only *one* object (not two) ascribe a preference to the agent if she *falsely believes* that she is confronted with a pair of objects, but *not* if the agent knows (as the infants do) that she is confronted with only one object.

Thus, the psychological investigation of early human social cognition is currently confronted with a puzzle different from that confronted by Millikan: on the one hand, robust findings show that the majority of three-year-olds fail elicited-response false-belief tasks such as the Sally-Anne test. On the other hand, more recent findings based on spontaneous-response

tasks show that preverbal infants expect others to act in accordance with the contents of their true and false beliefs. The puzzle is: how do we make sense of the discrepancy between both sets of experimental findings?

So far, psychologists have offered two broad strategies for this, one of which assumes (as Millikan does) that success at elicited-response false-belief tasks is a necessary condition of the ability to ascribe false beliefs to others, which is taken to be the output of "a cultural process tied to language acquisition" (Perner & Ruffman 2005, p. 214). Their burden is to explain away the findings about preverbal infants without crediting them with the ability to track the contents of others' false beliefs. Thus, the majority of "cultural constructivist" psychologists offer low-level associationist accounts of the findings about preverbal infants based on spontaneous-response tasks. Other psychologists (including Baillargeon et al. 2010; Bloom & German 2000 Leslie 2005; Leslie et al. 2004; Leslie et al. 2005; Scott et al. 2010) argue that the findings about preverbal infants show that they can track the contents of others' false beliefs. Their burden is to explain why elicited-response false-belief tasks are so challenging for three-year-olds. The prevalent non-constructivist explanation is the processing-load account offered by Baillargeon and colleagues.

The core of the associationist strategy is to account for findings about preverbal human infants based on spontaneous-response tasks on the basis of a three-way association between the agent, the object, and its location. It postulates that infants will look longer in the test trials at events that depart more strongly from the three-way association generated by the familiarization trials. For example, in the test trials of Onishi & Baillargeon (2005), infants should look longer when the agent reaches for her toy in the yellow box if in the familiarization trials the agent placed her toy in the green box on three repeated occasions.

The main obstacle for the associationist path is a recent study by Senju et al. (2011) based on the anticipatory-looking paradigm. In the familiarization stage, eighteen-month-olds experience the effect of wearing either an

opaque blindfold through which they cannot see or a *trick* blindfold through which they can see. In the first trials of the test phase, the children are familiarized to seeing an agent retrieve her toy at the location where a puppet has placed it in front of her. The agent's action is always preceded by a pair of visual and auditory cues. In the last test trial, the agent first sees the puppet place the toy in one of the two boxes; she then ostensibly covers her eyes with a blindfold, and finally the puppet removes the toy. After the puppet disappears, the agent removes her blindfold and the cues are produced. Using an eye-tracker, [Senju et al. \(2011\)](#) found that only infants who had experienced an opaque blindfold, not infants who had experienced a trick see-through blindfold, reliably made their first saccade towards the empty location in anticipation of the agent's action.

[Senju et al.'s \(2011\)](#) findings are inconsistent with the associationist strategy: since all infants saw exactly the same events, they should have formed exactly the same threefold association between the agent, the toy, and the location, and on this basis they should have gazed at the same location in anticipation of the agent's action. But they did not. Only infants whose view had been previously obstructed by an opaque blindfold, not those whose view had not been obstructed by a trick blindfold, expected the blindfolded agent to mistakenly believe that the object was still in the opaque container after the puppet removed it.

The evidence against the associationist strategy is also evidence against the assumption (accepted by Millikan) that success at elicited-response false-belief tasks is a necessary condition for having a representational theory of mind and being able to track the contents of others' false beliefs. But this assumption is unlikely to be correct if, as several critics of the cultural constructivist strategy have argued, the ability to ascribe false beliefs to others is not a sufficient condition for success at elicited-response false-belief tasks. As advocates of the processing-load account ([Baillargeon et al. 2010](#)) have argued, an agent could have the ability to ascribe false beliefs to others and still fail elicited-response false-belief tasks for at

least three reasons: she could fail to understand the meaning of the linguistically-encoded sentence used by the experimenter to ask the question. She could fail to select the content of the agent's false belief in the process whereby she answers the experimenter's question. She could fail to have the executive-control resources necessary to inhibit the prepotent tendency to answer the question on the basis of the content of her own true belief. I will now argue that solving the puzzle about early belief-understanding may well depend on acceptance of the Gricean thesis of the ostensive nature of communicative agency and the asymmetry between instrumental and communicative agency.

I now want to offer a speculative solution to the puzzle about early false-belief understanding based on two related Gricean assumptions. The first is the asymmetry between the non-ostensive nature of instrumental agency and the ostensive nature of human communicative agency. The second related assumption is that the human ability to track the content of the false belief of an agent of an instrumental action must be a by-product of the ability to deal with deception (e.g., lying) in the context of human communicative agency.

In the typical Sally-Anne elicited-response false-belief task, participants are requested to make sense of two actions performed by two different agents at the same time: they must track the contents of the motivations and epistemic states of a mistaken agent engaged in the execution of an instrumental action (Sally) and they must also make sense of the communicative action performed by the experimenter who asks them "Where will Sally look for her toy?" The findings based on spontaneous-response tasks strongly suggest that much before they become proficient in language use, young human children are able to spontaneously track the contents of the false beliefs of agents of instrumental actions. So the question is: what is it about the experimenter's question that biases them towards pointing to the toy's actual location?

In [Helming et al. \(2014\)](#), we have argued that two biases are at work, one of which is a referential bias and the other of which is a co-

operative bias. The referential bias itself turns on two components. On the one hand, the experimenter could not ask the question “Where will the agent look for her toy?” unless she referred to the toy. On the other hand, the experimenter shares the participants’ correct epistemic perspective on the toy’s location. In answering the experimenter’s question, participants have the option of mentally representing either the toy’s actual location or the empty location (where the mistaken agent believes her toy to be). The experimenter’s question may bias young children’s answer towards the actual location by virtue of the fact that the experimenter both referred to the toy (whose actual location they know) and shared the participants’ correct epistemic perspective on the toy’s actual location (at the expense of the mistaken agent’s incorrect perspective on the empty location). What we further call the co-operative bias is the propensity of young children to help an agent with a false belief about her toy’s location achieve the goal of her instrumental action by pointing to the actual location (cf. Warneken & Tomasello 2006, 2007; Knudsen & Liszkowski 2012), in accordance with their own true belief about the toy’s actual location. If so, then young children might interpret the prediction question “Where *will* Sally look for her toy?” as a normative question: “Where *should* Sally look for her toy?” Of course, the correct answer to the normative question is the toy’s actual location, not the empty location where the mistaken agent believes her toy to be.

7 Conclusion

The goal of this paper was to assess the gap between Millikan’s particular views about some of the proximate psychological mechanisms underlying human communication and three core assumptions of the Gricean approach: the mindreading thesis, the separability thesis, and the ostensive nature of communicative agency. I have criticized five of Millikan’s basic claims about psychological mechanisms: (i) verbal understanding is best construed as an extended form of perception; (ii) hearers can track the domains of intentional conventional signs

without representing any of the speaker’s psychological states; (iii) the overlap between the interests of speakers and hearers undermines the separability thesis; (iv) humans can predict others’ behavior out of social conformity; (v) developmental psychology supports the view that neither verbal understanding nor language acquisition requires a representational theory of mind.

Millikan’s major teleosemantic contribution has been to open an entirely novel approach to the continued reproduction of intentional conventional public-language signs. As was shown by the discussion of whether her view of the proper function of descriptive and prescriptive utterances is consistent with the separability thesis, there is room for disagreement about particular psychological mechanisms within a teleosemantic approach. I do not think that Millikan’s teleosemantic framework for addressing the continued reproduction of intentional conventional signs mandates the particular choice of proximate psychological mechanisms that she recommends. One of the major challenges for the scientific investigation of cultural evolution is to make sure that the proximate psychological mechanisms that underlie the continued reproduction of human cultural conventions are supported by findings from experimental psychological research, in particular developmental psychology.

Communicative Agency and *ad hominem* Arguments in Social Epistemology

A Commentary on Pierre Jacob

Marius F. Jung

A central point in Jacob's paper focuses on the incompatibility of Grice and Millikan's account of communicative agency. First, the Gricean mindreading thesis is incompatible with Millikan's direct perception account. Second, the account of cooperative devices, defended by Millikan, contradicts the Gricean separability thesis in a broad sense. While I agree with Jacob that these positions are indeed incompatible, I will shift focus and concentrate on issues concerning social epistemology with regard to communicative agency. A main issue in social epistemology concerns the accessibility of the speaker's reliability. How could the hearer remain epistemically vigilant without using fallacious reasoning? (i) I argue that the hearer, in order to be epistemically vigilant, could commit a local *ad hominem* attack, a process of inductive Bayesian reasoning which is an epistemic tool for assessing the speaker's reliability. (ii) Compared to this, a global *ad hominem* attack is a fallacious kind of reasoning, because it undermines knowledge transmission and it cannot be calculated in *Bayes' Theorem*. (iii) The account of a local *ad hominem* attack fits with Grice's mindreading thesis, which is incompatible with Millikan's account of direct perception. (iv) The Gricean separability thesis could better explain occurrences of *ad hominem* attacks than Millikan's assumption that speaker and hearer are cooperative devices.

1 Introduction: Grice's individualistic account of meaning and epistemic trustworthiness

One of the main findings of Jacob's paper is a detailed elaboration of the differences between Millikan's (1984, 2004, 2005) communicative agency and the Gricean (Grice 1957, 1969, Sperber & Wilson 1986) account of speaker's meaning and intention. Jacob argues that the Gricean mindreading thesis, the separability

thesis, and the ostensive nature of communication are not supported by Millikan's account of the direct perception of speaker's intention, which supports a non-inferential model of the understanding of intentional signs. Furthermore, the Gricean account is incompatible with Millikan's claim that speaker and hearer are co-

operative devices; the claim that the prediction of another's behavior could be explained through reliance on socially established conformities and conventions and that modern developmental psychology could get along without any theory of mind.

A very influential account of naturalizing the content of intentional mental representations is Millikan's teleosemantic framework (Jacob 2010). According to this view, the content of intentional mental representations can best be naturalized by relying on the history of the biologically-selected functions of these representations, namely the *direct proper functions* (cf. Millikan 1984, 1989). Interestingly, Jacob focuses on Millikan's concept of communicative agency, which is strongly connected to the teleosemantic framework, and argues that there are several aspects of the Gricean individualistic account of meaning that are more plausible than Millikan's when it comes to explaining social communicative agency. The most illuminating finding of Jacob's paper is the modern and precise presentation of the actuality of the Gricean separability thesis and the mindreading account, because it is explanatorily fruitful not only for philosophy of language, but also for social cognition, social epistemology, informal logics, and the relation between these different studies.

I generally agree with Jacob's main findings, nevertheless I will address some further issues of Millikan and Grice's account with regard to philosophical problems in social epistemology. Before I respond to these in detail, I first focus on the Gricean account and its implications for social epistemology.

The well-known Gricean (Grice 1957) account of the meaning of an utterance focuses on analysis of the speaker's meaning in a conversation. A speaker *S* means something *unnatural* if she intends something by the utterance of a sentence.¹ Let us suppose that the speaker is a politician with a specific agenda and with a propensity for aggressive propaganda. She utters the following:

(1) Speaker: "Our party will ensure that taxes go down".

The speaker *S* means (1) iff *S* utters (1) with the intention that a hearer *H* will gain the belief that *S*' party will make sure that taxes go down, if (i) the hearer *H* recognizes the speaker's intention (1) and (ii) because of that she gains the belief that *S*' party will make sure that taxes go down, (iii) since she recognizes that the speaker's intention is exactly that (cf. Grice 1957, 1969).

Since Gricean meaning is individualistic and subjective it is important to note which underlying cognitive states constitute this meaning. As Jacob puts it—relying on Sperber & Wilson's (1986) interpretation of the Gricean account²—there are three main assumptions upon which the psychological theory of meaning is based, namely the separability thesis, the mindreading thesis, and the asymmetry between an informative and communicative intention. Together with Jacob I shall focus on Sperber and Wilson's account, which argues that the Gricean theory can be summarized as a reciprocal process of intentions. The *informative intention* is an intention of a speaker who wants to inform a hearer about some state of affairs. In order to be successful, the speaker has also the intention that the hearer recognize the informative intention (Grice 1957). This means that at first the hearer has to understand the informative intention. If she understands it, the *communicative intention* of the speaker has been fulfilled. But the informative intention will only be fulfilled, if the speaker is trustworthy: a necessary condition for accepting a speaker's utterance. In effect, the hearer gains a new belief. The assessment of her trustworthiness depends on the hearer of that intention (Sperber & Wilson 1986). She must admit that the speaker has to be reliable in order to be trustworthy, or, to put it in Jacob's (this collection, p. 4) words, "the addressee must further accept the speaker's epistemic or practical authority". But a question arises: on which kind of epistemic practices does the hearer have to rely in order to accept the

1 Grice (1957) distinguishes between a *natural* and an *unnatural meaning*. Unnatural meaning is always characterized by the speaker's intention. The natural meaning of a sign characterizes meaning that is independent of a speaker.

2 I follow Jacob in relying partly on Sperber & Wilson (1986) when I talk about the Gricean account.

speaker as an epistemic authority? I will address this question in the following commentary.

In order to answer it, I will argue that (i) a hearer could commit a *local ad hominem attack*, a process of inductive *Bayesian reasoning* that secures epistemic vigilance. Roughly, an *ad hominem* attack is an argument that considers rather personal properties of an utterer than the argument itself. (ii) A fallacious kind of the personal attack is the *global ad hominem attack*, which undermines every testimony of a speaker because of its personal traits. (iii) The Gricean account of mindreading could better account for an inductive inference model than Millikan's direct-perception-account. (iv) Practices of *ad hominem* attacks, I will argue, support the Gricean separability thesis, while Millikan's co-operative devices account is less plausible.

The structure of this commentary will be as follows: first, I focus on Grice and Millikan's framework and its implications for social epistemology, namely the problem of epistemic reliability (cf. section 2). In section 3 I shall present Lackey's account of a social epistemological dualism, a hybrid theory in which Lackey tries to connect the most plausible findings of social epistemological reductionism and anti-reductionism. Then I argue that the Gricean account of informative intentions and Lackey's *positive reason component* could lead to the *personal attack* or *ad hominem argument* (cf. section 4). In section 5 I argue that there are two possible commitments of *ad hominem* arguments, to be specific, the *global* and the *local ad hominem attack* (cf. section 5.1, section 5.2). In the Gricean account of the *mindreading thesis* is compatible with the drawn picture of our social epistemological practices, because it supports the inductive inference model, while Millikan's account of *direct perception* could not account for this. The Gricean *separability thesis* fits nicely with the positive reasons component and the reliance on *ad hominem* arguments, while

Millikan's account of speaker and hearer as *co-operative devices* is less plausible (cf. section 6).

2 Epistemic intentions and epistemic reliability

The utterance of a speaker depends on two directions of fit. The first can be characterized as a *mind-to-world-relation*. Here, the speaker has the intention of conveying some states of affairs about the actual world. This direction of fit implies that the speaker wants to share some epistemic notions. If she is successful in doing so, the hearer will gain a true belief. This class of utterances is descriptive.

The second is a *world-to-mind direction* of fit of the speaker's utterance. Here the speaker wants to convey some of her desires to the hearer, who acts in a particular way in order to fulfill the speaker's desire. The intention is fulfilled if the hearer gains a new desire to act in order to fulfill the speaker's desire (Sperber & Wilson 1986). This kind of direction of fit is unimportant for the following account. Here I shall focus on descriptive utterances.

Before I address some implications of epistemic intentions, I shall focus on the *separability thesis*. This thesis addresses the problem of an asymmetry of interests between hearer and speaker. Since the interests are not identical, the speaker could deceive the hearer. And the other way around: the hearer could distrust the speaker even though she utters a true sentence. Sperber et al. (2010) claim that some amount of distrust is a stabilizer in the evolution of human communication, which they call *epistemic vigilance*. Imagine that humans believed almost everything they were told. Since not every speaker has the propensity to speak the truth, hearers would have a lower amount of knowledge because they would have no tool for distinguishing a reliable testimony from a non-reliable one. Communication would be very imprecise, because knowledge agency would be less successful. Hence, epistemic vigilance is a precondition for cooperative communication, because both speaker and hearer check the reliability of knowledge transition. I agree with Sperber et al. (2010) that epistemic vigilance is a

feature of a *source* and the *content* of information.³

Let me go back to the mind-to-world-relation of fit. If the twofold account given by Sperber & Wilson (1986) is correct, the hearer has gained a true belief (about some state of affairs). To count as knowledge, we have to ask whether the true belief is justified.⁴ What could count as a justification? Some social epistemologists would say that the testimony of the speaker is sufficient to count as a justification. This is the thesis of an *anti-reductionism* in social epistemology which contains the claim that the speaker must not rely on other sources of knowledge such as perception, inference or memory to justify her belief (Coady 1992). A *reductionist* would say that the testimony cannot count as knowledge without relying in addition upon other sources of knowledge (Fricker 1995).

In Millikan's (2005) account of an intentional conventional sign (which is the content of an intentional mental representation), she assumes that speaker and hearer are cooperative devices that have co-evolved. The relationship between sender and receiver can be characterized as beneficial in the long term. Millikan proposes a framework, in which the descriptive representations describe a mind-world-direction, whereas the *directive* representation describes the world-to mind relation. The long term beneficial communicative agency between sender and receiver characterizes a function of reproduction of conventional signs. The *direct proper function* in this particular case is that the hearer gains a new belief. Millikan (1984) is well known for this teleosemantic account that can deal with misrepresentations. In such a case, the proper function remains unfulfilled. It is unfulfilled if the speaker fails to cause a new belief in the hearer (Millikan 1984, 2005). But the hearer could also be responsible for the unfulfilled proper function if she mistakenly judges the speaker to be untrustworthy. The hearer is also

a constitutive part of the cooperative devices that establish the direct proper function (Millikan 1984, 2005).

3 Social epistemology: Lackey's dualism

Before I present a more detailed account of *ad hominem arguments*, I will say a few words about social epistemology and the position that is presupposed in this commentary. Jennifer Lackey's (2006) account of social epistemology relies upon a kind of dualism, in which she combines anti-reductionism and reductionism. According to her, social epistemology has made the mistake of addressing the debate between reductionism and non-reductionism unilaterally. *Reductionism* takes epistemic responsibility and the rationality of the hearer far too seriously, because the hearer has to rely upon other sources of knowledge like perception, memory, deductive inferences, etc. The claim here is that testimony is not a source of knowledge in the first place, because a hearer could never know the intentions of a speaker who held accidentally or intentionally false beliefs. In contrast, *anti-reductionism* always focuses on the speaker's perspective and her propensity for credible testimonials. Proponents of anti-reductionism claim that a large amount of our knowledge depends on testimonials. We would know almost nothing if we were as restrictive as the reductionist claims (Coady 1992). Lackey wants to combine these two accounts in a kind of dualism. Her dualism contains the presupposition of the reliability of the speaker along with *positive reasons* to accept the speaker's testimony, evaluated from the hearer's perspective. If the speaker utters a true sentence and the hearer has positive reasons to trust the speaker, then knowledge from testimony is possible. Lackey argues for the following conditional, which contains three necessary conditions:⁵

For every speaker A and hearer B, B justifiably believes that p on the basis of A's testimony that p only if: (1) B believes that p on the basis of the content of A's

³ I will address this topic with respect to the *ad hominem* argument in section 5.

⁴ I will not address Gettier cases with regard to social epistemology. For the sake of this commentary, I will use the term *knowledge* as meaning justified true belief. Issues concerning the *ad hominem* fallacy will concern the justification-condition.

⁵ Lackey claims that dualism accounts only for necessary conditions for a source of knowledge.

testimony that *p*, (2) A's testimony that *p* is reliable or otherwise truth conducive, and (3) B has appropriate positive reasons for accepting A's testimony that *p*. (2006, p. 170)

For the present account it is important that a testimony, given by A, qualifies as a source of knowledge that depends on the hearer having positive reasons to think that A's testimony is reliable. Recall the informative intention and the mind-to-world-direction of fit, which is fulfilled if the speaker causes a new belief in the hearer. The direct proper function of the co-operation between speaker and hearer in Milikan's (1984, 2005) account would be fulfilled. But according to Lackey's condition (3), the achievement of a new belief is only justified if there are various *positive reasons* that account for the reliability of the speaker's testimony. Consider the account of Sperber et al. (2010, p. 379) that "the filtering role that epistemic vigilance [...] in the flow of information in face-to-face interaction" is an important feature of communicative agency. But which kind of filtering do they mean? In other words, what are positive reasons, exactly? Could they be past experiences about the reliability of the speaker or even a group to which the speaker belongs?

4 *Ad hominem* arguments and epistemic injustice

I claim that the Gricean account of communication supports our social practices of committing *ad hominem* arguments. The committing of *ad hominem* attacks in communicative agency becomes patent when you look at *positive reasons* in more detail. During past events of communicative agency, a hearer has tested the trustworthiness of several speakers on the basis of her personal properties and the context to which these properties have been related (Lackey 2006; Fricker 2007). The ability of being epistemically vigilant emerges very early in human development. At the age of three years, infants already prefer testimony from a reliable source (cf. Clément 2010). From that age on, infants develop a "cognitive filter that enables children

to take advantage of testimony without the risk being completely misled" (Clément 2010, p. 545).⁶

Now back to the example: suppose that the hearer in question has been confronted with the testimony of politicians in the past. She then hears the following sentence from speaker *S*:

(1) "Our party will make sure that taxes will go down".

Would you, as a hearer, believe her? Consider past cases of political propaganda and ask yourself how reliable the politician, the speaker, really is. At first, let us assume you do not. You are a very skeptical person, especially when it comes to political issues. Is it rational to be skeptical, so are you guilty of prejudice? Let us assume that the speaker is surprisingly reliable. She speaks the truth. The party wins and reduces taxes. Have you treated the politician in an epistemic inequitable way or was it the only way to remain epistemic vigilant? These questions will be addressed in the following sections.

The hearer who does not believe *S*' utterance (1) has committed an *ad hominem* argument, a personal attack against the speaker. According to Walton (2008, p. 170) "[t]he *argumentum ad hominem*, meaning 'argument directed to the man', is the kind of argument that criticizes another argument by criticizing the arguer rather than his argument." A hearer takes some personal properties, such as being a politician, and infers that the expressed sentence is false. It is *prima facie* irrelevant to consider personal traits as indicators of a false testimony *t* (Yarp 2013; Walton 1998).⁷ Keeping Walton in mind, we are able to generalize *ad hominem* attacks as follows:

⁶ There is further evidence in developmental psychology that speaks of very early acquisition and practice of epistemic vigilance (cf. Clément 2010; Sperber et al. 2010; Mascaro & Sperber 2009). Another issue with regard to the positive reasons component in social epistemology is the so-called *infant/child-objection*. This concerns the hearer's competence in evaluating the speaker's reliability that small children lack, which is often construed as an argument against reductionism (Lackey 2006). For a general discussion see Lackey (2005).

⁷ As will be seen in section 5.1, there are some exceptions where personal properties are relevant.

Ad hominem attack

- (1) Speaker *S* gives a testimony *t*.⁸
 - (2) The speaker's *S* property φ is a negative property with regard to trustworthiness.
 - (3) Speaker *S* has a negative property φ , which is ascribed as relevant for her testimony *t* by hearer *H*.
-
- (C) The testimony *t*, uttered by speaker *S*, is false as assessed from hearer *H*.⁹

The arguments of the speaker (implicitly represented or explicitly formulated) have not been challenged seriously by the hearer. She just considers personal traits sufficiently to reject the given argument or proposition.¹⁰ The allegedly suboptimal personal characteristics of the person do not provide any evidence for rejecting the proposition *p*. The hearer neither shows that the deduction of the speaker includes fallacious reasoning nor that the premises on which her proposition is based are wrong. Informal logic does not support the hearer in this situation (Groarke 2011). Has the speaker been treated inequitably? Miranda Fricker (2007) tries to answer this question and introduces the notion of *epistemic injustice*. She generalizes the notion as follows:

Any epistemic injustice wrongs someone in their capacity as a subject of knowledge, and thus in a capacity essential to human value; and the particular way in which testimonial injustice does this is that a hearer wrongs a speaker in his capacity as a giver of knowledge, as an informant. (Fricker 2007, p. 5)

⁸ I assume that a testimony *t* expresses an argument that contains the relevant proposition *p*.

⁹ One could of course distinguish between a testimony and an argument. Here I presuppose that a testimony is somehow a conclusion of an argument. Fricker (2007, p. 61) supports this view as follows: "One might be inclined to put a familiar picture of justification to the fore and argue that in order to gain knowledge that *p* from somebody telling her that *p*, the hearer must in some way (perhaps very swiftly, perhaps even unconsciously) rehearse an argument whose conclusion is *p*."

¹⁰ For the purpose of this commentary I will defend a weak view of propositions. The utterance of a speaker expresses a proposition that is true if it represents a state of affairs. There is of course an asymmetry between the propositional content of an utterance and the propositional content of the speaker's belief or thought. I agree with Jacob (1987) that it is sufficient to assume similarity between the two.

It fits Fricker's generalization that the capacity of a speaker to convey true beliefs is undermined. The positive reasons clause of Lackey's dualism also supports this step of reasoning because the character or the identity of a speaker could be relevant for her evaluation of trustworthiness in epistemic contexts (cf. Fricker 2007; Lackey 2006). Crucially, stereotypes and prejudices—based upon *ad hominem* arguments—are paradigmatic cases of epistemic injustices (cf. Fricker 2007). But is it not rational for a hearer to distrust our politician? Jacob (this collection, pp. 4–5) claims that "not every speaker is (or should be) granted equal epistemic or practical authority on any topic by every addressee." Remember that the hearer's positive reason component is a remainder of the reductionist account with regard to testimony as a justifier of knowledge. Is it not a necessary condition for the positive reason component to remain vigilant in such contexts? If epistemic vigilance does not play a role in this context, then Lackey's suggestion of the necessary condition of positive reasons on the hearer's side is implausible. In the following I shall argue that epistemic vigilance is very important and that the dualistic account could account for it. Nevertheless, one has to accept what I call a local *ad hominem* argument in order to be epistemically vigilant in our particular case.

5 Two kinds of *ad hominem* attack

In the following section I make a suggestion in order to disarm the problem of the *ad hominem* argument with regard to the *positive reason* component. Does an *ad hominem* attack always include fallacious reasoning? Walton (2008, p. 170) claims that "the *argumentum ad hominem* is not always fallacious, for in some instances questions of personal conduct, character, motives, etc., are legitimate and relevant to the issue." Even though cases of *ad hominem* arguments might sometimes be informally fallacious, there are some highly relevant cases in which a particular *ad hominem* attack could be committed in order to remain epistemic vigilant. Since you, as a hearer, have a set of positive reasons—for instance being aware of the usual verbal

espousals of politicians during an election campaign—you are forced to commit a personal attack. Did your reliability assessment rely on fallacious reasoning? In the literature there is a common distinction between three types of the *ad hominem* argument: the *abusive*, the *circumstantial*, and the *tu quoque* argument (Groarke 2011; Walton 1998, 2008).¹¹ These kinds of personal attacks describe various pragma-dialectical reasoning in interpersonal communicative relationships. Below (cf. section 5.1, 5.2) I want to draw a further distinction between two kinds of *ad hominem* attack that are closely connected to communicative situations explicitly involving knowledge transmission. Hence I want to provide a framework that fits well with social epistemological dualism.

Before this, I want to address the *Bayesian argumentation model*, which is presupposed by the following account of *ad hominem* arguments. Few things have been said about the inductive reasoning model which is the underlying mechanism of an *ad hominem* attack. Roughly, one has to consider past experiences with regard to reliability, constituted by contexts and speaker properties, to adjust this experience for future communication. Harris et al. (2012) provide an account that fits well with an inductive model of reasoning, because, potentially evidence is not provided by deductive reasoning. They claim that the evaluation of a proposition or a given testimony is based on an individual's probabilities, which could be described formally using *Bayes' Theorem*. A big advantage of this account is that it describes our subjective evaluations in daily experiences very well. Often, when we are asked “do you believe *S*?” we are inclined to say something like “I am not sure. I guess not”. This could be well explained with the Bayesian model, where an individual's belief does not have a truth-value of 0 or 1. The relevant belief is instead estimated in one's subjective degree of that belief, as a probability between 0 and 1. Let us embed this in our current considerations. The utterance type of the politician is already embedded in a

kind of bias or in posterior beliefs about politicians in general: this is called the hypothesis *h*, and has a particular probability $P(h)$ in isolation from evidence *e*. Evidence *e* in this particular case is constituted by personal characteristics, properties, and circumstances of the utterance. The receiving of the new evidence *e* should update $P(h)$, the probability of the hypothesis. Individuals ought, according to the normative stipulation, if they receive any evidence, to let it influence the probability of the proposition: “[this] normative procedure by which individuals should update their degree of belief in a hypothesis *h* upon receipt of an item of evidence *e* is given by Bayes' Theorem:

$$P(h|e) = \frac{P(h)P(e|h)}{P(e)} \quad \text{“(Harris et al. 2012, p. 316)”}$$

$P(h|e)$ describes the conditional probability of a hypothesis being true after one has received evidence *e*. $P(e|h)$ terms the conditional probability of receiving evidence *e*, given hypothesis *h*. $P(e)$ just describes the evidence in isolation from the truth-values of the hypothesis *h* (cf. Harris et al. 2012).

5.1 Local *ad hominem* attack

I am now able to distinguish two kinds of *ad hominem* attack, a local and a global one. I will thus sketch out some considerations with regard to the presented Bayesian framework.

The positive reason component describes the practice of a speaker's credibility assessment. This process of credibility assessing could lead to what I will call a *local ad hominem* attack. Roughly, one commits a local *ad hominem* argument if one acknowledges someone to be trustworthy in general, but with some exceptions in particular cases. If you ask the politician what time it is or the straightest way to the subway station, it is very unlikely that she would have the intention of deceiving you (Sperber 2001). Hence, one would count her as a trustworthy person. Nonetheless, given the particular information about her party and the reduction of taxes, you might find it unlikely that she is telling the truth. As long as you do not dismiss her in general as an eligible bearer of

¹¹ For some very interesting empirical investigations with regard to these three kinds of *ad hominem* arguments, see van Eemeren et al. (2000) and van Eemeren et al. (2008).

knowledge, it is vigilant in a rational way to distrust her in this case. This view could be described as a subclass of epistemic vigilance, because it is an evolved tool that minimizes the risks of deception which is—according to Sperber et al. (2010)—a condition for cooperative communicators.

At this stage, subjective Bayesian probability comes into play. The general bias of your past experiences with regard to politicians, which enters the stage before you have received the evidence, could be described with (h) . The probability of the hypothesis $P(h)$ is the probability of your believing her without having received evidence e . Given (1), evidence e describes that the person is a politician during a campaign, which also has a particular probability, termed $P(e)$. The evidence condition is the part that divides the local *ad hominem* attack from the global, because the evidence is able to influence one's subjective degree of probability. The personal traits of the speaker as well as the context of utterance-use serve as evidence e . $P(h/e)$ is then the conditional probability of h , if the hearer H receives evidence e . Given the hypothesis h , the probability of receiving evidence e is described by $P(e/h)$. As presented above, this could be calculated within *Bayes' Theorem* (cf. Harris et al. 2012).

As you can see, the *content* and the *source* of information, which serve as evidence e , are both similarly relevant for a testimony (cf. Sperber et al. 2010). Buening (2005) calls this kind of reasoning *relevance-based* with regard to the relevant circumstances that could invoke *ad hominem* attacks. The context and content of the utterance or proposition in question is important for assessment. Walton (1998) calls such a context and content-related *ad hominem* attack a *credibility function*. The proposition in question undergoes an *ethotic rating*, a kind of evaluation of a person's epistemic input value (of her testimony), which can go up or down. When committing a local *ad hominem* attack, the rating goes down. Hence the credibility of the speaker is undermined in a specific case that affects the proposition, which fits with the account of Bayesian argumentation. The local *ad hominem* argument is an example of a non-

fallacious *ad hominem* attack because it is *content* as well as *context-related* and epistemically equitable. The normative stipulation of the Bayesian account that a hearer “should update [her] probabilistic degrees of belief in a hypothesis in accordance with the prescriptions of Bayes' Theorem” (Harris et al. 2012, p. 316) is fulfilled in the local version. The take home message of this passage could be presented in a more simplified way:

Local *ad hominem* attack (non-fallacious)

- (1) Speaker S gives a testimony t .
 - (2) Speaker's S property ϕ is a negative property with regard to trustworthiness.
 - (3) Speaker S has a negative property ϕ that is relevant evidence e for a hypothesis h with regard to the content of the particular testimony t by hearer H .
-
- (C) The testimony t , uttered by speaker S , is probably false as assessed by hearer h .¹²

5.2 Global *ad hominem* attack

I call the opposite kind of reasoning the *global ad hominem argument*, which I claim, is fallacious. The hearer commits a global attack if she does not believe the speaker in general. The hearer discredits her any kind of trustworthiness. Consider some stereotypes and prejudices that could suffice for such a radical conclusion.¹³ This behavior is clearly irrational, since it undermines any testimony of a speaker in every situation. As you can see, this kind of fallacy is neither a *content-related* nor *context-related ad hominem* argument. In distinction from the global attack, here the content does not play any role in the evaluation of the speaker's reliability. First, the evidence e only includes per-

¹² As Jacob (1987) suggests, beliefs are shared in different communities with different ideological backgrounds that are themselves constitutive of belief-formation. One could defend that the local *ad hominem* attack is an important tool for running a communicative society. If so, we would be using local *ad hominem* attacks as a form of self-deception, which would then be somehow an instance of a shared optimism bias. I will not discuss this phenomenon any further, because it is not a tool or cognitive filter that improves knowledge transmission. Hence, positive local *ad hominem* attacks, one could argue, have at least a propensity for being epistemically unvigilant mechanisms.

¹³ Yarp (2013) suggests that *ad hominem* fallacies like prejudices could be unconscious or at least not transparent to the hearer's reasoning.

sonal traits and not the circumstances of the utterance. Second, the evidence e does not influence the degree of belief that the hypothesis h is true. This is the reason why the belief, formed via the process of a global *ad hominem* fallacy, could not be calculated in *Bayes' Theorem*. The normative stipulation that evidence e should affect the probability of a hypothesis h is not satisfied.

Another reason why this type of personal attack is fallacious is because it includes irrelevant circumstances and personal traits as the basis of the speaker's evaluation (Buenting 2005). The speaker, as she is assessed, is not in any way disposed to maximizing the hearer's set of true beliefs.¹⁴ In other words, the hearer undermines any potential benefit she may gain through any of the speaker's testimony (Sperber 2001), which could be described as a paradigmatic case of epistemic injustice (Fricker 2007). Hence, a general assessment of the speaker's credibility has nothing to do with the process of positive reason formation. In other words, the global *ad hominem* attack is not an epistemic tool, because it lacks any *credibility function*, because the speaker assesses the testimony as necessarily false, because of her personal properties. Since it is not an epistemic tool, this kind of reasoning is not epistemically vigilant (Sperber et al. 2010). To summarize:

Global *ad hominem* attack (fallacious)

- (1) Speaker S gives a testimony t .
- (2) Speaker's S property φ is a negative property with regard to trustworthiness.
- (3) Speaker S has a negative property φ that is ascribed as relevant for every testimony t by hearer H .

(C) The testimony t , uttered by speaker S , is necessarily false as assessed by hearer H .

6 *Ad hominem* arguments and communicative agency

I agree with Jacob that some aspects of Grice's theory of meaning are in a broad sense incompatible with Millikan's account of communicat-

ive agency. The focus of this commentary so far has been communicative agency in epistemic contexts and its implications, and in particular the personal attack. I will now evaluate whether Millikan's account of direct perception or Grice's account of mindreading could account for *ad hominem* arguments in epistemic contexts. My answer is that the Gricean mindreading thesis is more plausible. I then compare the separability thesis with the cooperative devices. The separability thesis fits best with the practices of *ad hominem* fallacies. The presupposition of cooperative devices is less plausible.

6.1 Mindreading vs. direct perception

Recall from section 1 that the mindreading thesis relies on the twofold account of informative and communicative intention. First, the speaker has to recognize or understand the speaker's informative intention, which is the speaker's communicative intention. For the *fulfillment* of the informative intention, the trustworthiness of the speaker has to be accepted. In other words, in order to *fulfill* the informative intention, the hearer commits neither a local nor a global *ad hominem* argument (or she would not accept it). But in order to be an epistemically vigilant agent, the hearer has to make some further inferences, which are inductive (as well as the *ad hominem* fallacies). This inductive inference model involves some kind of mindreading that could affect the reliability judgment.¹⁵ Millikan claims that the acceptance of a given testimony as a source of knowledge is a form of direct perception without any kind of inference (Millikan 1984; Sperber et al. 2010). She talks about *translation* instead of inference. The hearer translates the utterance via direct perception into a new belief (Millikan 2004):

Forming a belief about where Johnny is on the basis of being told where he is I just as direct a process (and just as indirect) as forming a belief about where Johnny is on

¹⁴ I will not consider the ethical implications of this view any further in this commentary.

¹⁵ Unfortunately, I cannot address in this paper which kind of mindreading is supported by this view and how it could perhaps be related to social cognition and mirror-neurons. For a general discussion see Jacob (2008, 2013).

the basis of seeing him there. (Millikan 2004, p. 120) There is no reason to suppose that any of these ways of gaining the information that Johnny has come in requires that one perform inferences. (Millikan 2004, p. 125)

It is doubtful that these circumstances explain our everyday communicative agency, especially with regard to epistemic conversations. According to Millikan, the acceptance of a new belief does not involve any representation of the speaker's intention. But in order to assess the reader as benevolent and competent (or reliable), one has to rely—as argued in section 5—on inductive inferences which are of course derived representations manifested in beliefs about the speaker's intention.

In epistemic contexts of communication only the mind-to-world direction is involved, *qua* descriptive utterances. One criticism offered by Jacob is that Millikan's account of perception could only account for descriptive utterances, hence only for the mind-to-world direction. Another issue is closely related to this kind of criticism. It concerns testimony that has very little to do with perceptual capacities. With regard to very complex utterances like (1), I agree with Jacob (this collection, p. 9) that “it does not make much sense to assume that either the speaker or her addressee could perceive what the speaker's utterance is about.” Consider the nature of testimonial reports. Even some direct perception of a testimony about some state of affairs is perceptually impoverished compared to directly perceiving the state of affairs in question. Imagine some testimonial reports that have been heard through the radio. In such a case, you are not in a perceptually close relationship to the reported state of affairs. If you evaluate the credibility of the speaker, it is very likely that you would run through different processes of inductive inference in order to commit an *ad hominem* argument or avoid one. The more abstract the testimony, the more implausible it becomes that it has anything to do with direct perception. It becomes even more complicated with complex indexical utterances or a group of different but

equally eligible interpretations of a particular testimony. Consider again example (1). Here it is very likely that a hearer represents some intentions of the speaker that are linked to her psychological states. If one representation is that the speaker could deceive the hearer in particular circumstances, the hearer will probably commit a local *ad hominem* attack. To sum up: *Ad hominem* arguments are ascriptions that result from inductive inferences that also depend on belief-desire psychology, because the hearer gains a representation of the second-order representation of the sentence expressed by the speaker. The representation of the hearer is a third-order representation of the second-order linguistic representation of the speaker (cf. Jacob 1987).¹⁶

6.2 Separability thesis vs. cooperative devices

The problems addressed so far are closely related to the separability thesis. The separability thesis is the claim that the hearer and the speaker could have different interests, which are causes of the informative intention remaining unfulfilled, because there are two cases that suggest that the interests of both parties fall apart. In the first, the hearer gains a new belief that is not true, because the speaker has the informative intention to deceive the hearer. So her informative intention has the aim that the speaker gains a false belief and not one about some states of affairs, as described in section 2. In the second, the sentence, uttered by the speaker, is true, but nonetheless denied by the hearer on the basis of an *ad hominem* argument (Sperber & Wilson 1986).¹⁷ These two cases do not support Millikan's (2005) claim that the interests of both speaker and hearer are balanced. If a hearer commits a global *ad hominem* argument, it is even harder to ascribe balanced interests to speaker and hearer. Sperber (2001) defends a plausible weak version of coincidence of interests. It is only necessary that they over-

¹⁶ According to Jacob (1987), a belief-ascription is not constitutive of the subject's belief in the first place.

¹⁷ There are, of course, plenty of other options for different interests (cf. Sperber 2001).

lap in the long term in order to establish successful practices of social knowledge transmission.

Cases of global *ad hominem* arguments could only occur if a speaker understands the informative intention which she combines with some particular personal properties of the speaker in order to reject the testimony in question. Hence the speaker succeeds in establishing the communicative intention, but fails to fulfill the informative intention. In Millikanean terms, the direct proper function of the speaker is that the hearer gains a new belief. If the hearer commits an *ad hominem* attack, the direct proper function remains unfulfilled. But the communicative intention is still fulfilled, and that is all that is required for successful communication according to the separability thesis of communicative intentions (Sperber & Wilson 1986). The hearer recognizes that the speaker wants to inform her of her informative intention, which means that the communicative intention has been fulfilled. But the informative intention—which is that the hearer gains some new information or a true belief—fails, because an *ad hominem* attack has been committed. This circumstance could be well explained with the separability thesis and the weak account of communication that we addressed in section 6.1. To sum up, and in agreement with Jacob, if an *ad hominem* attack has been committed, even a weaker version, communicative agency is violated in the Millikan (2004, 2005) framework because the cooperative conventional transmission is violated in the first place.¹⁸

The picture I draw with regard to the *ad hominem* arguments rests on the assumption that trustworthiness has to be assessed by the hearer in order to be counted as epistemic vigilant, which would be the reductionist component. On the other side, the speaker has to utter a true sentence to transmit knowledge to a speaker, which would be the anti-reductionist-component. This view is supported by Lackey's dualism. As can be seen, the establishment of a dualistic account and all its implications for the

inductive reasoning model can be better explained with the separability thesis.

7 Conclusion

In this commentary I have extended the refreshing account given by Jacob, who presents Grice's individual account of meaning and assesses its plausibility with regard to communication and knowledge transmission. I defended the view that one promising way to talk about testimony as a source of knowledge is offered by Lackey's dualism. Here, both speaker and hearer are the important in knowledge transmission. In order to secure this transmission, the speaker has to utter a true sentence and the hearer has to check the speaker's trustworthiness. I distinguished two kinds of personal attack:

(i) The local *ad hominem* argument, which is not fallacious, focuses on the proposition and personal properties of the speaker, and is a content-related, relevance-based attack based upon one's subjective probabilistic estimation of the speaker's reliability, which can be calculated in *Bayes' Theorem*.

(ii) The global *ad hominem* argument, which is fallacious, is an extreme prejudice that denies that the speaker is reliable in any case. It is not usable as a tool for knowledge transmission, because it violates the stipulation of the Bayesian argumentation in which one should include some evidence in the subjective probability estimation. This extreme kind of a personal attack could be racism or stigmatizing, for instance.

(iii) Here I argued—in agreement with Jacob—that the Gricean account of mindreading is more plausible than Millikan's account of direct perception. To use the inductive model of reasoning when evaluating a speaker's reliability, one also has to rely on the use of belief-desire psychology. It is important to *infer* the intentions of the speaker, and to think about whether she has good reasons or a general propensity to speak the truth. Millikan's framework of direct perception does not account for this, because the direct perceptibility of some

¹⁸ The question, of course, is in which sense it is violated, in detail, and how this affects Millikan's theory of language in general. However, these implications cannot be addressed here.

abstract cases of testimony and their evaluated reliability is very implausible.

(iv) Last, I argued that the description of speaker and hearer as cooperative devices is implausible, too. First, we know that the speaker could have deceptive intentions. Second, if somebody is committing a global *ad hominem* attack, the interests of the utterer and her addressee fall apart. Nonetheless, the communicative intention still holds. Both parties communicate successfully, even if the hearer does not gain a new belief. So we could conclude with Grice and Sperber and Wilson that the communicative intention is sufficient for a successful communication. If the addressee commits an *ad hominem* fallacy, the proper function is unfulfilled. But in this case the conventional speaker action, which is part of successful communication, has been violated. I have argued that the Gricean account could well explain our communicative practices regarding epistemic contexts.

In terms of future research, it would be very interesting to see, how the Gricean philosophy of a speaker's individual meaning and mindreading could be embedded in theories about social cognition, social epistemology and informal logics. Jacob has presented an illuminating account of how the Gricean philosophy could be embedded in modern philosophy of mind and the cognitive sciences. I propose that one should further reflect on Jacob's arguments and adopt his conceptual framework, which I think is very precise and explanatorily fruitful. But for my own proposal of a distinction between local and global *ad hominem* attacks, it will be important to flesh out these accounts with regard to Bayesian reasoning and argumentation in epistemic contexts. A good candidate for elaborating this kind of research is the recent account of *predictive processing*, which is also based on Bayesian probabilities.

In this commentary I have claimed that these personal attacks are inductive mechanisms. But much more could be said about their functionality or even their instantiation in a cognitive system. Then it would be interesting to see if non-human cognitive systems could commit these kinds of *ad hominem* attacks. How precise could they be in evaluating a

speaker's reliability? Are instances of *ad hominem* attacks bound to a specific type of brain through which the relevant representational and functional architectures are realized? How could such a phenomenon like the global and local *ad hominem* attack evolve in *homo sapiens*, and what are the deeper underlying cognitive mechanisms of such attacks? These questions need to be answered if we want to understand these important mechanisms and processes of social knowledge, as well as our communicative society as a whole.

Acknowledgements

First of all, I am appreciative for the illuminating target paper. In addition to that, I would like to thank the two anonymous reviewers and Thomas Metzinger and Jennifer M. Windt for their editorial reviews. They really helped to improve this paper. I am also grateful to Thomas Metzinger and Jennifer M. Windt for the opportunity to contribute to this project.

Assessing a Speaker's Reliability Falls Short of Providing an Argument

A Reply to Marius F. Jung

Pierre Jacob

When confronted with a speaker's assertion, her addressee can either fulfill the speaker's informative intention and accept the new belief or not. If he does, he can either accept the new belief on the sole basis of the speaker's authority or not. If not, then the addressee can examine the reliability of the speaker's assertion. If he does, then he can either check the content of the speaker's assertion with the contents of his own beliefs or scrutinize the speaker herself as the source of the novel information. If the latter, then he can either examine the speaker's epistemic competence in the relevant domain of discourse or the speaker's moral benevolence (or both). None of the above processes amounts to the addressee producing an argument, let alone an *ad hominem* argument. Only if the speaker offers an argument to back her assertion could the addressee commit an *ad hominem* counter-argument in his attempt at rebutting the speaker's.

Argument | Assessment of the reliability of a speaker's assertion | Authority | Benevolence | Competence | Fulfilling the speaker's informative intention | Knowledge

In my paper, I probed the gap between the Gricean approach and Millikan's approach to human communicative agency. In particular, I argued in favor of the Gricean separability thesis, i.e., the thesis that the process whereby an addressee fulfills an agent's communicative intention (by understanding or recognizing her informative intention) is distinct from the process whereby the addressee further fulfills (if and when he does) the agent's informative intention (by accepting either a new belief or a new desire for action). I am grateful to Marius F. Jung for his valuable comments on my paper, in which he tries to offer positive suggestions to-

wards bridging the gap between the Gricean separability thesis and (social) epistemology.

In particular, I agree with Marius F. Jung that the issues of whether and to what extent a communicative agent's testimony should or can be assessed as reliable and justified, and thereby construed as knowledge (and not as mere opinion) by her recipient, are of fundamental importance. I also agree with him that it is worthwhile to try and bridge the gap between the psychological investigation of the process whereby an addressee assesses the reliability of a speaker's testimony and the major divide between the reductionist and the anti-reduction-

ist perspectives in the epistemology of testimony. However, I still want to resist using the particular bridge (or bridges) Jung is building for me. In the following, I want to briefly explain why.

First of all, let us be clear that what we are dealing with here is the addressee's basic epistemic task of assessing the reliability of a communicative agent's (the speaker's) *testimony* or *assertion*, i.e., utterances with truth-conditional contents, because only assertions can be assessed for their reliability or believability. Only a speaker's assertions, not a speaker's requests, can directly enlarge her addressee's knowledge of the world. For the purpose of the discussion of Jung's epistemological project, we should simply ignore addressees' responses to speakers' utterances of requests, i.e., of utterances that lack truth-conditional contents. (I ignore here the fact that a speaker's request may enlarge an addressee's knowledge of the speaker's own character traits.)

Secondly, as I understand it, Jung would like to directly link the investigation of the addressee's task of assessing the reliability of a speaker's assertion to the dispute between the reductionist and the anti-reductionist perspective in the epistemology of testimony. I will reconstruct Jung's basic strategy by means of the six following assumptions.

- He construes the addressee's overall process of assessment of the reliability of a speaker's assertion as an *argument*.
- As I understand it, he also accepts Sperber et al.'s (2010) view that the overall process whereby an addressee assesses the reliability of a speaker's assertion can be divided into two component processes: the assessment of the *authority* of the speaker (who is the *source* of the testimony) and the assessment of the *content* of the speaker's assertion.
- He further focuses on the addressee's assessment of the *authority* of the speaker as the source of the testimony, at the expense of the assessment of the content of the speaker's assertion.

- He links the addressee's assessment of the authority of the speaker as the source of the testimony to *ad hominem arguments*.
- He draws a distinction between local and global *ad hominem* arguments.
- Finally, he argues that only *local*, not global, *ad hominem* arguments are valid methods whereby an addressee can assess the reliability of the speaker's assertion.

I want mainly to take issue with Jung's very first assumption: when assessing a speaker's assertion, the addressee is evaluating the reliability or believability of her utterance. He is *not* arguing with her and therefore not producing an *ad hominem argument*. (Construing the addressee's process of appraisal as an *attack* against the speaker seems far-fetched to me.) In accordance with Jung's second assumption (at least, on my reconstruction of his train of thought), the addressee's appraisal can in turn be seen as a two-fold process: the addressee can focus on either the *content* or the *source* of the speaker's utterance (or both). If the former, then the addressee's task can be construed as a *consistency* check: he checks the compatibility of the truth of the speaker's assertion with the truths of a relevant sub-set of his own beliefs. In the latter case, he scrutinizes some of the speaker's relevant moral or "personal" properties (to use Jung's own phrase). In particular, he will assess the personal authority of the speaker along two main dimensions: her epistemic competence (or knowledge) about the relevant domain of discourse and her moral honesty, i.e., her benevolence towards him.

Of course, the addressee's assessment of the speaker's reliability along these two dimensions is an inferential process, which builds on the addressee's beliefs about both the content of the speaker's assertion and the speaker's personal authority. In an informal sense, it is a reasoning process. But I want to resist the view that this process should be construed as an *argument*, let alone as an *ad hominem* argument. As Sperber et al. (2010) and Mercier & Sperber (2011) have interestingly argued (no pun intended), to *argue* is to try and cause an addressee to accept a new belief (to endorse the truth of

some proposition), by providing explicit *reasons* for it, i.e., by construing it as the *conclusion* of a set of premises from which it derives either deductively or inductively. In fact, arguments are devices used by a speaker in order to try to *overcome* her addressee's reluctance to fulfill her informative intention (i.e., his reluctance to accept a new belief in accordance with her informative intention), on the *sole* grounds of her authority. If so, then speakers (communicative agents) argue, but an addressee doesn't: an addressee *evaluates* the speaker's argument. Of course, an addressee who disagrees with a speaker's argument in favor of some proposition P can turn into a speaker and offer *counter-arguments* to try to cause his opponent to *change her mind* about the truth of P.

1 Conclusion

When a speaker makes an assertion, she commits herself to the truth of some proposition. She thereby knowingly takes the risk that her addressee examines the reliability of her assertion by either checking the content of the asserted proposition or by scrutinizing her epistemic and moral authority. The addressee's choice is to either fulfill the speaker's communicative intention or not. She can further do it on the sole ground of the speaker's authority or not. As I see it, the issue of whether the addressee could *wrong* the speaker by committing some epistemic injustice towards her cannot arise in the process whereby the addressee assesses the reliability of the speaker's mere assertion of P. It can only arise if and when the speaker offers some explicit *argument* in favor of proposition P, in the reasoning process whereby the addressee evaluates the speaker's explicit argument in favor of P, i.e., the link between P and the premises selected by the speaker to justify P. Only then could the addressee produce an *ad hominem* counter-argument (either local or global) meant to successfully or unsuccessfully rebut the speaker's argument for P.

Wild Systems Theory as a 21st Century Coherence Framework for Cognitive Science

J. Scott Jordan & Brian Day

The present paper examines the historical choice points the led twentieth-century cognitive science to its current commitment to correspondence approaches to reality and truth. Such a “correspondence”-driven approach to reality and truth stands in contrast to coherence-driven approaches, which were prominent in the 1800s and early 1900s. Coherence approaches refused to begin the conversation regarding reality with the assumption that the important thing about it was its independence of observers because the reality-observer split inherent in correspondence-driven views often led to objective-subjective divides, which, within scientific theorizing, tended to render the latter causally unnecessary and in need of ontological justification. The present paper fleshes out the differences between coherence- and correspondence-driven approaches to reality and truth, proposes an explanation of why cognitive science came to favor correspondence approaches, describes problems that have arisen in cognitive science because of its commitment to correspondence theorizing, and proposes an alternative framework (i.e., Wild Systems Theory—WST) that is inspired by a coherence approach to reality and truth, yet is entirely consistent with science.

1 Introduction

Over the course of its history, cognitive science has often assumed that the important question regarding reality was its independence of an observer. Within this framework, epistemology becomes paramount as scientists work to discover the lawful connections between observer-independent reality and observers. Implicit, if not ex-

plicit, in this approach to cognitive science is the assumption that “truth” is to be measured in terms of the degree of discrepancy between observer-independent reality and whatever impressions, thoughts, representations, affordances, and other observer-dependent phenomena observers use to overcome this assumed epistemic gap.

In contrast to such correspondence-driven approaches to reality and truth, many coherence-driving philosophers of the late 1800s and early 1900s rejected correspondence as a starting point for ontology because they believed the subject-object divide it engendered ultimately made it difficult to defend the reality of the subjective (Gardner 2007; Hegel 1971; Priest 1991; Tseng 2003). Given their commitment to the reality of phenomena such as consciousness, value, and meaning, coherence theorists refused to accept the ontological risks inherent in correspondence approaches to reality. Instead, they proposed an alternative approach that admits the reality of consciousness, value, and meaning and assesses truth in terms of the degree of coherence (i.e., non-contradiction) (Oakeshott 1933; Tseng 2003).

In what follows, we flesh out the differences between coherence- and correspondence-driven approaches to reality, propose an explanation of why cognitive science came to favor the correspondence approach, describe problems that have arisen in cognitive science because of its commitment to correspondence theorizing, and propose an alternative framework (i.e., Wild Systems Theory—WST) which is inspired by a coherence approach to reality yet is entirely consistent with science.

2 Correspondence and coherence

2.1 A creation myth: The origins of the correspondence view

A professor walks into the first day of his graduate-level Learning and Cognition course. He tells the students the following story:

“A boy is riding his bike and sees a bracelet on the street. He stops his bike, picks up the bracelet, and realizes the bracelet is a snake.”

After reading the story, the professor asks the students to describe it using the concept “real.” The students share perplexed glances, as if to say, “I signed up for a science course, not a philosophy course.” The professor continues to press the issue, and eventually a student speaks.

“He thought the object was a bracelet, but it was really a snake.”

This prompts another student to say, “He misperceived the snake as a bracelet.”

The professor asks the class if they understand these statements and if they agree with the students’ use of the concept “real.” The vast majority of the class nods yes.

The professor then asks the following, “Is there anything real about the bracelet?”

Eyes roll and students laugh as the question comes across as being silly more than important. The professor waits patiently and asks the question again.

After some time, a student states, “He really believed he saw a bracelet.”

When the professor asks the class if they understand and agree with the statement, only half or less nods yes.

To cut to the chase, the professor asks, “How many of you had a dream in the last week?”

Surprised by the question, few students raise their hand.

Needing to get the class on-board, the professor pushes harder and asks, “Ok. How many of you have had a dream in the past year?”

Now everybody raises their hand.

“Good,” says the professor. “And was there anything real about the dream?”

Connecting the questions regarding the reality of the bracelet and the reality of dreams, a student says, “The dream was real in the sense that I had the experience.”

“Excellent,” states the professor. “Now you understand the type of thinking that lies at the root of our thinking about reality and truth.”

Students look back at him, slightly puzzled.

“According to what you just told me,” the professor begins, “both the snake and the bracelet are real.”

The class continues to stare.

“How many of you think the two are equally real?”

More staring.

“OK. How many of you think the snake is more real than the bracelet?”

Roughly two-thirds of the class raises their hand.

“Why?”

One student raises her hand and states, “The boy really experienced a bracelet, but since the bracelet was an incorrect perception, the snake is more real.”

“And when the boy finally had a snake perception,” states the professor, “his perception was correct?”

“Yes,” responds the student confidently.

“Excellent!” exclaims the professor. “How many agree?”

The students look back and forth to each other, seeking an answer. Eventually, most everyone in the class raises their hand.

“Now we are truly making progress,” states the professor, “and for my final question, how do we know the snake is more real than the bracelet?”

The same student answers without hesitation, “Because the snake perception accurately corresponds to the object.”

“There it is,” exclaims the professor. “We know the object is really a snake because our experiences correspond to it. In short, perceptions are true, or accurate, because they correspond to reality correctly.”

He centers himself in front of the class and states, “This way of describing reality is known as the correspondence approach to truth and reality. It has dominated the way we think about truth and reality for at least four hundred years, if not longer. And over the next two weeks I hope to show you that if you believe this approach to truth and reality, you, one, logically deny yourself access to reality, and, two, make it very difficult to defend the reality of phenomena such as love, hate, the sound of music, and the taste of ice cream.”

He looks out over the class and sees that he has their attention.

“How many of you really like ice cream?” he asks.

Everyone raises their hand instantly. Some students raise both hands.

“Good then,” the professor states. “Let us begin.”

2.2 A very brief history of correspondence, reality, and truth

While the story described above may seem rudimentary, the purpose is to give the reader, as well as the hypothetical student, a common entry point into the conversation regarding correspondence and coherence approaches to reality and truth. This is important because coherence approaches have not been proposed all that often over the past one hundred years. Thus, very few contemporary cognitive scientists know of them, let alone make use of them. This century-long waxing and waning of correspondence and coherence approaches, respectively, may have had something to do with the fact that alternatives to correspondence have come to be seen as increasingly irrelevant after a century of naturalism, physicalism, and realism. That is, the increasingly sophisticated view of the physical world that has developed over centuries of scientific practice has led the vast majority of practicing cognitive scientists to assume that the issue of reality and truth has been solved, and by using science, we decrease the degree of discrepancy between objective and subjective reality. From this perspective, science is metaphysical in the sense that science reveals how reality really is, independent of our personal perspective.

While this correspondence-driven, metaphysical take on science is practically implicit in contemporary cognitive science, we propose that the issues addressed in the snake/bracelet story are, in fact, unresolved. Furthermore, we believe that the current zeitgeist of correspondence thinking is due to historical choices regarding our conceptualization of the reality of human experience. In what follows, we briefly review some of these choice points in the hope of clarifying why a commitment to correspondence has seemed to be such an obvious step for cognitive scientists.

a. Spiritual versus mental subjectivity. Questions about whether or not the bracelet is real, or the manner in which it is real in relation to the reality of the snake, are the same kind of questions René Descartes asked himself when he addressed the reality of God and the

material world hundreds of years ago. To be sure, very few if any contemporary cognitive scientists would account for the reality of the snake and the bracelet via Descartes's notion of interacting yet qualitatively distinct physical and spiritual realities (i.e., dualism). However, despite their assumed distinctiveness from dualism, most contemporary cognitive scientists implicitly, if not explicitly, endorse the basic assumption of dualism that the interesting point about reality is the extent to which it is independent of observers. This commitment to correspondence thinking was evident in the writing of one of Descartes' major critics, [John Locke \(1700\)](#). Even after Locke took some of the first formal steps toward developing cognitive science (i.e., a "science of man") and re-described the spiritual side of Descartes' dualism as being "mental," the question for Locke's "science of man" was how it is that our sense impressions are able to accurately correspond to physical reality.

b. Radical skepticism. In response to Locke's non-spiritual correspondence approach to reality and truth, [David Hume \(2012\)](#) asked whether or not such an approach is even logically possible. Specifically, Hume's basic argument was that if one accounts for reality in terms of the "impressions and ideas" it causes within us, then all we can ever really know are the impressions and ideas we have about reality. This is because every test we could ever run to assess the extent to which our impressions and ideas about external reality are accurate would have to be mediated by impressions and thoughts. That is, once we claim that we know external reality through observer-dependent structures such as thoughts and impressions, we have logically doomed all of our knowledge to be trapped within us.

Though Hume's radical skepticism is hundreds of years old, and seems outdated to many contemporary scientists in general—and cognitive scientists, specifically—we believe Hume's radical skepticism constitutes both a historical choice point and an individual choice point for the issue of how we conceptualize the reality of the subjective. On the one hand, there were and are those scholars who took radical skepticism

to be diagnostic of a logically flawed approach to reality and truth. On the other, there were and are those who believed and continue to believe that the test for whether or not the correspondence approach to reality and truth is "correct" is empirical. That is, the "correctness" of science will ultimately be decided on correspondence grounds; that is, by whether or not science can eventually represent the entirety of observer-independent reality accurately. In what follows, we examine various historical attempts to sustain the correspondence approach in spite of radical skepticism.

c. Overcoming radical skepticism.

What is somewhat ironic about the attempt to overcome skepticism is that although those who did and do so tend to present themselves as being quite different from each other, they nonetheless avoid skepticism in roughly the same way; specifically, by nesting the correspondence relation within an assumed, larger-scale reality that guarantees the veridicality of the correspondence relation. Descartes, for example, after having doubted all but his ability to doubt, then went on to infer that his ability to do so could have only been created by a superior, omnipotent being (i.e., God). Then, to secure the correspondence relationship completely, he assumed that his subjectivity must correspond accurately to reality because God created both and would not have done so incorrectly. Bishop Berkeley made much the same maneuver when he proposed to overcome Hume's radical skepticism by asserting that the correspondence relation holds because we exist within God's mind.

Cognitive scientists, while certainly not dualists, nonetheless rely on evolutionary theory as a means of placing the correspondence relationship within a larger-scale reality as a means of validating the correspondence relationship. There are two dominant varieties of such thinking: indirect-realism and direct-realism. Realism is the assertion that objects exist as they are, with all of their intrinsic properties, independently of observers. Indirect realism asserts that our knowledge of reality is mediated by our sensory systems and knowledge structures. Direct realism asserts that our knowledge struc-

tures are directly in contact with external properties, exactly as they are.

Indirect realism is basically an evolutionarily inspired re-description of Locke's mediated theory of perception in which external events cause the internal formation of impressions and ideas. Though there are many varieties of indirect realism (Fodor 1983; Pinker 1999), common to most is the computationalist, representationalist view of cognition, which assumes that we know what is outside of us because of the representations that external events cause within our brains. Given that our brains co-evolved with the world and were naturally selected, it seems self-evident that our brains give us accurate access to external reality.

While in the early days of cognitive science indirect realists believed that internal, sensory-driven (i.e., bottom-up) representation of external events could be augmented by top-down, cognitive processes such as attention (Broadbent 1958; Cherry 1953), they still nonetheless believed that the bottom-up processes entailed accurate representations of their external causes. Such assumptions derived support from findings such as Hubel & Wiesel's (1962) discovery of neurons in the primary visual cortex (V1), that expressed spatially correspondent receptive fields (i.e., the activity of a neuron in V1 could be maximally stimulated by a visual stimulus emanating from a particular location in the visual field). Later research revealed a massive degree of spatial correspondence between locations in external space and neural space within a host of different modalities (e.g., visual, auditory, and kinesthetic space). Milner & Goodale's (1995) discovery of visual systems used for object identification versus visual systems used for guiding action (i.e., vision for perception versus vision for action) further solidified indirect realism because it seemed to clarify how internal representations of external events were used to accurately guide behaviors back onto external reality.

In light of this accumulating neural evidence as well as a host of perceptual-cognitive research that revealed our apparent ability to represent invariant properties of biologically relevant external events, Roger Shepard (2001)

stated the following in the opening line of the abstract to his seminal paper, *Perceptual-cognitive Universals as Reflections of the World*: "The universality, invariance, and elegance of principles governing the universe may be reflected in principles of the minds that evolved in that universe" (p. 581). Clearly, from this indirect-realist perspective, our connection to the world around us is mediated by internal representations that are phylogenetically derived stand-ins for what the world around us is like.

Critiques of indirect realism within cognitive science basically recapitulated Hume's critique of Locke's mediated theory of perception. That is, cognitive scientists dating back as far as the Six Realists (Holt et al. 1910) criticized the representational approach to cognition because they believed it logically denied one access to external reality. Interestingly enough, instead of challenging the correspondence view of reality and truth that lay at the heart of indirect realism, and which constituted Hume's biggest concern with Locke's approach, cognitive scientists who labeled themselves direct-realists argued that the connections between the internal and the external were not constituted of mediating representations of the external but, rather, of natural relations between the organism and the environment. Though this idea dates back at least as far as William James as well as the Gestalt psychologist Kurt Koffka (Ash 1998), perhaps its most influential expression was provided by J. J. Gibson (1979), who argued that we perceive the world in terms of behavioral possibilities, what he referred to as affordances.

Since Gibson (1979), many cognitive scientists have effectively investigated affordances. Given that most ecological psychologists who investigate affordances are simultaneously direct realists, it is important to their realism that affordances be real, and that we have direct access to affordances via our sensory systems. Instead of constructing representations, however, our sensory systems are described as having the task of picking up or detecting information (i.e., affordances).

The direct-realist appeal to the reality of directly perceivable affordances defends the

validity of the correspondence relation by arguing that organisms veridically perceive affordances because they evolved to do so. That is, just as was the case with Descartes, Berkeley, and indirect realism, the assertion of the correspondence relation is validated by placing it within an *assumed*, larger-scale reality. In the case of direct realism, that assumed, larger-scale reality is the evolved physical world.

By calling the *evolved, physical world* an assumed, larger-scale reality, we are not proposing that the theory of evolution is untrue, or that the phenomena referred to via the concept of the physical world do not exist. In fact, we believe the phenomena referred to via the concept of the physical world do exist, and we further believe that the theory of evolution is “true.” We just believe they exist and are true respectively, in a manner that is not couched in the correspondence framework espoused by realists. (We will describe how we believe they exist and are true at a later point in this paper.) Rather, what we are trying to accomplish by referring to the evolved physical world as an assumed, larger-scale reality is to point out the common strategy shared by correspondence theorists across the centuries. Specifically, if one espouses a correspondence account of reality, in which knowledge and/or perceptual structures are meant to correspond to reality, either via perceptually generated representations or via evolutionarily tailored relations, then, by definition, all we have contact with are knowledge and perceptual structures, and any statement about external reality is an *assumption*. This, in fact, was the gist of Hume’s critique of Locke’s mediated theory of perception. Radical skepticism does not argue that objects do not exist. Rather, it is simply a critique of a *particular* account of reality (i.e., the correspondence account), and the critique refers to the *logical coherence* of the account. If one espouses a correspondence framework for reality and truth, one has logically denied oneself access to external reality, and neither empirical data nor an assumed larger-scale reality is capable of overcoming this logical flaw. On logical grounds alone, one cannot use realism and its attendant correspondence arguments to overcome radical skepticism.

To be sure, direct realists might respond that their brand of realism overcomes radical skepticism because direct realism does not rely on internal representations to connect the internal to the external. Rather, the connections, as stated above, are conceptualized in terms of relations between organisms and environments that co-evolved in such a way that organisms are able to directly perceive these relations (i.e., affordances).

While at first glance the anti-representational slant of these arguments does seem to skirt the issue of radical skepticism, it’s appeal to relations or relational properties between relata (e.g., organisms and environments) still commits to the correspondence notion that truth is determined by the degree of correspondence between the system (i.e., the organism) and something external to the system (i.e., affordances). Again, this commitment to the correspondence relation stems from the centuries-old belief that the important thing about reality is its independence of observers. Armed with such an approach to reality and truth, science is believed to be metaphysical in that it reveals observer-independent properties of external reality. To be sure, the direct realist will argue that evolution has solved all of this. However, as was stated above, it is their commitment to realism that logically denies the correspondence scholar access to external reality. In short, it is the logically incoherent notion of correspondence that denies the realist access to external reality, not reality itself.

2.3 The coherence approach to reality and truth

In order to overcome the representationalism inherent in indirect realism, direct realists re-framed the connection between organisms and environments in terms of evolutionarily derived relations as opposed to internal representations. Doing so, however, begs the issue of the nature of the things that stand in relation to each other (i.e., the relata). Are the relata themselves constituted of relational properties? If so, just how far down is reality constituted of relations?

While questions regarding the relational nature of reality might seem silly to contemporary cognitive scientists, it was actually of paramount importance to the maintenance and perpetuation of the correspondence approach roughly a century ago. [Bertrand Russell \(1911\)](#), for example, went to great lengths to counter the notion of internal relations that was prominent in idealist philosophy in the 1800s and early 1900s. As described by Russell, the notion of internal relations is the idea that the relations between entity A and B are actually constituents of A and B. In other words, part of what constitutes A is its relationship with B. This idea was problematic for Russell because idealist philosophers often used it as a means of overcoming radical skepticism. Specifically, these philosophers proposed that the objectivity of supposed external reality was actually observer dependent, in that a subject (i.e., an observer) was internally related to its objects. That is, the objects do not have an existence independent of the subject, and vice versa ([Hegel 1971](#); [Oakeshott 1933](#); [Priest 1991](#)). Different idealist philosophers held different motivations for espousing this view. Many did so in order to maintain the reality of God. Others did so in order to maintain the reality of phenomena that Descartes had relegated to the subjective (e.g., values, meaning, and aesthetics).

Regardless of their motivations, the idealist notion of internal relations was problematic for Russell because he wanted to describe reality in terms of the objects of science and logic. In short, Russell wanted metaphysics to be empirical. In order to do so, he felt he needed to establish the logical independence of external reality. That is, he had to show that objects are not internally related to subjects. As a result, he argued that not all relations are internal, and that some are external. By external relations, Russell meant that a relationship between entity A and entity B is not constitutive of entities A and B. An example of an external relation would be the relative height of two people, say Mary and Sam. While it is logically coherent to state that Mary is taller than Sam, the “taller” relation is not constitutive of either Mary or Sam. That is, the “taller” relation de-

pends, of course, upon Mary and Sam, but it exists externally from Mary and Sam in the sense that it plays no role in the properties that constitute Mary or Sam. Russell uses this notion of external relations to propose a correspondence approach to reality and truth in which entities share relations and via those relations constitute components of complexes. Having assumed that he had logically negated the notion of internal relations, Russell then proposed that we get on with the empirical, metaphysical business of scientifically describing reality “as it is,” independent of observers.

The use of the notion of externally related entities as a means of sustaining the correspondence approach to reality and truth is also evident in the work of direct realists such as [Holt et al. \(1910\)](#) and [Gibson \(1979\)](#). By utilizing this relation-driven form of realism, all three were implicitly asserting the belief that the issue of reality was to be solved via epistemology. That is, they were continuing the centuries-old argument that the important thing about reality is its independence from observers.

a. The relational nature of reality. As stated above, the direct-realist assumption that we have contact with external reality via relations begs the issue of the nature of the things that stand in relation to each other (i.e., the *relata*). In other words, if we claim that two *relata* share a relation, we imply that there is a difference between *relata* and relations. This leads to another choice point that historically influenced the manner in which we describe the reality of the subjective: Are the *relata* themselves constituted of relational properties, or are they constituted of non-relational properties, what one might refer to as *intrinsic* properties? The answer to this question is important, for if one argues for a difference between intrinsic and relational properties, then realism seems the obvious choice; the purpose of science is to uncover the intrinsic properties of reality. If, however, one assumes that *relata* are themselves constituted of relational properties, we have a much different problem. For if all *relata* are constituted of relations, then there can be no intrinsic properties. This is because the constitution of all properties, by definition, would be re-

lational. In short, reality would constitute a unity in which all things were constituted of all things.

The notion that all things are about all things sounds much like the idealist notion of internal relations. And while the idea might seem outdated in contemporary cognitive science, it has recently gained traction in the philosophy of science as a possible explanation of properties. For example, mass is often considered an intrinsic property in that the mass of an object is considered to be independent of its context, while weight is considered to be an extrinsic property because the object's weight is determined by how its mass interacts with its context. Jammer (2000), however, proposes that all particles receive their inertial mass via their interactions with the Higgs field, "a scalar field that 'permeates all of space' and 'endows particles with mass'" (p. 162). Bauer (2011) argues that the dependence of mass on the Higgs field renders mass *externally grounded*. This means that the mass of the particle is not independent of its context. As a result, the object's mass is a *relational, non-intrinsic* property.

Bauer's notion of external grounding should not be confused with Russell's (1911) notion of external relations. Bauer uses the notion of external grounding to make the case that a property (i.e., mass) that was assumed to be intrinsic (in order to distinguish it from the property of weight, which was assumed to be contextually relative) was actually contextually relative. "External" in this sense was used to flesh out the relative nature of a previously assumed to be non-relative (i.e., intrinsic) property (i.e., mass). Russell, on the other hand, used the concept "external" in the opposite way. That is, he wanted to demonstrate that certain properties were independent (i.e., were not entailed in the constitution) of other properties. In short, Russell used the notion "external" to create independent properties in a reality the idealists had described as an internally related unity, while Bauer, roughly a century later, uses the concept "external" to re-contextualize properties that post-Russellian realists had conceptually isolated from reality by describing them as *intrinsic*.

While one could see Russell's (1911) and Bauer's (2011) uses of the concept "external" as contradictory and leave it at that, one might also argue that their different uses of the same concept are diagnostic of the success of Russell's efforts. Specifically, Russell used the concept external to de-contextualize certain parts of reality (i.e., make them intrinsic), while Bauer, one hundred years later, uses the same concept to re-contextualize what Russell had worked so hard to de-contextualize. In short, one might argue that while Russell represented a first conceptual step away from holism, contemporary works such as Bauer's represent initial conceptual steps back toward holism. Further evidence of a tendency to conceptually move the philosophy of science away from the notion of intrinsic properties can be found in the work of Harré (1986), who proposes the notion of *ultra-grounding*, the idea that a property may be grounded by a property, or properties, of reality as a whole.

Such an anti-intrinsic take on the nature of properties is also proposed by both Schaffer (2003) and Dehmelt (1989). These authors assert that there may be no fundamental level to reality at all (i.e., no final, non-relational, intrinsic property that forms "relations" into "complexes"). Rather, they propose that reality may be constituted of infinite levels of microstructure. Consistent with the notion of external grounding, Prior et al. (1982) propose the Global Groundedness Thesis. This thesis asserts that all dispositions (i.e., properties) are grounded (i.e., externally grounded) rather than ungrounded (i.e., intrinsically grounded). Ladyman et al. (2007) implicitly, if not explicitly, express a similar critique of the notion of intrinsic properties when they assert that contemporary analytic metaphysics needs to abandon the idea that reality is constituted of self-subsistent individual objects.

b. Truth in a relational reality. The idea that reality is infinitely relational is inconsistent with the correspondence approach to reality and truth because a relational reality can never be subdivided into final, intrinsic, "in-and-of-themselves"-type properties. In an infinitely relational reality, all objects

and subjects are composed of relations (i.e., they are contextually grounded), and all intrinsic properties are inherently relational. This implies that dialectic counterparts such as objective versus subjective, or relational versus intrinsic, come to be introduced into one's description of reality, not because they reflect accurate, final, ontological subdivisions of reality, but for the same reason one describes the snake in the snake-bracelet story as being more real than the bracelet—specifically, because one accepts the subjective-objective divide inherent in the correspondence view and tries to defend the assumed greater reality of the snake by asserting its independence of oneself. It is this assumption that the important thing about reality is its assumed observer-independent nature that drives the correspondence approach and leads one to further believe that the goal of science is to overcome subjectivity and reveal the objective truth about reality. Once such independence is no longer assumed, then truth can no longer be measured by assessing the degree of difference between reality and an impression, idea, or representation we have of it, or by investigating an assumed relation we share with it. There exists nothing “as it is” to which anything else can accurately correspond. The final, ontological description of what something *is* must include reality as a whole. In short, truth must be assessed in a non-correspondence fashion.

One way to measure truth without asserting a correspondence relationship is to do so on the basis of coherence. By coherence we mean lack of contradiction. In contemporary philosophy, lack of contradiction (i.e., coherence) is most often used to refer to the means by which a belief is justified (Kvanvig 1995; Lycan 2012). Specifically, a subset of contemporary epistemologists, who might be loosely referred to as “coherentists” (Lycan 2012; Quine & Ullian 1978; Thagard 1978), propose a view akin to the following:

[...]what justifies [...] the formation of any new belief—is that the doxastic move in question improves the subject's explanat-

ory position overall and/or increases the explanatory coherence of the subject's global set of beliefs. (Lycan 2012, p. 6)

While the coherentist approach to propositions clearly relies on the notion of “lack of contradiction” to measure the justifiability of beliefs, it does not make use of “lack of contradiction” as a measure of the truth inherent in experience. As a result, it is logically possible for one to be a coherentist about beliefs while simultaneously holding an implicit or explicit correspondence view that conceptualizes beliefs as subjective propositions that refer to external, objective reality. It is not clear where Lycan (2012) stands on this issue.

At any given moment, we find ourselves involuntarily holding any number of beliefs, at least those produced by perception and by memory; however, [...] I do not make any primary appeal to those faculties as justifying. Call such unconsidered beliefs “spontaneous beliefs”; they are primarily about our immediate environment, past events, sometimes our own mental states, and more. (p. 6)

Although Lycan (2012) makes no claims regarding the metaphysical status of *perception*, or where he stands on the issue of reality and experience, his use of the word *perception* allows him to interject other phrases such as “primarily about our immediate environment,” that then implicitly connect beliefs to external reality via a correspondence relation. Regardless of whether or not this was Lycan's intent, it is clear that coherentism is about the justifiability of beliefs and not about reality, per se. As a result, it may not have much to offer in our attempt to develop a coherence approach to reality and experience.

One possible way to apply the coherence approach to the issue of reality and experience is the very same test entailed in the snake-bracelet problem. If one assumes that reality constitutes an internally related unity that defies that logic of correspondence tests of truth, then statements regarding the truth of the

snake and the bracelet should be stated in terms of contradiction. That is, the statement “the boy saw a bracelet while riding his bike” is true in the sense that the boy had a persistent flow of “bracelet” experience. The notion of persistent flow is important here because it calls attention to the fact that from moment to moment during the bracelet phenomenon, the phenomenon did not contradict itself; that is, the “bracelet” phenomenon at one moment was not followed by a different “non-bracelet” phenomenon the next. Jordan & Vandervert (1999) propose that it is this coherent flow of phenomena, what they refer to as “within-instance” coherence, that underlies our propositions regarding the reality of phenomena. To be sure, later on in the story, when the boy picked up the “bracelet,” he suddenly did have a contradiction in the flow of the bracelet phenomenon; specifically, the bracelet phenomenon was contradicted by a “snake” phenomenon. Given that the snake phenomenon persisted in a more coherent fashion than the bracelet phenomenon (i.e., no matter what he did, the boy could not convert the snake phenomenon into another type of phenomenon), one then asserts that the snake phenomenon is more real than the bracelet phenomenon. From the coherence perspective, what this means is that the snake phenomenon was more coherent (i.e., more persistent, or less contradictory) than the bracelet phenomenon.

Such a coherence approach to the reality and truth of phenomena is rather similar to the approach advocated by Michael Oakeshott. In perhaps his most famous book, *Experience and its Modes*, Oakeshott (1933) described reality in a manner that is consistent with the idea that reality constitutes an internally related unity. He did not say it this way, however. Rather, as was consistent with both his idealist background and the philosophical context of his time, he described reality in terms of experience and stated, “[...]experience is a single whole, within which modification may be distinguished, but which admits of no final or absolute division” (Oakeshott 1933, p. 27). Also,

[s]ubject and object are not independent elements or portions of experience; they

are aspects of experience which, when separated from one another, degenerate into abstractions. Every experience [...] is the unity of these, a unity which may be analysed into these two sides but which can never be reduced to a mere relation between them. (Oakeshott 1933, p. 60)

To be sure, the manner in which Oakeshott uses the concept of experience makes it difficult for those who have already made correspondence-driven commitments to the meaning of “experience” to follow his arguments. For correspondence theorists, “experience” refers to the subjective side of Descartes dualism. But given that Oakeshott did not define experience in terms of the mental, spiritual, transcendental, or absolute, it seems reasonable to assume that when he described reality as a world of experience, he was using the concept differently than it had been used by Locke, Kant, or Hegel. This is important, for when most contemporary cognitive scientists refer to idealism, they tend to mention Locke and Berkeley (Charles 2011). Locke and Berkeley both accepted the correspondence relation. Locke accepted it without reservation. Berkeley accepted it and then placed it within the assumed larger-scale reality of God’s mind in order to avoid skepticism. Oakeshott, on the other hand, denied the correspondence relation (as did most all the German idealist philosophers). Thus, for Oakeshott, the terms “reality” and “experience” were synonymous, not because he believed reality was ultimately subjective, but because he believed reality constituted an internally related unity that defied any ontological, final division into dialectic categories such as subjective and objective, or reality versus experience.

c. Coherence, truth, and modes.

Oakeshott proposed his coherence approach to reality and truth because he believed that the correspondence approach was, first, logically incoherent, and second, improperly applied in contexts in which it was not relevant. Specifically, Oakeshott argued that within the confines of the correspondence approach, it was easy to believe that the task of science was to uncover the intrinsic, observer-independent properties of

reality. In addition, given its supposed ability to accumulate a stockpile of context-independent, universal knowledge, it became easy to believe that its criterion for truth (i.e., correspondence) should have dominion over all arenas in which truth was at stake.

Agreeing with his idealist predecessors about the logical incoherence of correspondence thinking, Oakeshott argued that endeavors such as “science” constituted modes of experience. What he meant by “mode” is that science constitutes a distinct means of generating abstractions about the internally related unity in which we are embedded. It is an abstraction in the sense that it is constitutive of reality (i.e., it is “within” the reality it is attempting to describe) and can therefore never be “outside” of reality, looking “at” reality. As a result, it should be conceptualized as a recursion on reality—an abstraction about that from which it emerged and within which it is entailed.

Oakeshott described at least four different modes: science, daily practice (i.e., politics), history, and poetry. What distinguishes these modes, in addition to the content they are about, is the means by which truth is determined within each. In the mode of science, truth is determined by the degree of quantitative coherence that can be achieved in the description of a phenomenon, both individually and collectively. Given that quantitative coherence within and between individuals is paramount, factors such as personal opinion are irrelevant to the truth criteria of the mode of science. In the mode of daily practice (i.e., politics), however, opinion and desire (i.e., how people want to live their lives) constitute the issue at hand. Truth, therefore, could not be measured in terms of the degree of quantitative coherence within and between individuals. Rather, it was reflected in the degree to which members of a group treated each other in accordance with a normatively determined system of expectations. As a result, the truth criteria of the modes of science and politics (i.e., daily practice) were similar in that they were both measured in terms of coherence but were fundamentally different in terms of the phenomena whose coherence was being as-

sessed (i.e., quantification of a phenomenon versus normatively determined expectations).

Because of this qualitative difference in the relation of science and politics, Oakeshott argued that the truth criteria of one could not coherently be used to measure the truth of the other. That is, just as personal opinion and desire were to play no role in the truth status of scientific statements, quantitative coherence in both individual and collective descriptions should not play a role in determining the truth status of political statements (i.e., statements of how people should live their lives).

Oakeshott went to such great lengths to distinguish science as a mode of experience because he felt he needed to provide an alternative to the correspondence approach. By appealing to the notions of *coherence* and *internally related unity* that were common to idealist philosophers, without making appeals to the mental, spiritual, transcendental, or absolute, Oakeshott presented a coherence approach that was capable of addressing the physicalist, naturalist forms of correspondence thinking that were emerging during his time. The difference between Oakeshott’s coherence approach and the correspondence-driven naturalism of his time was not that the former did not believe in the reality of objects or that the former was created to maintain a place for God in metaphysics, as had been the case for Berkeley and Kant. Rather, the difference was that the former recognized the logical incoherence of the latter and worked to develop an approach to reality that avoided the logical pitfalls historically encountered by the latter. Given that direct realists such as [Holt et al. \(1910\)](#) and [Gibson \(1979\)](#), who were, to some extent, contemporaries of Oakeshott, had probably developed fairly robust associations between coherence, idealism, and the religious agendas of Berkeley and Kant, they probably had no reason to assume that an idealist-inspired philosophy had anything to offer.

Regardless of who did or did not read Oakeshott’s work while he was alive, his lack of appeal to mental, spiritual, transcendental, or absolutist themes, coupled with his persistent attacks on the correspondence approach, collectively support the idea that when he referred to

reality as a world of experience, he was using it more as a placeholder in his arguments with the correspondence approach as a way to slowly transform the reader's meaning of the word experience from the subjective-mental denotation it had acquired in the midst of the correspondence approach to the holist-driven, internally related unity of all phenomena it was meant to imply in the coherence framework.

d. Coherence and science. To correspondence ears, the description of the coherence approach given above might be interpreted as antiscientific. That is, since we take seriously the logical incoherence of the correspondence approach and assert that it does not inform us about context-independent, intrinsic properties of reality, one might assume we are proposing that science does not reveal truth. This is a common reaction of those who implicitly hold a correspondence view. They assume that those who acknowledge the strength of Hume's insight are actually denying the existence of "things." This is simply not the case. As stated above, radical skepticism is a critique of the internal logic of the correspondence approach to reality and truth, not a critique of the existence of "things." Oakeshott's coherence approach constitutes a means of addressing reality and truth in a way that does not beg incoherent correspondence assumptions. In order to further demonstrate the compatibility of science and the coherence approach, we present WST as a case in point. As we present WST we will also point out how various choice points in the theory's construction were guided by the notion of coherence.

3 Wild systems theory

WST is a recently developed theory of cognitive systems (Jordan 2008, 2013; Jordan & Ghin 2006, 2007; Jordan & Heidenreich 2010; Jordan & Vinson 2012) that conceptualizes organisms in a different light than technological metaphors such as switchboards and computers, or dynamical metaphors such as Watt Governors and convection rolls. Rather, WST follows the lead of physicists (Schrödinger 1992), theoretical biologists (Kauffman 1995) and ecologists (Odum

1988), and conceptualizes organisms as multi-scale, self-sustaining energy-transformation systems. What is meant by *self-sustaining* is that the *work* of the system (i.e., the energy exchanges that actually constitute the system, such as the chemical work that constitutes biological systems) gives rise to products (e.g., other chemicals) that serve as a catalyst for the reaction that produces the product or some other reaction in the system. When a self-catalyzing system of work emerges, it is able to *sustain* itself as long as the proper fuel source remains available.

What is meant by *multi-scale* is that an organism can be coherently conceptualized as being constituted of different scales of self-sustaining work. Jordan & Vinson (2012) describe the notion of multi-scale, self-sustaining work in the following manner:

At the chemical level, self-sustaining work has been referred to as autocatalysis (Kauffman 1995), the idea being that a self-sustaining chemical system is one in which reactions produce either their own catalysts or catalysts for some other reaction in the system. At the biological level, self-sustaining work has been referred to as autopoiesis (Maturana & Varela 1980), again, the idea being that a single cell constitutes a multi-scale system of work in which lower-scale chemical processes give rise to the larger biological whole of the cell which, in turn, provides a context in which the lower-scale work sustains itself and the whole it gives rise to (Jordan & Ghin 2006). Hebb (1949) referred to the self-sustaining nature of neural networks as the 'cell assembly', the idea being that neurons that fire together wire together. Jordan & Heidenreich (2010) recently cast this idea in terms of self-sustaining work by examining data that indicate the generation of action potentials increases nuclear transcription processes in neurons which, in turn, fosters synapse formation. At the behavioural level, Skinner (1976) referred to the self-sustaining nature of behaviour as operant conditioning, the idea being

that behaviours sustain themselves in one's behavioural repertoire as a function of the consequences they generate. [Streeck & Jordan \(2009\)](#) recently described communication as a dynamical self-sustaining system in which multi-scale events such as postural alignment, gesture, gaze, and speech produce outcomes that sustain an ongoing interaction. And finally, [Odum \(1988\)](#) and [Vandervert \(1995\)](#) used the notion of self-sustaining work to refer to ecologies in general. (p. 235)

3.1 Wild systems theory and coherence

Conceptualizing organisms as being composed of multi-scale, self-sustaining work is consistent with coherentism ([Lycan 2012](#)). That is, the notion of self-sustaining work increases the coherence of our conceptualization of organisms (i.e., beliefs about organisms) because it reveals the dynamic homologies that transcend both the phyla and the nesting of multi-scale, energy-transformation systems that constitute a single organism. From plants, to neurons, to behavior, to persons, to human societies, increasingly complex systems of work (i.e., energy transformation) have evolved precisely because the work of which they are constituted is self-sustaining in that the work produces catalysts for either the work itself or some other level of work in the multi-scale system.

When we conceptualize organisms with technical metaphors such as switchboards and computers, we leave out these homologous, multi-scale, energy-transformation dynamics that living systems do not have in common with technological systems. This use of technological metaphors then forces us to generate explanations of the means by which our technologically inspired model of the organism is “connected” to the external context. To be sure, the issue is not unique to science. Descartes ran into the same problem when he divided humans into physical and spiritual substrates, and most scholars who have taken Descartes's correspondence problem seriously have had to do something similar. Locke proposed causal connections between external events and internal im-

pressions and ideas. Kant proposed a priori conceptions of space and time. Indirect realism proposed evolutionarily derived representations, and direct realism proposed evolutionarily derived “relations.”

Given its focus on multi-scale, self-sustaining homologies, WST is able to focus on that which is common across the internal and external contexts of an organism; namely, energy transformation. As a result, WST's focus on internal/external homologies renders it consistent with the coherence approach to reality and truth. Specifically, its focus on internal/external homologies prevents WST from internal/external conceptualizations that lead to the connection problems experienced by correspondence-driven approaches. Within contemporary correspondence frameworks (e.g., indirect and direct realism), the external context tends to be conceptualized as physical. Historically, the concept physical has garnered its meaning from its dialectic relationship with concepts such as “mental” and “spiritual.” As a result, its usage implicitly intimates a correspondence relation and leaves us having to determine whether or not the internal context is likewise physical, mental, or something altogether different, as well as how it is that the internal context is connected to the external context.

Within WST, the internal and external contexts of an organism are both conceptualized in terms of energy transformation. Specifically, the external context is conceptualized as a self-organizing, energy-transformation hierarchy ([Odum 1988](#); [Vandervert 1995](#)), while brains and organisms are conceptualized as multi-scale, self-sustaining energy transformation systems that are able to sustain themselves in the larger-scale energy transformation hierarchy because the work of which they are constituted produces its own catalysts. Inspired by this idea, [Jordan & Ghin \(2006\)](#) proposed that *the fuel source dictates the consumer*. This means that any system that sustains itself on a certain fuel source (e.g., plants on sunlight, herbivores on plants, or carnivores on herbivores) must be constituted such that it is able to address the constraints involved in capturing that fuel source.

Conceptualizing organisms as self-sustaining embodiments of the contextual constraints entailed within an energy-transformation hierarchy renders WST consistent with a coherence approach to reality and truth because an embodiment of context is necessarily “about” that context. By “necessarily” we mean that the system’s internal dynamics are phylogenetically and ontogenetically emergent from the energy-transformation hierarchy in which it sustains itself; it is an embodiment of the reality (i.e., context) within which it emerged. In short, it is reality within reality. The idea that organisms constitute embodiments of context is consistent with [Friston’s \(2011\)](#) assertion that organisms constitute an embodiment of an optimal model of their environment. Interestingly enough, Friston is led to this assertion for much the same reason WST is led to its notion of organisms as embodied contexts; specifically, because both begin with the idea of the organism as an energy-transformation system. As a result,

there is no epistemic gap between an organism and its environment. Organisms do not need to be ‘informed’ by environments in order to be about environments because they are necessarily ‘about’ the contexts they embody. Rather, what self-sustaining systems need do is sustain relationships with the contexts in which they are embedded in ways that lead them to sustainment. According to WST, meaning is constitutive of embodied context (i.e., bodies). As a result, living systems are necessarily meaningful ([Jordan, 2000a](#)), not because a body is alive or dead, because it is physical, or because it is biological. Living is meaning because it is sustained, embodied context. ([Jordan & Vinson 2012](#), p. 9)

Given this lack of an epistemic gap between embodiments of context and the contexts in which they sustain themselves, WST dissolves the subjective-objective epistemic barrier created by the correspondence approach. Embodiments of context are naturally and necessarily “about” their context and, as a result, are inherently meaningful.

Our use of the word *meaningful* is not meant to imply that the evolutionary emergence of living systems simultaneously constituted the emergence of meaning into a reality that had been, up until then, *meaningless*. Rather, our equating the notion of *embodied context* with *meaningfulness* is meant to demonstrate the serious metaphysical consequences that emerge from our earlier description of reality as an internally related unity. If all phenomena are, in the end, contextually dependent, then part of what constitutes them is their relation with the rest of reality. In short, as was stated previously, self-sustaining systems are reality within reality. It is this irreducible, inherent relationality that we are conceptualizing as *meaning*.

Within contemporary philosophy of mind, it might seem as though we are asserting that embodied contexts (i.e., self-sustaining bodies) *instantiate* phenomenal properties. While this assertion is not incorrect, our concern with such an interpretation is the implicit, correspondence-driven assumption that phenomenal properties are subjective while other properties of the system are objective. Our take on this issue is that embodied contexts do not represent the emergence of phenomenology into reality as much as they represent the emergence self-sustaining relationality into reality. And it is this self-sustaining relationality that phylogenetically scales up to the phenomenon we refer to via terms such as consciousness and phenomenology.

Defining meaning in this way allows for meaning (i.e., embodied context) to be constitutive of what organisms are. As a result, phenomena traditionally referred to via concepts such as phenomenology, consciousness, meaning, and value, which tended to be relegated to the subjective/internal side of correspondence frameworks and had to be described as being emergent from, identical with, or fundamentally different from “physical” properties ([Chalmers 1996](#)), are considered phylogenetically scaled-up versions of the embodied meaning inherent in all embodied contexts. [Jordan & Vinson \(2012\)](#) describe why it is that self-sustaining embodiments of context entail meaning:

In a single-cell organism, the internal dynamics (i.e., the micro scale) and the organism as a whole (the macro scale) are coupled in such a way that changes in the micro-scale (e.g., low energy levels) give rise to changes at the macro-scale (e.g., behaviors such as swimming and tumbling) that recursively influence the micro-scale (i.e., give rise to energy intake) and, in the end, foster the sustainment of both levels of scale. In short, the micro-macro coupling is self-sustaining. In the case of a rock, the micro-macro coupling is not recursively self-sustaining. The coupling generates no dynamics that serve to sustain a particular aspect of either the macro or micro organization. (Jordan & Vinson 2012, pp. 11-12)

Jordan & Ghin (2006) refer to the embodied aboutness of a single-cell organism as *proto-consciousness*. They do so for the following reasons: (1) to acknowledge the meaning (i.e., embodied context) inherent in a single-cell (i.e., a small-scale, self-sustaining embodiment of context), and (2) to set the groundwork for an explanation of how the proto-consciousness of a single-cell system could possibly scale up to the full-blown self-awareness entailed in humans. As regards this scaling up, Jordan & Vinson (2012) say the following:

It was possible for self-sustaining systems to scale-up from the level of single-cell organisms to the level of human beings because their status as energy-transformation systems simultaneously rendered them a potential fuel source for any system that embodied the constraints necessary to sustain itself on such embodied energy. As an example, the emergence of herbivores gave rise to a context that afforded the emergence of carnivores. A significant constraint of being a carnivore, however, was the need to capture a moving fuel source. Doing so required, and still requires, anticipatory structures regarding the future location of the moving target. Jordan and Ghin (2006) assert that the embodiment of

anticipatory dynamics in the neuromuscular architecture of organisms capable of propelling themselves as a whole toward anticipated locations constituted the phylogenetic emergence of anticipatory aboutness. That is, the self-sustaining dynamics of one system came to be ‘about’ the future dynamics of another system. WST equates such anticipatory aboutness with the traditional notion of mind, and proposes that phenomena that have received labels such as memory, thought, phenomenology, and self-awareness constitute evolutionary recursions (i.e., scale-ups) of the anticipatory dynamics embodied in self-sustaining systems. Given that all self-sustaining systems constitute embodiments of context and are, therefore, necessarily ‘about’ context, their anticipatory dynamics likewise entail ‘aboutness.’ Thus, as self-sustaining systems evolved and became increasingly abstract (i.e., about increasingly abstract events such as tomorrow, next week, and/or next year), meaning, too, became increasingly abstract. (Jordan & Vinson 2012, p. 12)

WST’s conceptualization of meaning as embodied context is consistent with Oakeshott’s (1933) coherence approach to reality and truth in that it does not assume that subjects and objects are independent and in need of connection. Rather, subjects (i.e., organisms) are considered embodiments of their context and are, therefore, internally related to their context. The contexts in which they are and have been embedded are constitutive of what they are. Said in a more familiar way, a thoroughgoing (i.e., maximally coherent), ontologically minded explanation of what an organism *is* must include all aspects of the organism as well as the contexts it embodies.

To be sure, WST is not the only approach to propose that (1) organisms constitute embodiments of their contexts, and (2) such systems necessarily entail anticipatory dynamics. As was stated previously, Friston (2011) makes a similar claim when he asserts that (1) organisms constitute optimal models of their environ-

ments, and (2) they utilize anticipatory coding as a means of optimally maintaining homeostasis. (See Andy Clark's, Jakob Hohwy's, and Anil Seth's contributions to this collection for other approaches to cognition that posit a reliance on anticipatory coding.). A potential difference between WST and Friston's position is the degree of metaphysical commitment WST makes to the assertion that reality constitutes an internally related unity. That is, while Friston's view is consistent with the notion of embodied contexts, it is not clear he also agrees with the coherence approach to reality. As a matter of fact, much of his explanation of how it is that organisms generate and maintain minimum free energy is couched in the epistemic language of external stimuli and internal representations. Though the use of these terms does not, in and of itself, indicate a commitment to direct or indirect realism, it does reveal, at the very least, a minimal, implicit commitment to a correspondence approach to reality and truth.

This comment on Friston's position should not be construed as a critique of his framework, as much as it should be taken to constitute a means by which the unique metaphysical commitments of WST can be thrown into sharp relief. Friston's goal is to provide a maximally coherent account of the causality underlying cognition. The goal of WST is to provide a scientifically informed approach to reality and truth that does not rely on the correspondence relation. The difference in these missions fairly thoroughly accounts for the differences between WST and Friston's free energy approach, and the jury can still be out as to whether or not the free-energy principle constitutes a correspondence approach to reality and truth.

3.2 Wild systems theory and truth

As was stated previously, a coherence approach to reality and truth assesses the degree of truth in experience and beliefs via the degree of coherence entailed in and across both. As was also previously stated, this coherence approach to truth differs from coherentism (Lycan 2012) in that the latter applies the criterion of coher-

ence (i.e., lack of contradiction) to beliefs, while the former applies it to both experience (i.e., moment-to-moment contradictions in experience) and beliefs.

Given this notion of the organism as a self-sustaining prediction, WST is able to apply the coherence criterion to both experience and beliefs because it conceptualizes organisms as embodiments of context and avoids the correspondence relation. As a result, truth is not measured in terms of the degree of correspondence between the subjective and the objective. Rather, it is measured in terms of the degree of non-contradiction entailed within one's moment-to-moment embodied context (i.e., phenomenology) and across the beliefs one derives from the moment-to-moment flows of embodied context. In Friston's (2011) language, the degree of coherence in an embodied context might be taken to refer to the degree of prediction error minimization that has been achieved by the organism's current model of reality. To make this work however, and to avoid the implicit epistemic gap implied by the notion of a "model of reality," the meaning of the word *model* would have to be stretched to such a point that the organism itself constitutes a model of reality. To be sure, Friston intimates as much when he describes organisms as optimal models of their environments. To make this use of the word *model* simultaneously imply that the organism-as-model *constitutes* anticipation, the organism itself would have to be seen as constituting a prediction. While this use of the concept prediction seems strange, it is actually consistent with how Friston uses the term when describing the chemotactic behaviors exhibited by *E. coli*:

...by selective modulation of tumbling frequency, these bacteria show chemotaxis. This is a nice example of an itinerant policy based on the prior expectation (endowed by natural selection) that the organism will only change its motion through state-space when it encounters unexpected (costly) generalized states (here, a decrease in the concentration of attractants). (2011, p. 114)

What is at issue here is the degree of ontological commitment entailed in Friston's assertion that natural selection endows organisms with prior expectations. Is he claiming that organisms are constituted of phylogenetically derived prior expectations, or is he simply presenting prior expectations as a productive way to model organisms? While his assertion that organisms constitute optimal models of their environments seems to favor the former interpretation, his later use of terms such as sensations and representations seems to favor the latter. Whatever the case, if Friston's notion of minimizing prediction error is to be used as a description of what it means for there to be a contradiction in the flow of contingent context, then the concept *prediction* has to be used in a way that does not engender an epistemic gap. In short, the organism has to be conceptualized as a self-sustaining prediction.

In order to better clarify this admittedly abstract means of talking about truth, we offer certain arguments presented in the present paper as a case in point. As was mentioned previously, indirect- and direct-realist approaches to reality and experience rely on evolutionary theory as a means of connecting the subjective and the objective. In our critique of these views, we argued that they validated the correspondence relation by conceptually placing it within the assumed, larger-scale reality of the evolved physical world. WST, however, also makes use of an assumed, larger-scale reality, specifically, the self-organizing, energy-transformation hierarchy (Odum 1988). The difference between the two uses of evolutionary theory lies in what the two approaches are believed to reveal about evolution. To realists, be they direct or indirect realists, evolutionary theory is believed to reveal reality as it is, independent of observers. Within WST, evolutionary theory is definitely seen as being "true," but in the coherence sense that it is the most coherent account of the existence of species yet given.

When describing the "truth" of evolutionary theory in coherence terms, it is important to remember that WST is not radically skeptical about whether or not the phenomena referred to via the realist notion of an *evolved physical world* (e.g., organisms, rocks, and plants) exist. To the contrary, it would be incoherent to deny our belief

that such phenomena exist and do so outside of our skin. What is at stake is the issue of *how* something exists beyond our skin. In a correspondence framework, what is important about something existing on the other side of our skin is that it be observer-independent. Given this conceptualization, one has to explain how observer-independent and observer-dependent phenomena are connected. In the coherence framework, the existence of objects beyond the skin, as well as the idea that they exist as such without the presence of an observer, is conceded. However, defining their reality status in terms of their observer-independence is seen as being insufficient, for even though they may exist independently of the presence of an *observer*, such observer-independence in no way implies such objects exist independently of all context. No phenomenon, no matter how universal, exists as it does independently of all other phenomena. In short, all phenomena are context-dependent.

WST's notion of embodied context implies that we should measure the truth status of claims made in cognitive science in terms of their degree of coherence, both within experience and across beliefs. Given that most contemporary cognitive scientists are direct or indirect realists, either explicitly or implicitly, they tend to assume the correspondence relationship (again, either explicitly or implicitly), which, in turn, makes it difficult for them to coherently address the reality of "subjective" phenomena such as phenomenology, meaning, and value. To be sure, by aligning itself with a coherence approach to truth, WST logically denies itself access to objective, intrinsic reality. But given that WST conceptualizes the notion of objective, intrinsic reality as an incoherent assumption derived from the coherence of moment-to-moment experience, WST, simply given its commitment to coherence, could not accept such a notion in the first place.

3.3 Wild systems theory and cognitive science

Given that WST is not designed to reveal intrinsic properties of objective reality, its beliefs about science are inconsistent with the correspondence notion that science is metaphysical.

Let us recall that the slogan “science is metaphysical”, which was briefly mentioned at the beginning of the present paper, is just shorthand for the philosophical thesis that the goal of science is to overcome the objective-subjective divide and reveal the “real,” observer-independent, intrinsic properties of reality. By asserting that all properties are contextually grounded and cannot therefore be intrinsic, WST posits that science cannot reveal intrinsic properties. As a result, there is no final, thing-as-it-is essence to which any “experience” or “theory” can correspond. As a further result, there can be no correspondence test of reality. Science, therefore, cannot be metaphysical. This lack of belief in the metaphysical nature of science, however, is in no way anti-scientific. On the contrary, it is wholly consistent with Oakeshott’s (1933) contention that the practice of science constitutes a mode of experience. That is, if reality is an internally related unity, then theories are constitutive of that reality and can never “point to” reality as if to do so outside of it. They are, by definition, “in it” just as we are. Thus, they are, by definition, incomplete, what Oakeshott referred to as an arrestment of the whole (i.e., a mode of experience). As an example, WST’s scientifically inspired conceptualization of organisms as self-sustaining embodiments of context does assume a “larger-scale reality” within which organisms are nested, just as direct and indirect realism do. The different reasons for doing so are important. In WST, a larger-scale reality is assumed because it would be incoherent not to do so. That is, we would be contradicting both our experiences and our beliefs about those experiences if we claimed we did not exist within something larger than ourselves. From the correspondence perspective, a larger-scale reality is assumed, and it is believed to comprise observer-independent, intrinsic properties that science will ultimately reveal.

An immediate implication of coherence-versus correspondence-driven approaches to science is that while the latter conceptualizes science as inherently metaphysical (i.e., it reliably reveals intrinsic, observer-independent properties of objective reality), the former conceptual-

izes science as a method by which we are able to increase the coherence of our statements about that within which we are embedded (i.e., coherentism; Lycan 2012). Such coherentism is valuable because it affords us more influence over our context; that is, it affords us the ability to more effectively sustain ourselves.

To be sure, the idea that the value of science is pragmatic, as opposed to metaphysical, is not new. Dewey (1929) proposed much the same:

But the search does not signify a quest for reality in contrast with experience of the unreal and phenomenal. It signifies a search for those relations upon which the occurrence of real qualities and values depends, by means of which we can regulate their occurrence. To call existences as they are directly and qualitatively experienced ‘phenomena’ is not to assign to them a metaphysical status. It is to indicate that they set the problem of ascertaining the relations of interaction upon which their occurrence depends. (Dewey 1929, pp. 103–104)

Interestingly enough, Dewey espoused his pragmatic approach to science for much the same reason Oakeshott proposed his coherence approach to reality and truth—specifically, because they both believed that the realist, physicalist naturalism of their time was inspired by a logically incoherent correspondence framework that had been historically derived from dualism’s assumed split between spiritual and material reality. Dewey states,

The notion that the findings of science are a disclosure of the inherent properties of the ultimate real, of existence at large, is a survival of the older metaphysics. It is because of injection of an irrelevant philosophy into interpretation of the conclusions of science that the latter are thought to eliminate qualities and values from nature. This created the standing problem of modern philosophy:— the relation of science to the things we prize and love and

which have authority in the direction of conduct. (1929, p. 102)

As regards cognitive science specifically, WST's coherence approach to the meaning of science provides a way for cognitive scientists to experience their theories and models as pragmatic tools versus metaphysical tests. In addition, WST's reliance on the concept of embodied context provides a means for cognitive scientists to discuss those phenomena traditionally associated with the subjective side of correspondence theorizing (e.g., phenomenology, value, and meaning) without relying on the subjective-objective correspondence relation. This is important, for as was mentioned in the latter half of the preceding quote by Dewey, by conceptualizing the practice of science as a means of overcoming the correspondence relationship, realist philosophers ultimately put the reality of the "subjective" at risk as more and more naturalists came to conceptualize the subjective in terms of inherently meaningless, physical properties (Gardner 2007). As was stated previously, by conceptualizing organisms as self-sustaining embodiments of context, WST renders properties that had been historically associated with the subjective, such as phenomenology, value, and meaning (see Jordan & Vinson 2012, for a thorough review of this issue), constitutive of what organisms are. As a result, cognitive scientists can avoid distracting arguments about such correspondence-driven issues as the grounding problem (i.e., how do concepts and symbols garner their meaning; Harnad 1990), or the relationship between the physical brain and consciousness. These issues are only experienced as important, hard problems within the conceptual confines of correspondence theory and the belief that the answer will be found via cognitive science.

4 Conclusions

To be sure, there were twentieth-century philosophers other than Dewey and Oakeshott whose approach to reality and truth was very consistent with the coherence approach. Heidegger and Merleau-Ponty are two examples. Perhaps these rela-

tionships will be fleshed out to a greater extent in future papers. For the present paper, the purpose was to (1) illustrate for the reader that there is another, historically relevant, robust approach to reality and truth other than the correspondence approach, and (2) illustrate that this other approach is completely consistent with science.

Maybe it was the fact that many idealist philosophers used their anti-correspondence frameworks as a means of defending the reality of God that led so many scientifically minded philosophers to avoid it to the point that now, after more than one hundred years of neglect, it is rarely if ever mentioned or utilized in cognitive science. This is precisely why we began this paper with the snake-bracelet story. Coherence approaches have been out of fashion for so long that we felt it necessary for the reader to experience, first hand, the type of thinking that has always fostered questions about reality. Our assumption was that by experiencing the tension between what it means to describe the snake as real and what it means to describe the bracelet as real, the readers would be in a better position to understand that although the coherence approach was ignored during the past century, Oakeshott's presentation of a non-spiritual, non-absolute, non-transcendental coherence framework leaves the coherence and correspondence frameworks on similar, logical ground. Given the advent of concepts such as external grounding, ultra grounding, and *global groundness* in contemporary philosophy of science, it seems the coherence approach to reality and truth is, at the very least, once more being discussed.

Wild Systems Theory is only one possible theory of "what people are" that could emerge from a coherence-driven perspective, and we suspect there will be others. But given WST's description of phenomenology as an evolutionarily, scaled-up form of self-sustaining embodied context, phenomena such as the taste of ice cream are rendered just as "real" as the cream and sugar that constitute the ice cream. We believe this is an important achievement. And when one considers WST's compatibility with science, it seems reasonable to propose WST as a twenty-first-century coherence framework for cognitive science.

Thickening Descriptions with Views from Pragmatism and Anthropology

A Commentary on J. Scott Jordan & Brian Day

Saskia K. Nagel

How can we as biological systems that are self-organizing and constantly adapting make sense of our surroundings? How can the rich connections between organisms and environment lead to our particular lifeworlds, lifeworlds that allow individual experiences and that are themselves constantly changing in reaction to them? This commentary suggests, extending the framework provided by Scott Jordan and Brian Day, an integration of recent neuroscientific evidence with perspectives from pragmatism, anthropology, and phenomenological thought. Much experimental evidence demonstrates that human beings are systems comprised of a brain as part of a body and an environment, which is constantly regulating and adapting. This evidence resonates with reasoning from pragmatism and anthropology that describe the continuous, dynamic interaction of mind, body, and world. Employing those various perspectives leads to a dense description of human experience and cognition that specifies details and patterns, which considers contextual factors that allow us to enrich human self-understanding, and which aids attempts to answer the questions raised at the beginning of this paper.

Mind as background is formed out of modifications of the self that have occurred in the process of prior interactions with environment. Its animus is toward further interactions. Since it is formed out of commerce with the world and is set toward that world nothing can be further from the truth than the idea which treats it as something self-con-

tained and self-enclosed. ([Dewey 1934](#), p. 269)

Knowing does not lie in the establishment of a correspondence between the world and its representation, but is rather immanent in the life and consciousness of the knower as it unfolds within the field of practice set up through his or her presence as a being-

in-the-world [...]. Like life itself, the unfolding does not begin here or end there, but is continually going on. It is equivalent to the very movement—the processing—of the whole person, indivisibly body and mind, through the lifeworld. (Ingold 2001, p. 159)

1 Introduction

Philosophers and scientists alike have long been interested in the question of how our being-in-the-world allows us to experience in a plethora of ways and to behave meaningfully. In extending the framework suggested by Scott Jordan and Brian Day, this commentary suggests integrating recent neuroscientific evidence with perspectives from pragmatism, anthropology, and phenomenological thought. The commentary shall be programmatic in the sense that it prepares the way for further argument and discussion by making available new perspectives that invite the reader to look beyond the “classical” argument and thus benefit from various disciplines. The driving questions are: How can we as biological systems that are self-organizing and constantly adapting make sense of our surroundings? How can we grasp our world via perception? How can we skillfully engage with the world? How can the rich connections between organisms and environment lead to our particular lifeworlds; lifeworlds that allow individual experiences and that are themselves constantly changing in reaction to them?

One dominant approach to reality and truth has been the correspondence approach of computational cognitive sciences that assumes that reality can be revealed by science, independently of the personal perspective of an observer. The task of correspondence theories is to understand the relation between observer and observer-independent reality; a task that assumes dichotomies between inner and outer, between objective and subjective. Facing the limits of those approaches, [Scott Jordan & Brian Day \(this collection\)](#) suggest bridging the riff between the inner and the outer by acknowledging that there is in fact no gap between the organism and its environment. If one wants to

avoid the dualistic trap that asks how something inside the “mind”—such as thoughts or ideas—can represent the outside world, one challenges the seemingly essential dependence of cognitive science on representations.

Much neuroscientific, psychological, anthropological, and philosophical work, both old and new, suggests that we understand cognition as arising from the actions of embodied agents that engage skillfully in a meaningful world ([Beauchamp & Martin 2007](#); [Brooks 1991](#); [Clark 1997](#); [Graziano et al. 1994](#); [Lakoff & Johnson 1999](#); [Noë 2004](#); [O'Regan & Noë 2001](#); [Thompson 2010](#); [Varela et al. 1991](#); [Wilson & Knoblich 2005](#)). This understanding can ultimately help us avoid the correspondence theorists' notorious problem, how the external is connected to the internal. Organisms that are embedded and situated do not need to represent the external environment as they are always already about the contexts in which they live. Moreover, for the situated organism, “the situation is organized from the start in terms of human needs and propensities which give the facts meaning, make the facts what they are, so that there is never a question of storing and sorting through an enormous list of meaningless, isolated data” ([Dreyfus 1992](#), p. 262). Understanding organisms as always already existing in meaningful interaction¹ with their environment and thereby constantly adapting and changing is relevant not just for topics in philosophy of mind but also for epistemology and metaphysics. The metaphysical question of how mind, body, and world are related is tightly linked to epistemological questions about how we can experience the external world. The central tenet is how experience can happen at all, i.e., how the experiencing organism can relate meaningfully to the world.

This commentary furthers the line of thought described by [Scott Jordan & Brian Day](#)

¹ Due to lack of a better concept, the term “interaction” will be used throughout this article even though it entails clearly separable entities that have previously been independent—an assumption that is contested by the approach suggested here. Moreover, due to limited space, this commentary cannot take into account the aspect of intersubjectivity. The relevance of others with whom interaction takes place is inherent in the concept of mind and its interdependence with the environment (see e.g., [De Jaegher & di Paolo 2007](#)).

([this collection](#)) by suggesting further perspectives from neuroscience, pragmatism, and anthropology for approaching cognitive systems as experiencing, bodily systems that are in constant, value-laden interaction with the world; rather than as systems that primarily mirror an external reality from a position separated from the world. Here, I will combine arguments from John Dewey, in particular his work on experience, and anthropologist Timothy Ingold, with recent neuroscientific approaches that support a view that challenges classical correspondence approaches. This will allow a thicker description, i.e., a dense description specifying details and patterns and considering contextual factors, of human experience and cognition.

2 Pragmatism and anthropology meet the neurosciences

In line with much neuroscientific work today, Dewey describes how life is about constantly striving for greater adaptation and for a balance of energies. He beautifully elaborates:

Life itself consists of phases in which the organism falls out of step with the march of surrounding things and then recovers unison with it—either through effort or by some happy chance. And, in a growing life, the recovery is never mere return to a prior state, for it is enriched by the state of disparity and resistance through which it has successfully passed. If the gap between organism and environment is too wide, the creature dies. If its activity is not enhanced by the temporary alienation, it merely subsists. Life grows when a temporary falling out is a transition to a more extensive balance of the energies of the organism with those of the conditions under which it lives. ([Dewey 1934](#), p. 535).

This view resonates with Wild Systems theory, as suggested by [Jordan & Day \(this collection\)](#), which explains an organism not as a computational input–output system but as an open energy-transforming system that must absorb, transform, and use energy to sustain itself. This

does not forestall computation, of course, but it describes the computational process in a different context.

The description of this context can be developed further to challenge correspondence theories: correspondence theories suggest that we understand cognition when we understand how humans represent the external world internally, and when we understand how they process this representation. The focus on a potentially disembodied input–output machine that passively receives information about an observer-independent reality and that has an isolated computational system processing representations cannot tell us how the internal relates to the external—the notorious problem of traditional cognitivism—or how the internal can be enacted in real-world situations that are often vague and constantly changing. As Andy Clark explicates:

Real embodied intelligence [...] is fundamentally a means of engaging with the world—of using active strategies that leave much of the information out in the world, and cannily using iterated, real-time sequences of body-world interactions to solve problems in a robust and flexible way. The image here is of two coupled complex systems (the agent and the environment) whose joint activity solves the problem. In such cases, it may make little sense to speak of one system’s representing the other. ([Clark 1997](#), p. 98)

Cognition and experience arise from ongoing interaction with an unstable, changing environment. The entanglement of the brain, the rest of the body, and its particular environment—which includes other organisms—is essential for experience and reason. This is not the trivial claim that the brain cannot exist without a body; even though the bodily context is often neglected in research studying brain processes.²

2 The importance of the body was put forward by Maurice Merleau-Ponty in the *Phenomenology of perception*: “[t]he body”, he wrote, “is the vehicle of being in the world, and having a body is, for a living creature, to be involved in a definite environment, to identify oneself with certain projects and be” “continually committed to them” (1962, p. 82), and further: “[o]ur bodily experience of movement is not a particular case of knowledge; it provides us *with a way of access to the world* and the object, with a ‘praktognosia’, which has to be recognized as original and

The message is that reason, cognition, mind arise from this very entanglement. How the body relates to the environment structures experiences; there is an immediate coupling between perception and action. Cognition is not a transcendent aspect detached from “matter” (the brain and the rest of the body in particular) but is constantly shaped, fostered, and constrained by the environment and the body’s peculiarities.

Anthropologist Timothy Ingold consequently questions whether it makes sense:

to attribute that quality of the operation of a cognitive device [...] which is somehow inside the animal and which, from its privileged site, processes the data of perception and pulls the strings of action. Indeed it makes no more sense to speak of cognition as the functioning of such a device than it does to speak of locomotion as the product of an internal motor mechanism analogous to the engine of a car. Like locomotion, cognition is the accomplishment of the whole animal, it is not accomplished by a mechanism interior to the animal and for which it serves as a vehicle. (Ingold 1993, p. 431)

It is thus the interaction of the different systems that is the most fascinating research topic in cognitive science—a topic that requires a holistic approach. Such reasoning that considers circular causalities can be traced back to earlier thinkers such as Bateson 1973, Kelso 1995, Maturana & Varela 1980, Thompson 2010, Varela 1996 or von Uexküll 1940. This idea of circular causality as a property of living, self-organizing systems refers to the connection of perception and movement that underlies the ongoing co-constitution of organism and environment. There is continuous top-down-bottom-up interaction that captures the interrelations between several levels in a hierarchy. The gen-

eral underlying idea is that individual small-scale parts enable the existence of order parameters that in turn determine the behavior of the individual parts. Thomas Fuchs (2012) refers to physicist Hermann Haken’s 2004’s work on synergetics, the science of self-organization, to further illustrate the mutually-constraining relation between the microscopic and macroscopic elements of a complex system. Dynamic system modeling in various fields relies on multi-level causal processes in which higher-order processes are mutually entrained with lower-order processes, without one taking precedence over the other (Engel et al. 2001; Freeman 1995; Lewis 2005; Thelen & Smith 1994).

While a purely cognitivist approach that fosters “The Myth of the Inner; The Myth of the Hidden; and The Myth of the Single” (Torrance 2009, p. 112) is still fairly mainstream, in recent years we have seen a growing interest on the part of cognitive scientists and neuroscientists in particular in the relevance of the complex interplay of brain, body, and world. Today, this interplay is finally considered in the empirical study of cognition, which resonates in the growing body of work in cognitive science.³ The importance of embodiment is widely appreciated in cognitive science today. There is a large body of evidence from the neurosciences on how an ongoing organism–environment interaction is essential for cognition (Beauchamp & Martin 2007; Brooks 1991; Chiel & Beer 1997; Engel et al. 2001, 2013). While we still see attempts to describe what has been termed the “‘filing cabinet’ view of mind: the image of the mind as a storehouse of passive language-like symbols waiting to be retrieved and manipulated by a kind of neural central processing unit” (Clark 1997, p. 67)—there is growing consensus that cognition can best be studied and understood in dynamic, interactionist terms, as bound to bodily organisms that are confronted with particular problems in specific environments.

perhaps as primary. My body has its world, without having to make use of ‘symbolic’ or ‘objectifying function’” (1962, p. 140–141; emphasis mine). This has been elaborated and enriched in the last years with views on recent empirical work by Shaun Gallagher (2005), who offers an account of the body that emphasizes the role of embodied action in perception and cognition.

³ Curiously, there is little direct reference to the pragmatists and in particular to John Dewey’s work. Notable exceptions are Mark Johnson (e.g., 2007) and Jay Schulkin (2009), who offer nuanced and explicit pragmatist views on neuroscientific research. Philip Kitcher (2012) offers a wide and detailed demonstration of the importance of pragmatism for philosophy.

Dewey once again can serve as an inspiring reference point:

To see the organism in nature, the nervous system in the organism, the brain in the nervous system, the cortex in the brain is the answer to the problems which haunt philosophy. And when thus seen they will be seen to be in, not as marbles are in a box but as events are in a history, in a moving, growing never finished process. (Dewey 1991, p. 224)

With this focus on the context and the ongoing interaction of the organism and its surroundings, one can avoid assumptions of ontological separations. Going one step further and elaborating on the moral dimensions that Dewey expresses, neo-pragmatist Robert Brandom, in his account of intentionality, explicates the very idea of pragmatism in a way that links it to the enactivist approach to cognition: “[a] founding idea of pragmatism is that the most fundamental kind of intentionality (in the sense of directedness towards objects) is the practical involvement with objects exhibited by a sentient creature dealing skillfully with its world” (Brandom 2008, p. 178). This skillful engagement with the world is crucial for challenging prevailing paradigms surrounding correspondence theories.

The respective holistic approach envisioned by Dewey that he powerfully elaborates with his conception of *continuity* (Dewey 1934), and which is furthered by some neo-pragmatists, is reinforced by research in the neurosciences that questions the understanding of cognition as a centralized mirroring process that uses perceptual input to generate the appropriate behavioral output. Brains are studied and described as embodied, situated, and embedded.⁴

⁴ For reasons of space, I cannot discuss the rich debate around the concepts of embodiment, embeddedness, and enactivism let alone their relation to the extended mind hypothesis (for parts of the discussion see: Adams & Aizawa 2008; Clark 1997, 2001; Clark & Chalmers 1998; Rupert 2009; Shapiro 2011; Sprevak 2009; Thompson 2010; Varela et al. 1991; Ward & Stapleton 2012; Wheeler 2011). These approaches vastly differ regarding their views on representations and their general approach to cognition and action. However, each of them can offer a way of moving beyond the traditional mind-

3 Challenging the “myth of the inner” from within the Neurosciences

In the following, approaches in the empirical sciences that seek to consider the dynamic, interactionist nature of cognition will be introduced in order to enrich the view of the complexities of adaptive behaviour in self-organizing systems.

Computational cognitive neuroscientist Olaf Sporns provides a state-of-the-art synthesis of the sciences of complex networks in the brain and suggests a view beyond neurocentrism. He introduces his work as follows:

To understand these systems, we require not only knowledge of elementary systems components but also knowledge of the ways in which these components interact and the emergent properties of their interactions [...]. We cannot fully understand brain function unless we approach the brain on multiple scales, by identifying the networks that bind cells into coherent populations, organize cell groups into functional brain regions, integrate regions into systems, and link brain and body in a complete organism. (Sporns 2011, pp. 1–3)

While he does not (yet) consider the further complexities that come into play when one includes the environment of the organism, his description can be seen as a relevant, though timid first step away from a purely neurocentric view. The next step will be to recognize the relevance of environmentally attuned actions, i.e. to investigate how actions can be understood, rather than as isolated from the environment, as being in constant dynamic relation with it, adapting to requirements from the environment and in turn shaping it.

There is no doubt that the developmental perspective is crucial for understanding the dynamic interplay between social and biological processes and thus the role of the environment for experiences in developing cognition. From

body dichotomy. Specifically, enactivism focuses on the precise coupling of brain, body, and environment and might therefore be particularly promising for action-oriented approaches.

early childhood onwards, the brain is shaped by constant interaction with the world. Experiences impact on brain structure and function, as demonstrated by abundant evidence on the brain's plasticity (for classical studies, see: [Buonomano & Merzenich 1998](#), [Pascual-Leone et al. 2005](#)). Susan Oyama, in her account of developmental systems theory, argues that the mind-world dichotomy inherent in descriptions that follow dualistic accounts claiming strong gaps between the biological realm and sociocultural realm cannot do justice to evolving systems. Oyama invites us to focus on change, rather than constancy. She points to the conglomerate of heterogeneous influences that allows development. A developmental system is "a heterogeneous and causally complex mix of interacting entities and influences that produces the life cycle of an organism" ([Oyama 2000](#), p. 1). This multi-scale, interaction-driven dynamics requires an approach that does justice to context-dependency, since it is a particular context that leads to the emergence of a specific phenotype. Neglecting the context would thus necessarily lead to a failure to understand the developmental system.

Complementary to this view, Tim Ingold describes how the specificities of an environment and an organism's history with it matter for its very existence:

What goes for the relations between internal parts of the whole organism also goes for the relations between the organism and its environment. Organic forms come into being and are maintained because of a perpetual interchange with their environments not in spite of it [...]. But since an 'environment' can only be recognized in relation to an organism whose environment it is—since, in other words, it is the figure that constitutes the ground—the process of formation of the organism is the process of formation of its environment [...]. Moreover, the interface between them is not one of external contact between separate and mutually exclusive domains, for enfolded within the organism itself is the entire history of its environmental conditions. ([Ingold 1990](#), p. 216).

Consequently, rather than speaking of distinct organisms, Ingold suggests that we would be better served by speaking of the "whole-organism-in-its-environment" ([Ingold 2001](#)). In a similar way, Richard Menary suggests cognitive integration as a dynamical account of how the bodily processes of an organism in its environment lead to cognition ([Menary 2007](#)), and elaborates how manipulation of the organism's specific environment, development in that environment, and the resulting transformation of cognitive capacities in this cognitive niche matter for actual cognitive processes and our explanatory models thereof ([Menary 2010](#)).

In line with such descriptions, [Andreas Engel et al. \(2013\)](#) recently noted what they saw as a "pragmatic turn" in cognitive science, a turn that leaves aside frameworks focusing on computation over mental representation to instead study cognition as being essentially action-oriented. Building on reasoning from [Clark \(1997\)](#) and [Varela et al. \(1991\)](#), Engel and colleagues focus on the relevance of action for cognition. They discuss evidence of perception as not being neutral with respect to action but rather as part of sensorimotor couplings that are always specific for the organism, given its previous learning, experiences, and expectations. This focus implies embodiment and situatedness just as the context-sensitivity of processing. The "pragmatic turn" is based on much experimental evidence from studies on sensorimotor integration and neuronal plasticity that highlight how cognition is, in a fundamental way, grounded in action.

Taken together with many more research lines in the experimental field, these approaches can further our understanding of the essential value of what beforehand was seen to be "merely" subjective, and not necessarily real. Experience and skillful engagement with the world have a relevant, even an essential role for cognition. This insight opens the way for a more encompassing view of human experience and thus enriches Jordan and Day's account with phenomenological, anthropological, and pragmatist perspectives.

4 Why a systems approach matters

While Wild System Theory primarily seems to offer new possibilities for how to study human experiences and engagement with the world, it actually does more: it helps to develop a “theory ‘of what people are’” (Jordan & Day this collection, p. 20) by shifting our understanding of the relationships between brain, mind, body, and world. These possibilities challenge dichotomies that have for a long time dominated classical philosophical views of what human beings are and how they reason and experience. John Dewey argued against a series of dichotomies that were abundant in philosophy, such as those of mind versus body, fact versus value, internal versus external, and experience versus nature by explicating the role of continuities, e.g., between mind and body, and the importance of action for experience. A better understanding of circular causalities is necessary in order for us to be able to see humans as continually changing bodily organisms that incorporate their histories of past interactions with their environments, successful adaptations, and learning processes—each shaped their particular way of being in the world.⁵ Such a systems perspective does not seek to understand the brain in isolation, but a person in his or her idiosyncratic context.

Crucially, the approaches fostered already by John Dewey, which have today been rediscovered by philosophers and neuroscientists alike, are in fine accordance with phenomenological descriptions of what it is like to experience. How those perspectives converge into a science of mind is still to be elaborated and might receive inspiration from neurophenomenology, with its call to take seriously introspective phenomenological reports (Lutz & Thompson 2003; Varela 1996). In particular, it can be worthwhile to take this view to psychiatry, as a clinical field deeply dependent on a sensitive understanding of the relation between mind, brain,

the rest of the body, and the environment. In psychiatry it becomes particularly evident that dealing with persons is not the same as dealing with brains. For example, explaining depression as a mere chemical imbalance based on a lack of serotonin (a popular statement that does not by any means hold universally, even if one follows a strong reductionist account) does not do justice to the complex causal relationships leading to the pathology. Thomas Fuchs compellingly suggests giving up the classic physical–mental dichotomy that is present in biomedical reductionism, to develop a proper understanding of the circular causality between an organism and its environment (Fuchs 2009, 2011). Fuchs explains how an ecological concept of mental illness does justice to findings about how disorders are a product of the complex interaction of subjective, neuronal, social, and environmental influences. This does not only matter for our understanding of mental illnesses, but also importantly impacts on how we approach treatments at various levels. The essential relevance of recognizing circular causalities in the brain–body–world interaction can also be seen in neurological treatment and in the psychological reactions of patients to treatments. Beliefs about the relationship between brain and mind and how they relate to one’s personality and psychological well-being might influence reactions to neurological or neurosurgical interventions. In particular, for treatment with deep brain stimulation it has been argued that a framework that is neither dualistic nor brain-centric, but which offers a perspective that recognizes the manifold interaction between mind, body, and world can have beneficial effects on patients and their surrounding (Mecacci & Haselager 2014; Keyser & Nagel 2014). Thus, the quality of therapeutic approaches might benefit from examining more holistic approaches to psychiatric disorders and therapies. Ultimately, these theoretical considerations can be crucially relevant for life in all its facets.

5 Outlook

Abundant experimental evidence demonstrates that human beings are systems comprised of the

⁵ *The implied essentialisation of biology as a constant of human being, and of culture as its variable and interactive complement, is not just clumsily imprecise. It is the single major stumbling block that up to now has prevented us from moving towards an understanding of our human selves, and of our place in the living world, that does not endlessly recycle the polarities, paradoxes and prejudices of western thought* (Ingold 2004, p. 217).

brain as part of a body and the environment in a constant regulatory, adaptive process. Consequently, we suggest a systems view that considers such complex feedback loops in terms of circular causality (Crafa & Nagel forthcoming). As there are manifold fluctuating organismic levels that create feedback loops for continuous adaptation, studying those feedback loops will in all likelihood improve our understanding of how our experience is action-oriented and based on skillful engagement with the world. Notably, this approach does not in itself forestall by definition the assumption of representations (see e.g., Dennett 2000). I suggest that a computational view of cognition might not be opposed to the dynamic, embodied view. It is likely that we need both approaches in order to understand how self-organizing dynamic systems constantly adapting to their environment are able to reason, solve abstract problems, use language, etc (c.f., for another synthesizing suggestion, Grush 2004). Computational explanations of how the body and the environment interact can be useful tools here, possibly benefiting from ideas such as predictive coding or deep learning in Artificial Intelligence.⁶ Such a step includes blurring the boundaries between cognitive and sensory-motor processes. So-called low-level and high-level processes cannot be understood independently, since they constantly interact and influence one another. While symbolic abstraction is necessary for reasoning, problem solving, or language, those are strongly coupled to lower-level processes, such as perception, object manipulation, or movement. Much conceptual and empirical work must be undertaken, for which a mixed methods approach considering multiple dimensions seems to be necessary and most promising. Such an approach—or better, combination of approaches—can help to integrate

multiple levels of analysis. It might combine neurobiological concepts (and these on different levels as well, reaching from molecular studies up to studying systems and interacting systems) with psychological, anthropological, and philosophical studies. For the laboratory, a systems approach would ask for frameworks that allow us to study ‘active’ subjects using a variety of methods. Mobile technologies for physiological measurements are an important step towards this goal, as are set-ups that combine different physiological measurements. This is an ambitious task, which demands technological and computational innovation and effort. And, not least, studying mental capacities can be massively enriched by combining phenomenological accounts of experience with cognitive science approaches as suggested from the field of neurophenomenology (Varela 1996).

It is likely that a more holistic view on human cognition and experience will help us focus on topics that truly matter to people and that do justice to their experience. One practical consequence of a different understanding of the relationship between mind, body, and world is its potential effect on human self-understanding, which in turn can have significant psychological effects (e.g., Vohs & Schooler 2008). As Gregory Bateson frames it: “[t]he living man is thus bound within a net of epistemological and ontological premises which—regardless of ultimate truth or falsity—become partially self-validating for him” (Bateson 1973, p. 314). Thus, theoretical considerations in the field of philosophy of mind, together with the pragmatists’ understanding of experience and neuroscientific findings on the relevance of the interdependence of the brain, the rest of the body, and the environment shall lead to thicker descriptions of the multifaceted human condition.

⁶ Predictive coding is a framework for understanding the reduction of redundancy and efficient coding in the nervous system. It is suggested that highly redundant natural signals are processed by removing the predictable components of the input, thereby transmitting only what is not predictable. Hierarchical predictive coding can explain response selectivities in networks (Clark 2001; Hohwy et al. 2008; Friston et al. 2010; Friston & Stephan 2007; Rao & Ballard 1999). Inspired by neural network processing, deep learning methods in machine learning aim to produce learning of features at multiple levels of abstraction, thus allowing learning of complex functions (e.g., Arel et al. 2010; Bengio 2009; Hinton et al. 2006).

After Naturalism: Wild Systems Theory and the Turn To Holism

A Reply to Saskia K. Nagel

J. Scott Jordan & Brian Day

We agree with Dr. Nagel's assertion that explanations within cognitive science can be *thickened* by an infusion of pragmatism and anthropology. We further propose that because of its direct challenge of the correspondence thinking that tends to underlie contemporary indirect- and direct realism, Wild Systems Theory provides a *coherence* framework that conceptualizes reality as inherently context dependent and, therefore, inherently *meaning-full*. As a result, pragmatists can appeal to the reality of lived experience, anthropologists can appeal to the meaningful, multi-scale influences that shape an individual, and both can do so without having to justify the reality status of meaning in relation to the meaning-less view of reality we have been led to via the indirect- and direct-realism inherent in contemporary naturalism.

Coherence theory of truth | Correspondence theory of truth | Direct realism | Embodiment | Epistemic gap | Indirect realism | Intrinsic properties | Modes of experience | Multi-scale self-sustaining systems | Reality | Wild systems theory

"We are caught up in an inescapable network of mutuality..."
Dr. Martin Luther King, Jr., 1964

1 Introduction

In her commentary on our paper, Dr. Saskia Nagel calls for a thickening of the descriptions we give in cognitive science. By *thickening* she means, ...a dense description specifying details and patterns and considering contextual factors, of human experience and cognition. ([Nagel this](#)

[collection](#), p. 3). Dr. Nagel further asserts that one way to achieve such a thickening is to infuse cognitive science with the views of pragmatism (i.e., John Dewey) and anthropology (i.e., Timothy Ingold). We couldn't agree more, and we applaud Dr. Nagel's appeal to Dewey and

Ingold as a means of allowing multi-scale contextual factors to play a much larger role in our accounts of cognition and consciousness.

Given our agreement on the important contributions that pragmatism and anthropology can make to cognitive science, we also feel the need to express our belief that WST (Wild Systems Theory) and its conceptualization of organisms as *self-sustaining embodiments of context* (versus physical-mental, or mind-body systems) actually creates a conceptual framework within which the views of Dewey and Ingold can move beyond the conceptual constraints of contemporary pragmatism and anthropology.

2 Pragmatism and Wild Systems Theory

In a recent paper regarding WST, [Jordan & Vinson \(2012\)](#) propose that Dewey's brand of pragmatism represented a rather unique combination of an idealist approach to metaphysics and an epistemic (i.e., pragmatic) approach to science. Specifically, Dewey's early training as an idealist philosopher led him to reject the objective-subjective, correspondence-driven approach to reality and truth that was prominent in the *indirect*- and *direct-realist* versions of naturalism that were emerging during his time. Instead, Dewey believed, as did his idealist, *coherentist* mentors, that meaning and value were *constitutive* of reality. In addition, given his *coherence*- (versus *correspondence*-) driven metaphysics, Dewey believed that science was a practice that afforded us the opportunity to reveal patterns of contingency within the contexts in which we are embedded. He repeatedly emphasized this epistemic, pragmatic approach to science as a way to challenge the more ontologically minded, metaphysical approach to science that was being espoused by indirect- and direct-realist forms of naturalism:

The search for 'efficient causes' instead of for final causes, for extrinsic relations instead of intrinsic forms, constitutes the aim of science. But the search does not signify a quest for reality in contrast with experience of the unreal and phenomenal.

It signifies a search for those relations upon which the *occurrence* of real qualities and values depends, by means of which we can regulate their occurrence. To call existences as they are directly and qualitatively experienced 'phenomena' is not to assign to them a metaphysical status. It is to indicate that they set the problem of ascertaining the relations of interaction upon which their occurrence depends. ([Dewey 1929](#), pp. 103-104)

Despite Dewey's concerns, his unique combination of idealist ontology and scientific pragmatism eventually gave way to what [Gardner \(2007\)](#) refers to as the *Hard Naturalism* of our time, in which meaning and value are seen as completely unnecessary in a scientific, causal description of reality:

By the time we get to Freud ... let alone Quine, naturalism is conceived as resting exclusively on theoretical reason and as immune to non-theoretical attack—it is assumed that nothing could be shown regarding the axiological implications of naturalism that would give us reason to reconsider our commitment to it: we have ceased to think that naturalism is essential for the realization of our interest in value, and do not believe that it would be an option for us to reject naturalism even if it were to prove thoroughly inimical to our value-interests. (p. 24)

Within the contemporary context of Hard Naturalism, pragmatic philosophers such as [Richard Shusterman \(2008\)](#) tend to downplay and even eschew ontology. Specifically, Shusterman asserts that 20th century ontological approaches to the mind and body that were espoused by the likes of William James and Merleau-Ponty actually led us to devalue bodily sensations in the name of developing our rational capacities.

Merleau-Ponty's commitment to a fixed, universal phenomenological ontology based on primordial perception thus provides further reason for dismissing the value of

explicit somatic consciousness. Being more concerned with individual differences and contingencies, with future-looking change and reconstruction, with pluralities of practice that can be used by individuals and groups for improving on primary experience, pragmatism is more receptive to reflective somatic consciousness and its disciplinary uses for philosophy. (Shusterman 2008, p. 66)

Clearly, there are important continuities between the pragmatic philosophies of Dewey and Shusterman (Jordan 2010). Specifically, Shusterman's focus on *practice* overlaps with Dewey's conceptualization of science as a practice as opposed to a tool for metaphysics. In addition, Shusterman's emphasis on *primary experience* is consistent with Dewey's idealist commitment to the reality of experience. The major difference between the two seems to be Shusterman's lack of interest in, or perhaps outright disdain for metaphysics.

One possible reason for Shusterman's (2008) lack of interest in metaphysics may be our contemporary commitment to Hard Naturalism. As was stated in the quotation by Gardner (2007), Hard Naturalism seems so implicitly accepted these days, it seems difficult, if even possible, to propose a metaphysics in which value, meaning, and experience are constitutive of reality. Because of its commitment to the reality of experience however, as well as its clear questioning of the indirect- and direct-realism that lie at the core of Hard Naturalism, WST seems perfectly situated to take-up Dewey's anti-correspondence arguments and place them within a 21st century coherentist framework. Instead of remaining within the centuries-old conceptual framework of *mind* and *body* however, as Dewey did, WST takes the philosophical risk of creating a new concept: specifically, *embodied context*. We say *philosophical risk* because the notion of embodied context conceptualizes meaning in the exact opposite fashion as Hard Naturalism. Specifically, it renders meaning ubiquitous throughout reality. Given the century of philosophical work that has ultimately led to the Hard Naturalist belief that reality is inher-

ently meaningless, we suspect some might see it as simply silly or heretical to assert that reality is inherently meaningful, through and through. This is why we consider the concept of *embodied context* risky. Regardless of the risks however, we see WST as a means of getting meaning back into reality. It does so by following the lead of the idealists, particularly Oakeshott (1933), who did not appeal to the a priori, the transcendental, or the absolute, and refused to describe reality in terms of the observer-independent intrinsic properties that ultimately make it difficult, if not logically impossible, for meaning to be constitutive of reality. Within WST's coherentist perspective, Dewey's pragmatism is restored as a 21st century framework, and pragmatism, in general, can commit itself to the reality of lived experience in an ontological fashion that does not require justification in relation to Hard Naturalism.

To be sure, there have been those scholars who have attempted to introduce meaning back into Hard Naturalism by referring to it via terms such as *emergent* and *irreducible*. Gardner (2007) however, refers to such attempts as *Soft Naturalism* and states the following:

If, then, it is demonstrated successfully by the soft naturalist that such-and-such a phenomenon is not reducible to the natural facts austere conceived, this conclusion is not an end of enquiry, but rather a reaffirmation of an explanandum, i.e., a restatement that the phenomenon stands in need of metaphysical explanation. Irreducibility arguments, if successful, yield data that do not interpret or explain themselves, but call for interpretation: the soft naturalist needs to say something on the subject of why there should be, in general, phenomena that have substantial reality, but do not owe it to the hard natural facts. (p. 30)

WST avoids collapsing into Soft Naturalism because it directly challenges the Hard Naturalist assumption of intrinsic, context-independent properties. It does so by asserting that all properties are necessarily context-dependent and

thus, inherently meaning-full. In short, meaning is constitutive of reality.

3 Anthropology and Wild Systems Theory

In addition to providing a contemporary framework for pragmatism, WST also provides a straightforward means of integrating cognitive science and anthropology. For example, in her comment on our paper Dr. Nagel points to the work of [Timothy Ingold](#) as a contemporary example of an anthropologist whose work can *thicken* our understanding of cognition and experience.

Knowing does not lie in the establishment of a correspondence between the world and its representation, but is rather immanent in the life and consciousness of the knower as it unfolds within the field of practice set up through his or her presence as a being-in-the-world. (2011, p. 159)

While WST couldn't agree more with [Ingold's](#) (2011) critique of correspondence approaches to the nature of knowledge, WST's conceptualization of living systems as multi-scale, self-sustaining embodiments of the phylogenetic, cultural, social, and ontogenetic contexts within which they emerged and within which they sustain themselves provides a straight forward explanation of why *knowing* is, "...immanent in the life and consciousness of the knower..." ([Ingold 2011](#), p. 159). Specifically, knowing is immanent in *being-in-the-world* because organisms, as embodiments of context, *are* knowledge ([Jordan 2000](#)). In short, they are *world in world*. Thus, as implied by Ingold, to *be* is to *mean*.

A potential advantage of WST's approach to this issue is that it directly addresses the Hard Naturalism that underlies the correspondence-driven thinking [Ingold](#) (2011) critiques. That is, by problematizing the realist assumption of context-independent, intrinsic properties, WST asserts it is logically impossible for meaningless *things* to exist. That is, it is logically impossible to *be* and *not mean*. By engaging in this ontological spadework, WST does not suffer

the risk of collapsing into Soft Naturalism, as does Ingold's position, or any position for that matter, that attempts to establish the reality of experience without addressing Hard Naturalism's assertion that meaning is not constitutive of reality.

In addition to addressing [Ingold's](#) (2011) *being-in-the-world* approach to meaning, WST also addresses Dr. Nagel's assertion that anthropology can *thicken* cognitive science by leading us to consider the continuous, un-ending influence that multiple scales of context (e.g., phylogenetic, cultural, social, and ontogenetic) have on the nature of bodies and meaning. She develops this point by referring to [Susan Oyama's](#) (1985) assertion that in addition to inheriting genes, infants also inherit a heterogeneous collection of multi-scale contexts, including other persons, that continuously shape, and are shaped by, the developing individual. Oyama refers to this collection of contexts as a *developmental system*. While describing Oyama's work, Dr. [Nagel](#) states:

This multi-scale, interaction-driven dynamics requires an approach that does justice to context-dependency, since it is a particular context that leads to the emergence of a specific phenotype. Neglecting the context would thus necessarily lead to a failure to understand the developmental system. ([this collection](#), p. 6)

Again, we couldn't agree more with Drs. Nagel and Oyama. What WST potentially adds to the notion of a developmental system is the idea that self-sustaining systems constitute embodiments of their developmental contexts. The advantage here is the same advantage we encountered when addressing WST's relationship to [Ingold's](#) (2011) *being-in-the-world* approach to meaning. By providing a coherentist ontology that renders reality inherently meaningful, WST constitutes a meaningful alternative to Hard Naturalism's correspondence-driven assertion that reality is inherently meaningless. As a result, WST allows one to utilize [Oyama's](#) (1985) notion of *developmental contexts* in a way that prevents one from having to explain how it is that developmental contexts

render an inherently meaningless reality meaningful. Specifically, developmental contexts don't have to render meaningless reality meaningful because, according to WST, all phenomena are context dependent and, therefore, inherently meaningful.

4 Conclusions

In the end, we agree with Dr. Nagel's assertion that pragmatism and anthropology provide a means of *thickening* our descriptions of bodies and meaning. We further propose that WST helps achieve such a *thickening* because it asserts that bodies (i.e., embodied contexts) *are* meaning. From this perspective, anthropology and cognitive science both involve the study of meaning, and differ only in that they focus their descriptions on different levels of nested context, or, to say it another way, different levels of nested meaning.

In addition to providing a means of integrating cognitive science and anthropology, WST's focus on a coherence approach to truth, as opposed to a correspondence approach to truth, puts it in a position to provide an integrative framework for scholarship in general (Jordan & Vandervert 1999; Jordan & Vinson 2012). In short, all disciplines study some scale of reality, and any scale being measured, because of its inescapable context dependence, is inherently meaningful. This observation leads to yet another point at which we are in agreement with Dr. Nagel. Specifically, we very much appreciate her assertion that WST helps to develop a different approach to *what people are*. By modeling all of reality as context-dependent, and self-sustaining systems as embodiments of context, WST conceptualizes each and every one of us as *world in world* instead of as meaningless physical systems. As a result, we are all inescapably meaningful and efficacious. Everything we do alters the contexts within which we sustain ourselves. Everything we do matters.

Given WST's ability to provide a means of bypassing the meaningless view of reality we have been led to via Hard Naturalism, it is not clear to what extent philosophy is so much ex-

periencing a *pragmatic* turn (Engel et al. 2013) as it is experiencing a *holist* turn (Jordan 2013). If it proves to be the latter, sustaining such a turn will be difficult, for it will force us to experience our scientific concepts (e.g., physical, chemical, biological) as epistemic tools we must necessarily utilize if we are to get on with the cooperative, social practice of science. As was stated by Oakeshott (1933) however, science as a mode of experience is inherently an abstraction, an arrestment from the whole. This means that while the practice of science necessitates that we generate conceptual abstractions regarding that within which we are nested, we must always remember that our abstractions can never satisfy a correspondence-driven definition of truth. In short, while we must necessarily represent, we must simultaneously commit to uncertainty. Perhaps it was the potential pathos of this conundrum that W. G. Sebald was referring to in his poem *After Nature*:

For it is hard to discover
the winged vertebrates of prehistory
embedded in tablets of slate.
But if I see before me
the nervature of past life
in one image, I always think
that this has something to do
with truth. Our brains, after all,
are always at work on some quivers
of self-organization, however faint,
and it is from this that an order
arises, in places beautiful
and comforting, though more cruel, too,
than the previous state of ignorance
(2003, p. 2)

The Crack of Dawn

Perceptual Functions and Neural Mechanisms that Mark the Transition from Unconscious Processing to Conscious Vision

Victor Lamme

There is conscious vision, and there is unconscious visual processing. So far so good. But where lies the boundary between the two? What are the visual functions that shape the transition from “processing in the dark” to having a conscious visual percept? And what are the neural mechanisms that carry that transition? I review the findings on feature detection, object categorization, interference, inference, Gestalt grouping, and perceptual organization, and examine to what extent these functions correlate with the presence or absence of conscious vision. It turns out that a surprisingly large set of visual functions is executed unconsciously, indicating that unconscious vision is much “smarter” than we might intuitively think. Only when these unconscious mechanisms fail, and more elaborate and incremental processing steps are required, is consciousness necessary. The function of conscious vision may be to add a final layer to our interpretation of the world, to solve relatively “new” visual problems, and to enable visual learning.

1 Qualia 2.0

What do we need to know about consciousness? Which aspect of it is most mysterious? What do we want philosophy, psychology, neuroscience, computer science, or even physics to tell us about consciousness that we do not already know? The answer to that question may vary from person to person. To me it is this very simple thing: why do I see? Why do I have conscious experiences whenever I open my eyes? What makes the 1.5 kilograms of protein and fat in my head give me the wonderful sensations I experience every day,

from the second I wake up until the moment I fall asleep?

The point is probably best illustrated by the difference between a digital photo camera and the human mind. A camera nowadays can do wonderful things. It can record an image at extreme resolutions, with the right focus and exposure, all by itself. It can identify a face, putting it in a frame on the screen, and writing the name below it of the person it recognizes. You can leave it to push the button at the moment everybody smiles. Connect it to a com-

puter, and it will detect emotions, recognize objects, or read handwriting on a letter. Surveillance cameras can detect suspicious movements or strange behaviours in crowds, outperforming human night-guards or intelligence agents. There is one big difference between the camera and the human mind, though. The camera does not see.¹ I do. And so does the night guard, most of the time. It is this aspect of visual processing that is in need of an explanation. Not the fact that I recognize the person in front of me, can read his emotions, talk to him, or pick up the cup of coffee he gives me. I can vaguely understand how my brain enables me to do that. What I do not understand is how it is that I see all those things.

Is that the “hard problem” all over? Am I talking Qualia? Not in the strict sense. In its original formulation, the hard problem would argue that there is no function, no neural process whatsoever that could ever explain conscious sensations (Chalmers 1995). Functions explain functions, but not the fact that I see. Qualia are defined as ineffable aspects of information: the redness of red, stripped of every possible functional property or reactive disposition. And with that comes the whole charade of inverted spectra, colour scientists called Mary, and explanatory gaps. Which didn’t get us all that far—so let’s not chase that unicorn again.

It’s not that I don’t want to address the hard problem, or bridge the explanatory gap. That is in fact exactly what I am after (Lamme 2010a, 2010b). But I would like to leave that for later. What we need to recognize, first, is that there must be some functions and some neural processes that are more closely connected to seeing than others (Crick & Koch 1998, 2003). For example, it is fairly reasonable to assume that an understanding of the neural basis of a reflexive motor response—like the pulling away of your hand when it touches fire—does very little towards explaining consciousness (Lamme & Roelfsema 2000; Lamme 2006). Other func-

tions may offer a better gateway. For example because they explain some fundamental aspect of seeing (Seth 2010), such as its unity, or because they coincide with the difference between conscious visual processing and visual processing that occurs “in the dark” (Lamme 2010a, 2010b). In trying to bridge the explanatory gap, I think it is important to first find the right tree up which to bark. We must first identify the exact boundaries between conscious and unconscious processing. The hard problem can then be attacked afterwards. Or maybe that whole explanatory gap will vanish right before our eyes once we are there.

This paper is about exactly that. Let’s find the visual functions and neural processes that take us as close as possible to the hard problem, as close as possible towards explaining why we humans see, while photo cameras do not. And let’s avoid barking up the wrong tree.

2 Why dolphins are not fish

To find the cognitive functions and neural processes that take us towards understanding the phenomenality of consciousness it is important to establish a boundary—a boundary with what we should call unconscious processing. This will by no means be an easy job (Lamme 2006). In fact, the whole issue of understanding consciousness and solving the explanatory gap is about positioning that boundary. There are situations where it is in fact unclear whether we should talk about a conscious sensation or not. Take the situation of a split-brain patient: here, a stimulus presented to the left visual field will be processed by the right half brain, typically devoid of communication via language. Hence, the subject will *tell* you that she did not see that stimulus. He may draw the stimulus, however, using his left hand. Or the left hand may point at the stimulus, or match it to a related subject (Gazzaniga 2005). Who are we to believe, then? The hand or the mouth? What types of behaviour may count as evidence for conscious sensations? Just speech? What about aphasic subjects, then? Similarly, there are conditions like neglect, or manipulations of attention (change blindness, inattention blindness),

¹ Or at least we assume it does not. This is the basic intuition we start from in trying to explain consciousness. If not, one easily slides into pan-psychism. That is a viable option of course: it could be that the camera does see, yet cannot “tell” us. However, the arguments put forward in the remainder of this paper seem to suggest that the camera does not see.

where it is difficult to be entirely sure that what appears to be not seen is in fact maybe just not attended to, and hence forgotten or not cognitively accessible and hence not reportable (Lamme 2003, 2006, 2010). This uncertainty has sparked a lively debate on the nature of consciousness, its potential independence of cognitive functions like attention, working memory, or access (Lamme 2004, 2010a, 2010b), and whether consciousness can ever be separated from a *report* about consciousness (Block 2005, 2007; Dehaene et al. 2006; Cohen & Dennett 2011; Fahrenfort & Lamme 2012). This debate is all about the difference between seeing and knowing, between phenomenality and access (P-consciousness and A-consciousness), between qualia and higher-order thoughts. In this debate, the issue that seems unsolvable is where exactly the boundary between conscious and unconscious processing should be laid.

In such attempts to establish boundaries, it is perhaps good to start from the extremes, as an example from zoology will illustrate. Superficially, one could argue about whether a dolphin is a fish or a mammal. Science has resolved that argument by looking at animals that we all agree are either mammals (such as dogs, cows, or monkeys) or fish (such as sole, tuna, or piranha). From that perspective, the key differences between these species lies in the way they breathe and reproduce.² Why are these the key differences? Well, differences in breathing do all the explaining for why fish are generally more adept at living in water instead of on land. Similarly, evolution towards the land has called for eggs with protective layers (amnios), as anamniotic eggs (that fish lay) cannot survive on land. The most extreme version of that is the intrauterine development of the egg. Mammals and fish are thus at the two extreme ends of evolutionary adaptation towards breathing and reproducing on land.³ We understand why a mammal behaves differently to a fish from these key properties. From these key properties we understand why mammals roam the surface of the earth, why they look the way they look, and

why they behave the way they do.⁴ In classifying animals, we use these features for a discrete taxonomy. This means that there are other features that do not qualify as defining characteristics, which are disregarded in animal taxonomy. Among these are behaviours like swimming in water, or living in groups. The key differences, obtained from looking at the extreme ends of the spectra, lead us to conclude that dolphins are mammals and not fish, even though appearances may suggest otherwise. We can draw a sharp boundary, and do not have to resort to saying that dolphins are “fishy mammals”, because we recognize that the swimming behaviour of dolphins is irrelevant to their taxonomy.⁵ *Defining features* and *irrelevant features* enables a proper and discrete taxonomy, making most sense of all the available data. Moreover, a taxonomy based on such features allows for an understanding that goes towards a deeper level, in this case the evolutionary pressure that came from the transition from sea to land dwelling.

I propose to undertake something similar with consciousness. What is the proper taxonomy of conscious versus unconscious vision? What are the defining features of this difference, and what features are irrelevant? And do the defining features take us towards a somewhat more fundamental level of understanding consciousness (Lamme 2010a, 2010b)? To find those features, we start from the extreme ends: the mammals and fish of consciousness research, the things most people will agree on as representing either conscious or unconscious processing.

3 The mammals and fish of consciousness

When I am awake and say I see a face, am able to report its identity; I can identify the colour of its eyes and hair, and judge its emotional ex-

² Among other things, like whether they maintain body temperature or have hairy skin.

³ With reptiles and birds in between, laying amniotic eggs on the land.

⁴ Of course there is the occasional mammal that lays eggs (e.g., the platypus) or fish that give birth to live young (e.g., the hammerhead shark). Still, calling these mammals or fish depends on the relative weight of other defining features, such as their way of breathing, feeding, body temperature maintenance, etc.

⁵ In a somewhat more mathematical analogy one could take all properties of all animals in the world, and perform a cluster or factor analysis. A good taxonomy has clusters that are aligned along the primary factors. Traditional taxonomy seems to have operated in this way implicitly.

pression. There is little reason to doubt that I have a conscious sensation of that face.⁶ If we study the properties of visual processing in this condition, we can be pretty sure we are studying the properties of conscious visual perception. This is our “mammal” of consciousness. We can study the properties of this species fairly easily. We can resort to introspection, verbal reports, or more strictly formalized approaches like detection or discrimination tasks. In favour of using introspection is that our introspective idea of consciousness is the very thing we are trying to explain. I would like to understand why the world looks the way it looks in my mind’s eye. This is the explanandum. Even so, we should be cautious in fully “trusting” introspection,⁷ and that is where more formal approaches may come in handy.

What would be the proper “fish” of consciousness? Are there conditions where everyone agrees that consciousness is absent? Dreamless sleep (Tononi & Massimini 2008) and anaesthesia (Alkire et al. 2008) seem to be good candidates, although not very useful ones, given that visual stimuli are difficult to deliver, and that one can only resort to objective measures (brain signals) to assess what is still processed or not. Awake subjects are easier to assess in that respect, but there it is hard to find truly unequivocal manipulations of consciousness. “Unequivocal” in this context means that the manipulation can truly be regarded as a manipulation of consciousness, i.e., in the case of vision is a manipulation of visibility (Kim & Blake 2005; Lamme 2006). An example of the latter

would be visual masking (Breitmeyer & Ogmen 2000; Enns & Di Lollo 2000). Here, a target stimulus is presented very briefly, and immediately followed by another stimulus, known as the mask. When properly done, this will render the target completely invisible. People will be at chance detecting presence or absence, or in judging another property of the target stimulus. It is safe to assume invisibility in masking, because there is no conceivable reason that could prevent the subject from reporting his visual percept, had he had one: the subject is sitting there, focussing his full attention to the target location, ready to push the button as soon as he sees the target. The not-seeing can therefore not be attributed to the absence of attention, to a lapse of memory, or to any other cognitive function sitting between a potentially conscious sensation and its report (Lamme 2003, 2010a, 2010b). As we are ready to believe the presence of consciousness in the case of someone verbally describing the face he sees, we should be equally ready to believe its absence in the case of masking (or dreamless sleep and anaesthesia).⁸

Another popular paradigm to render stimuli invisible is continuous flash suppression (CFS; Tsuchiya & Koch 2005). Here, the target stimulus is shown to one eye, while the other eye receives a rapid stream of brightly coloured patches, serving as a mask. This typically results in the target stimulus being rendered invisible, although stimuli may “break through” after a while.⁹ A third paradigm is dichoptic masking, where two oppositely coloured stimuli are shown to the two eyes, that when properly fused combine into an invisible stimulus (Mout-

6 One could do so, of course, which would lead to the denouncement of consciousness as a scientific phenomenon altogether, much along the lines of eliminative materialism (e.g., Churchland 1981). Daniel Dennett, in his categorical denouncement of anything coming close to qualia or even the phenomenology of consciousness, seems to follow a similar agenda (1993). It is entirely possible indeed that consciousness is a figment of our imagination, one that will evaporate upon close scientific scrutiny. Something like that happened to ‘elan vital’—the unique property of living matter—once we learned about chemistry, biology, DNA, and natural selection. For now, let’s assume that consciousness exists, and is in need of an explanation. If not, I would rather not be spending my years in neuroscience.

7 One important caveat is that for introspection we have to resort to cognitive functions like attention, memory, and “internal report”. This may result in both a potential underestimation of what we actually see (see for example the iconic/fragile/working memory discussion), and to an overestimation of what we actually see (as in the illusion of peripheral colour vision). This has been dealt with extensively elsewhere (Lamme 2010a).

8 Note that a proper treatment of response bias is important in this case. “Shy” subjects may feel inclined to respond “not seen” on most trials, more liberal subjects may feel inclined to respond “seen” on most trials. Only treating the responses in terms of signal detection theory (Swets et al. 1978) can truly establish the absence of any sensation (because the number of false alarms—subjects saying “seen” on trials without a target—is taken into account). From that perspective, using only partially-effective masks is not a proper method, not even when only those trials are used in which subjects reported not seeing the target.

9 A potential problem with the CFS manipulation is that “time to breakthrough” is often used as a measure of relative awareness of stimuli. Time to breakthrough is more or less analogous to a “yes” response (or hit) in a masking paradigm, and hence can suffer from response bias. CFS studies where responses are more rigorously treated in terms of signal detection theory are scarce. See Stein et al. (2011) for a more elaborate discussion on this problem with the CFS paradigm.

oussis & Zeki 2002; Fahrenfort et al. 2012). From all the available neuropsychological patients, patients suffering from hemianopia due to a V1 lesion (often accompanied by blindsight) are probably the clearest cases of impaired visual consciousness (Weiskrantz 1996).

I select these consciousness manipulations because they seem to be the safest bets for highlighting situations where conscious vision is really absent. The absence of conscious vision in these cases has purely visual origins. There is no other function precluding the report of a potentially present visual sensation, as may be the case in split-brain patients or neglect, or in manipulations like inattentive blindness, change blindness, or the attentional blink (Lamme 2003). The two extreme ends—the mammals and fish of consciousness—may serve as a guideline towards establishing the properties of conscious versus unconscious processing. What are the differences between awake conscious vision and vision in sleep, anaesthesia, blindsight, and the various forms of masking?

4 Categorization: From low to high level features

Above, I used the example of seeing a face. What does seeing a face mean, in terms of the visual functions being executed? Recognizing a face first of all entails that one identifies the stimulus as belonging to the class “faces”, as opposed to any other class of stimuli, such as “animals”, “teapots”, “houses”, or “letters”. This is a process of categorization. Intuitively, categorization seems a key property of consciously seeing and recognizing a face. It is not, however. Since the first findings of blindsight it has been recognized that categorization can occur fully independently of conscious sensations (Weiskrantz 1996; Boyer et al. 2005). Patients without awareness of stimuli in the blind part of the visual field can nevertheless categorize these stimuli, as long as the categorization is framed in a two-alternative forced choice: is it a square or a circle, is it moving upwards or downwards, is it red or green, vertical or horizontal? In such cases, patients’ responses fall well above mere chance, indicating that the categorization of

stimuli in two distinct classes is still functioning, and hence does not necessarily require consciousness.¹⁰

Categorization is the main function of cortical visual neurons, in that each neuron is *feature-selective*: it only responds to a stimulus when that stimulus possesses certain visual features. A Nobel prize was awarded for this finding, as it is fundamental to the operation of the visual cortex (Hubel 1982). It ranges from low level features such as spatial frequency, orientation, direction of motion, or colour to higher-level features such as the geometry of a shape or the class of an object. Each feature-selective neuron can be seen as doing a simple, often one-dimensional categorization: it signals “vertical orientation”, “moving upwards”, or “rectangular shape” (Lamme & Roelfsema 2000). Face-selective neurons shout “face!” (Oram & Perrett 1992). The categorization responses of visual neurons are so fundamental to their operation that they are fully independent of consciousness: most neurons are equally feature selective in anaesthesia as they are in the awake condition (Dow et al. 1981; Snodderly & Gur 1995; Lamme et al. 1998a). Feature-selective responses of neurons are mediated via feedforward connections, and visual categorization proceeds along these feedforward connections in an unconscious way (Lamme et al. 1998b; Lamme & Roelfsema 2000).

Additional evidence dissociating categorization from consciousness comes from a multitude of sources. Unseen stimuli in backward-masking are also categorized, as can be judged from the specific priming effects they may evoke. For example, a fully masked digit 7 may speed up (or slow down) responses to categorizing a second digit (or number word) as either being above or below 5, showing that the masked and unseen number (the 7) is categorized according to its numeric value (Dehaene et al. 1998).¹¹ Many similar examples exist. Moreover, it has been shown that masked and hence unseen stimuli evoke category-specific responses from the brain, either in the form of se-

¹⁰ Note, however, that categorization is typically far better for stimuli than patients—or normal subjects—are aware of.

¹¹ Or more precisely: as being either below or above 5, in this experiment.

Figure 1: Faces and houses were made invisible using dichoptic masking—i.e., presenting oppositely coloured versions to each eye. Regardless of (in-)visibility, these faces and houses evoked selective activations of category specific regions of the brain (from: Moutoussis & Zeki 2002).

lective single unit responses (Rolls & Tovee 1994; Macknik & Livingstone 1998), or in the form of selective activation or category-selective regions such as the Fusiform Face Area (FFA) (figure 1) (Moutoussis & Zeki 2002; Kouider et al. 2009),¹² or in the Visual Word Form Area (Dehaene & Naccache 2001)—indicating that they are categorized up to the level of face vs non-face or word vs non-word (Dehaene et al. 2004). There is a large body of literature covering the unconscious processing of emotional valence in either faces or words (Straube et al. 2011).

Particularly far-reaching levels of unconscious categorization have been reported for behaviourally or socially relevant stimuli. Tools evoke selective activation of the dorsal stream

areas—and selective priming effects—when made invisible with CFS (Fang & He 2005; Almeida et al. 2008). Faces that have their eyes turned towards the viewer break from CFS sooner than faces that are turned away—a finding that is probably explained by the fact that faces turned towards the viewer pose a very relevant or even threatening social signal (Gobbini et al. 2013). Similarly, the gender of naked bodies is processed during CFS (Jiang et al. 2006). Also, the mismatch between object categories is identified for stimuli made invisible using CFS: scenes with mismatching objects (e.g., a cook taking a chess-board out of the oven instead of a dish) break from CFS sooner than matching scenes (Mudrik et al. 2011).

The latter finding is related to various non-visual “categorization” processes that occur for invisible stimuli: it has been shown that masked stimuli travel throughout the brain, even reaching high-level areas involved in inhibitory cognitive control, response error selection, or evidence accumulation, exerting high-level cognitive effects (Van Gaal & Lamme 2012). So invisible stimuli not only activate visual categorization processes, but also activate extremely high-level and very abstract categories such as the stimulus being a “stop signal”, an “error”, or “evidence for a right button press”.

¹² It is unclear to what level invisible faces are processed exactly. Clearly, face/non-face categorization takes place for masked stimuli (see below), but whether face identity is also preserved depends on the exact experiment. Some find face-identity-specific priming and suppression of activation of the FFA and related face-selective-regions for backward masked stimuli (Kouider et al. 2009). However, this effect was only present for famous faces, not for unknown faces, showing that it may not be identity itself that is processed but “level of fame” or something similar. Others have made faces invisible using CFS, and found that face-specific adaptation only occurred for visible, and not for invisible faces (Moradi et al. 2005). The two studies are hard to compare, partly because of the different techniques used to make faces invisible (masking vs. CFS), but mostly because the latter used an adaptation effect as independent variable. It may be that unconscious categorization still occurred, yet did not result in learning (e.g., Meuwese et al. 2013; Meuwese et al. 2014).

From a neural perspective, categorization is feature selectivity, which may range from very simple to highly complex features and categories. This kind of categorization proceeds entirely independent of consciousness.¹³ So how does conscious recognition differ from categorization? To answer this question, we have to take a closer look at categorization responses. What a face-selective cells does, is to categorize a face as belonging to the class of faces versus non-faces. That's all. When we consciously see a face, however, we do much more than this: we classify the stimulus as a face, but at the same we identify its shape, colour, identity, and emotional expression. So we distinguish between “that brown face of my sad-looking friend Peter” and very many other faces—and also between that face and millions of other potential visual stimuli.

Gulio Tononi uses the metaphor of a photo-diode to illustrate the point (2008, 2012). For a photo-diode a black screen is different from a white screen. That's a distinction it can make. The photo-diode carries information about the brightness of the screen, so its signal carries one bit of information (or a few bits, depending on its sensitivity). For us, however, consciously seeing a black screen is very different. Seeing the black screen implies that we distinguish it from a grey screen, a red screen, a black table, a green house, a pink face, a dog, a sound, a feeling, or any other sensory event that would have been possible. Consciously seeing the black screen thus carries a huge amount of information, as it excludes an almost endless set of alternative sensations. And that makes seeing “that brown face of my sad-looking friend Peter” very different from what a face-selective neuron does when it signals “face”. The neuron behaves much like the photodiode, in that it signals presence or absence of a feature along a single dimension. That is because neurons tend to combine feature-selectivity with invariance

for other features: a face-selective cell signals faces regardless of colour, size, identity or expression (Rolls 1992).¹⁴

Tononi proceeds from a photo-diode to the photo camera as a metaphor for explaining another central feature of conscious sensations (2004, 2008, 2012). He argues that the critical difference between a conscious representation in the human mind and what happens in a camera is that in the camera information is distributed and not integrated. Each and every pixel signals a particular level of luminosity, but it does so entirely on its own. It does not “know” what other pixels are doing. To the camera it would not matter if all the pixels were cut apart and became separate cameras. Conscious sensations, on the other hand, are integrated.

It thus seems that to find for visual operations that are more closely linked to consciousness, we must look for something beyond basic categorization. We must look at processes where the individual pixels in our camera—the billions of neurons each signalling particular features—are interacting, and are integrating their information.

5 Interference: A loss of independence

The pixels in the “camera of the human mind” do not work independently. A strong case in point are illusory brightness or colour shifts. Patches of the exact same brightness may be perceived as entirely different, depending on their surroundings, and depending on the global configuration of brightness and contrast. A striking example is the cylinder with checkerboard illusion shown in the right half of figure 2. Similar illusions exist in the domain of colour (figure 2, left). Relatedly, everyone who has ever tried to paint a picture has experienced that it takes an astonishingly rich palette of reds, purples, browns, yellows, and even greens or blues to construe a veridical depiction of a simple red apple. The unitary experience of see-

¹³ Another illustration of the separation between feature selectivity and conscious experience is the observation that many neurons signal features of which we are not aware: V1 neurons signal the orientation of gratings that are of too finely spaced for us to perceive (He et al. 1996; Foster et al. 1985), respond to 3D disparity where we do not see depth (Cumming & Parker 1997), or signal invisible temporal frequencies (such as the flickering of light beyond the flicker-fusion frequency of about 15–25Hz, Maier et al. 1987).

¹⁴ Responses are modulated by such features, but typically this happens only after some delay (Sugase et al. 1999). The initial feedforward response is typically fully governed by a basic feature, like face vs non-face. Later on, responses are modulated by face identity or expression, and this is mediated by horizontal or recurrent interactions between neurons. We then enter the domain of feature integration, which is a hallmark of conscious recognition; see below.

Figure 2: Two strong shifts in the perception of colour and brightness. Although the indicated patches are identical, they are perceived as having quite different colour and brightness. Visit Michael Bach’s website (<http://michael-bach.de/ot/>) for these and many other examples.

ing a red apple is in fact composed of the detection of a multitude of wavelengths, all interacting to compose that one colour. Only with extreme focused scrutiny (or by covering surrounding elements) are we able to isolate the elements that make up our unitary conscious experiences.

Another illustration is the phenomenon of colour constancy. When we look at a bowl of fruit in the blue morning light the spectral composition of wavelengths reflected from the fruits is very different from the wavelengths coming from the fruits at sunset (figure 3). Nevertheless, we see the banana or the apple as having the same colour whether it is dusk or dawn. Our visual system is not interested in the wavelength coming from fruits; it is interested in their potential taste or edibility. Therefore, it discounts the illumination, and computes “colour”, which is a property of the object, rather than of the light coming from it.¹⁵ Colour is not wavelength; colour is a meaningful property of

objects that is based on wavelengths, yet transcends it.

To what extent do these phenomena depend on consciousness? Harris et al. (2011) studied a brightness illusion much like that in figure 2. Two circles were shown, of either the same or different brightness. By placing these circles in a dark and bright surround respectively, their brightness suffered from an illusory shift. In the critical condition, the surrounds were made invisible by presenting them to one eye, and filling the other eye with a continuously flashing Mondrian stimulus. This resulted in CFS of the surrounds. Cleverly, the two circles were shown in both eyes, so remained visible throughout. Regardless of the CFS-induced invisibility of the surrounds, the circles still showed illusory brightness shifts.¹⁶

The neural mechanisms of illusory brightness perception were studied extensively

¹⁵ It probably discounts the illumination by very much the same mechanisms as the illusory brightness shifts discussed above (via inhibitory lateral interactions). However, precise neural mechanisms may be different, as might be the cortical level at which neural responses reflect colour rather than wavelength.

¹⁶ It must be noted that in this experiment, the surrounds were not always fully invisible. In 86% of the trials, subjects reported not seeing the surrounds. Only these trials were used for the analysis. Within these trials, discrimination of the background (is the darker half left or right?) was at chance level, leading to the argument that indeed there was a full absence of awareness of the surround.

Figure 3: These images show a bowl of fruit photographed in three lighting conditions—artificial light (left), hazy day-light (middle), and clear blue sky (right). Notice the marked variation in colour balance caused by the spectral properties of the illuminant. We are not normally aware of this variation because colour constancy mechanisms discount illumination effects (image and legend from <http://www.psypress.co.uk/mather/resources/topic.asp?topic=ch12-tp-04>).

in the macaque monkey and cat visual cortex. It was found that perceived brightness (modulated by flanking regions) influenced neural responses in area V1 of the cat, but not at earlier stages such as the LGN or the optic tract, thereby showing a gradual progression from physical brightness to perceptual brightness in the visual pathways (Rossi & Paradiso 1999; Rossi et al. 1996). Using the Cornsweet brightness illusion,¹⁷ it was found that in the monkey's visual cortex, V2 cells represents surface brightness whereas V1 cells do not, pushing the level at which perceived brightness is calculated somewhat higher (Roe et al. 2005). Either way, these results were recorded in anaesthetized animals, showing their independence from consciousness.

How the visual system goes from the detection of wavelength towards the representation of colour is still a topic of controversy. Initially, there was thought to be a modular progression from V1 cells encoding wavelength towards V4 cells encoding colour. That view was challenged by various findings showing that the responses of V1 cells are influenced by surrounding hues. The view that V4 is the “colour module” has also been challenged, in part by strong disagreement on the homology between monkey V4 and alleged human counterparts.¹⁸ Moreover, the coding of colour is intricately

linked to the coding of object shape, and hence can no longer be viewed as a simple “add-on” to our visual percept.¹⁹ It is now thought that the perception of colour depends on the interaction between neuronal groups, or is best understood as a population code (Shapley & Hawken 2011).

Given this controversy, it is difficult to know to what extent colour perception depends on consciousness. Many of the recordings in monkey visual cortex were performed in awake animals, some in anaesthetized animals (Shapley & Hawken 2011). A clear-cut difference in results between the two conditions is hard to establish. A remarkable finding is that blindsight patients report no conscious sensation of colour, yet may have spectral sensitivity curves that have a similar shape in the lesioned and intact hemi-fields (Stoerig & Cowey 1989). Spectral sensitivity is, however, mostly carried by wavelength. Similarly, patients with cortical colour blindness (achromatopsia) do not consciously perceive colour, yet can detect objects or patterns based on wavelength contrasts (Cowey & Heywood 1997). Colour constancy mechanisms, on the other hand, are absent in the lesioned hemi-field of blindsight patients (Barbur et al. 2004; Barbur & Spang 2008), and

¹⁷ In this illusion, two surfaces of identical brightness are perceived as having different brightness, because there is a contrast edge between them.

¹⁸ I am not even going to dare mentioning their names here.

¹⁹ The fact that black-and-white photography works so well, has led us to believe that colour is a feature that is “painted” onto objects, as a sort of extra, independent of any other feature. We are now coming around from this view. For example, to compute the colour of an object, the object's shape has to be taken into account, otherwise shadings would be misinterpreted. Object identity also influences colour perception: a brownish colour on a banana will be seen as more yellow than it would on a tomato.

Figure 4: Left: the Kanizsa triangle. Note the illusory brightness increase inside the region of the illusory triangle. Middle: the 2D projection of a cube can in fact originate from a multitude of 3D objects. We regularly interpret it as a cube, however. Right: we see the woman as small, despite our cognitive ability to realize that “this cannot be true”. Our 3D “priors” force us to see her as small (from <https://richardwiseman.wordpress.com/2009/09/09/great-table-illusion/>).

hence seem more closely linked to conscious perception.²⁰

The difference between perceived colour and wavelength, and its relation to conscious vision, has been directly addressed in a masked priming experiment. In this experiment, subjects were shown desaturated blue, green, or white coloured disks. Perceptually, the white was closer to the blue disk. From the point of view of the phosphor activations on the monitor screen, on which the disks were shown (i.e., their “wavelength composition”), the white disk was, however, closer to the green disk. What was studied was the effects of these disks when they acted as primes for a subsequent colour discrimination. It was found that masked, and hence invisible white disks, acted more like green primes than like blue ones. Visible white disks, on the other hand, acted more like blue primes than like green ones (Breitmeyer et al. 2004; Breitmeyer et al. 2007). Apparently, unconscious priming acts on wavelength similarity,

whereas conscious priming acts on perceived colour similarity.

All in all, it remains difficult to assess the relation between consciousness and phenomena like brightness or perceived colour illusions, or mechanisms related to colour constancy. Perceived brightness seems to depend on largely unconscious mechanisms, and on fairly low level and short range mechanisms. The transition from wavelength analysis to the perception of colour is more likely to accompany the transition from unconscious processing to conscious vision. A firm conclusion, however, relies upon settling the debate about mechanisms of colour perception and their neural substrates in humans and animals, and more direct experimentation on how these mechanisms are affected by manipulations of consciousness.²¹

6 Inference: Beyond the input

In the phenomenon of colour constancy we have already seen a hint of another visual function.

²⁰ This argument is, however, weakened by the fact that other long-range colour interactions remain in the blind hemi-field (Barbur et al. 2004), and by the finding that colour constancy mechanisms may depend on fairly early, monocular mechanisms (Barbur & Spang 2008). Moreover, it is reckoned that several colour constancy mechanisms exist, some of which are based on retinal adaptation mechanisms (Kamermans et al. 1998).

²¹ Obviously, these empirical issues about colour perception and consciousness have very direct consequences for many philosophical debates as well, given the many thought experiments that rely on colour perception and the whole notion of qualia.

Colour is not about the wavelength coming from objects. It is a property of objects that we infer from wavelengths. At some point, conscious perception starts to diverge from the mere physical properties of the input, in a process we call *inference*. There are many more examples of inference, and many visual illusions capitalize on the fact that our visual mechanisms are constantly trying to make sense of the world. Figure 4 shows the famous Kanizsa triangle. The minimal, strictly physical interpretation of the image is that of three Pac men pointed at each other and three arrowheads pointing outwards. But our perceptual interpretation goes beyond this, in that we *see* a white triangle hovering over three black circles, occluding another outlined triangle. The illusory triangle is seen as slightly brighter than its surround, and illusory contours mark its “borders”.

This process of inference seems to strongly fit the intuitive difference between a camera and conscious vision. It requires the integration of multiple “pixels”, their interaction, and their interpretation beyond what is strictly given by the image itself. And it is in this last aspect in particular that prior knowledge about the world comes into play, and starts to interfere with the stimulus-driven feature-selective categorization of the input.

The Kanizsa triangle can be seen as a specific example of the more general propensity of the visual system to arrive at a representation of surfaces in 3D space (also called the 2.5D sketch). In that representation we seek the most natural interpretation, consistent with our existing experience of how things are in the world. It is simply much more likely that there is a triangle covering circles than that there are three Pac men that happen to be facing each other at exactly 60° angles. The triangle interpretation is generic, whereas the Pac men one would be accidental (Albert & Hoffman 2000). Nakayama & Shimojo (1992) studied various configurations of 3D stimuli, and found that our visual system always strives towards the interpretation that is most generic, i.e., that would least depend on an accidental viewing position of the observer. Interpretations that would not change when the observer happened to shift position are fa-

voured, given that we are constantly moving relative to objects. For example, the 2D image of a cube can in fact arise from an infinite number of shapes (figure 4, middle), yet we tend to favour the “cube” interpretation because it is the most generic one.

Another way of putting it would be to say that the cube interpretation fits our common experience, in that most of the time, these kinds of 2D projections arise from regular 3D cubes: it is the most ecologically valid interpretation. In a modern guise, this aspect of inference is formalized as a Bayesian approach, where vision uses a set of prior probabilities to arrive at the most likely 3D interpretation of a 2D image. The cube has the highest prior, compared to the more irregular shapes. Illusions like the Ames room (where someone changes size when he walks from one corner to the other), or the size illusion shown in figure 4 (right) capitalize on these assumptions: we assume that rooms have rectangular floors and walls, we assume the woman is sitting on a chair. These assumptions are so strongly embedded in our visual hardware that even in the face of strange consequences, such as people growing in size within a few steps or a man holding his hand over a mini-woman, this inference is maintained.

Many more illusions display non-veridical inferences. In the Ebbinghaus illusion, the perceived size of a disk depends on the size of surrounding disks. In the Ponzo and Müller-Lyer illusions we see line segments as having different lengths, while in fact they are the same. These illusions show that the size of an object is an inference that we draw from its context, rather than from the space it occupies on the retina.

To what extent does inference depend on conscious vision? When we have to pick up the disks in the Ebbinghaus illusion, it appears that our hands open at a pre-grip aperture that is in accordance with the disk’s actual size, not its perceptual size. Apparently, size context effects influence perception, and not automatic action—which has led to the idea that we have two largely separate neural pathways, one transforming visual input into conscious perception, and the other translating visual input into automatically guided action (Goodale & Milner 1992).

Figure 5: On the left, we see a textured square overlying a textured background. This is because we automatically group all line segments with the same orientation into one object, and segregate it from the line segments with the orthogonal orientation. The small circle represents the receptive field of a V1 neuron, that would not be able to differentiate between the “figure” and the “background” stimulus, because the line segments within that receptive field are identical. Indeed, V1 responses are identical up to about 100ms after stimulus onset. Beyond that, the two responses start to diverge, however, indicating that the response of the V1 neuron is modulated by the perceptual context of what is within its receptive field (Lamme 1995; Lamme et al. 2000).

There is more evidence linking perceptual inference to conscious vision. Harris (Harris et al. 2011) studied whether Kanizsa triangles were still inferred when the inducers were made invisible using CFS. The same setup was used that showed the presence of brightness illusions under CFS (see above). Subjects had to indicate whether the triangle in the suppressed eye was pointing left or right. They were at chance level, indicating that the Kanizsa-type inference depends on consciousness. Another study, however, found that Kanizsa triangles broke through CFS earlier than control stimuli with inducers pointed outwards (Wang et al. 2012), suggesting that Kanizsa-type inference does occur pre-consciously.

At the single neuron level, the detection of illusory contours has been studied quite extensively. Initially, it was found that V2 cells respond in an orientation-selective manner to Kanizsa-type illusory contours (Von der Heydt et al. 1984). More recently, other areas have been shown to be involved as well (Sáry et al. 2008)—area V4 in particular (Cox et al. 2013). And in human neuroimaging studies it was found that Kanizsa-type illusory contours activate many early visual areas (Seghier & Vuilleumier 2006). All these studies used awake animals or humans, so it is difficult to

infer whether these responses depend on the conscious state.

Marcel studied the processing of illusory triangles in two blindsight patients. Two inducers were presented in the sighted hemi-field, while one critical inducer was presented in the blind field, either completing the triangle or not. Completed triangles were detected far above chance (~80%), while the detection of the inducer shape was at chance. Moreover, one of the subjects described the illusory triangles as “brighter”, “out there on the screen” and “on top of something” (Marcel 1998).

All in all, the relation between inference and consciousness is unclear, mostly because fairly little work has been done as yet to study the relation directly (i.e., to study the effect of consciousness manipulations on inference and its neural correlate), but also because much of the work that has been done focuses on a single (though very important) phenomenon: the Kanizsa triangle.

7 Integration: Feature grouping and segregation

Both in interference phenomena such as brightness or colour shifts and in inference phenomena like the Kanizsa triangle we see some

aspects of the integration of information. Visual responses go beyond the encoding of individual pixels, and start to influence each other, either on the basis of more or less hardwired lateral interactions, or on the basis of the incorporation of prior knowledge. In the end, conscious vision seems to be about reaching *full* integration.²² We have one visual percept, where all information is combined.²³ This is a property of conscious vision that has interested scientists for a long time. Gestalt psychologists formulated a multitude of laws, along which image elements may be combined into larger wholes (Rock & Palmer 1990; Wagemans et al. 2012). In this grouping process, all features, together with their interactions, inferences, and meanings are combined into a final percept: the thing we see, the whole scene containing shapes, objects, and backgrounds. This is a highly dynamic process in which various Gestalt laws may compete for one interpretation or another, and where subtle changes may influence the meaning of pixels at long distances. We enter the domain of feature integration, grouping, binding and segregation. In short; the domain of perceptual organization.

Two levels of integration may be distinguished, where a subdivision between “base groupings” and “incremental groupings” may be useful (Roelfsema 2006). Base groupings are those that depend on the fact that some feature combinations automatically ride together. An orientation-selective cell in the primary visual cortex, for example, is often at the same time

also direction-selective. It may be tuned to particular binocular disparities as well. And it will have a limited receptive field. So the firing of that neuron already goes beyond a one-dimensional feature-detector, beyond the photo-diode. It signals an orientation, moving in a particular direction, at a particular 3D depth, and located in some part of the visual field. Such base groupings exist for many feature combinations, such as colour and shape (e.g., V4 cells), or motion and disparity (e.g., middle temporal, MT, cells).

Another type of base grouping is visible in the feature selectivity of a particular cell, where we may recognize the combination of feature-selectivity of cells at earlier levels. From the start, Hubel and Wiesel recognized that orientation selectivity could be viewed as a convergence of information from retinal ganglion cells lying in a row. The feedforward convergence of information from orientation selective simple cells leads to the receptive field structure of complex cells, which are orientation and direction selective (Hubel & Wiesel 1968). Many higher-level feature-selective cells can be seen as converging information from lower level cells (Tanaka 1996).

Base grouping does not depend on consciousness. The combined feature selectivity of neurons, as well as high-level feature selectivity based on the feedforward convergence of lower-level feature selectivity are still present in anaesthesia or masking (Lamme & Roelfsema 2000; Roelfsema 2006).

Of a very different nature are “incremental groupings”. Here, the information from separate neurons has to be combined to obtain a higher level categorization. A good example is texture based figure-ground segregation, shown in figure 5 (Lamme 1995; Zipser et al. 1996). Here, we automatically perceive a textured square overlying a textured background. This is entirely due to the fact that the centre square is made up of line segments of a particular orientation, different from the line segments that make up the background. There is no luminance difference or any other cue that gives the square “away”. Line segments of one orientation are automatically grouped into a coherent surface—the square—that is segregated from the surface that is

²² Tononi similarly argues that consciousness always strives for “maxima of integrated information”, for which he uses the metaphor of the internet (2012). Like the brain, the internet is a highly interconnected structure where information travels from one part to other parts. In contrast to the brain, however, the internet is designed to transfer information from one specific part of the net (computer A) to a specified other part of the net (computer B), and it would in fact be rather counterproductive if this information were influenced by other information flowing from computers C to D or E to F. At another moment information may flow from A to C or D or F. The internet therefore does not strive for “maxima of integrated information”, whereas the brain typically does. Focussed attention, in such a view, would then be in fact a mechanism that counters this propensity towards maximally-integrated information, and which enables the brain to operate more strongly along the principles of the internet.

²³ This is in fact such a strong intuition that it has led us to believe for a long time that consciousness must be some place in the brain “where it all comes together”. Descartes envisaged the pineal gland as such a place, and hence theories that lean towards such an explanation of consciousness are often said to suffer from the fallacy of the “Cartesian theatre”.

Figure 6: Contextual modulation of V1 responses follows the global perceptual interpretation of images. In all cases, the V1 receptive field is stimulated with the exact same line segments. When these line segments belong to a homogeneous background texture, a response indicated by the thin line is given. Left: when the line segments belong to a figure that is defined by differences in disparity, colour, or luminance, the responses are larger. Right: differences in 3D disparity were used so that the patch of texture was either part of a figure square “floating in a moat behind it” or in the background with a “frame” hovering in front of it. The contextual modulation always followed these perceptual interpretations, in that “figure” interpretations always evoked larger responses (Zipser et al. 1996).

formed by line segments of the other orientation—the background. Orientation-selective neurons in V1 typically have small receptive fields, which would only cover a small part of either the figure or background. The grouping of line segments into coherent surfaces, segregating from each other, requires the integration of information from a large set of separate V1 cells. This constitutes “incremental grouping” (Lamme & Roelfsema 2000; Roelfsema 2006).

The neural basis of the integration of image elements into larger units, and the subsequent segregation of such units into figure and ground has been studied extensively at the single unit level, both in anesthetized and awake monkeys. The key finding is that of “contextual modulation”, where the response of a neuron to a particular feature within its receptive field is modulated by the larger perceptual context of that feature (Lamme 1995; Zipser et al. 1996; Lamme et al. 1999). In the example of figure 5, the small circle represents a V1 receptive field,

which typically has a size of ~ 1 degree of visual angle. From the “point of view” of that receptive field, there is no difference between the “figure” or the “background” stimulus: in both cases, identical line segments cover the receptive field, and if the neuron were just signalling the presence of this feature (“left diagonal orientation present”), the responses of this neuron should be identical for the two stimuli. Indeed they are, as shown in the panel on the right, showing fully overlapping responses, until ~ 100 ms after stimulus onset. At that point, however, the responses for figure and background start to diverge. Apparently, information on the context of the line segments starts to influence the response, so that the response is larger for the “figure” than for the “background” context (Lamme 1995).

These kinds of figure-ground modulations follow the perceptual interpretation of scenes to a large extent. For example, when figure-ground relationships are ambiguous, or reversed, the

Figure 7: Contour grouping. In all cases shown here, oriented image elements are grouped together to form either a line (left), a circle (center), or an animal (right). They group according to the Gestalt principles of proximity, similarity, and colinearity. These stimuli were also used in neurophysiological experiments, typically showing that elements that group and segregate evoke larger neural responses than isolated or background elements.

modulation follows the globally-organized percept, rather than local orientation differences or gradients (figure 6, right panel) (Zipser et al. 1996; Lamme & Spekreijse 2000).

The perceptual grouping of image elements into larger units follows certain rules and principles, the formulation of which was the largest contribution of the Gestalt psychologists to modern vision theory (Wagemans et al. 2012). Among these Gestalt laws of perceptual organization are “similarity” (elements that look alike will be grouped), “common fate” (elements that go together in time, e.g., move together, will be grouped), “proximity” (elements that are close together will be grouped), and “good continuation” (elements that lie along a smooth line will be grouped). Contextual modulation of V1 neurons behaves according to these rules, in that elements that share luminance, colour, disparity, orientation, direction of motion, or co-linearity induce facilitatory interactions (figure 6 & 7) (Lamme et al. 1993; Lamme 1995; Kapadia et al. 1995; Zipser et al. 1996; Lamme et al. 2000).

How does Gestalt grouping and segregation depend on consciousness? To some extent, contextual modulation seems to survive during anaesthesia. This is, however, largely limited to fairly short range interactions between neurons, barely beyond or entirely within the receptive field (Allman et al. 1985; Gilbert & Wiesel

1992; Nothdurft et al. 1999). More long-range interactions, and interactions that express more global scene interpretations can only be recorded in awake monkeys (Knierim & Van Essen 1992; Lamme 1995; Kapadia et al. 1995; Zipser et al. 1996). For example, the figure-ground specific modulation of V1 responses shown in figures 5 and 6 (and structure from motion defined figure-ground modulation) is fully absent when monkeys are anaesthetized. At the same time, the orientation and motion selectivity of these neurons (i.e., their ability to categorize certain features) is not affected at all (Lamme et al. 1998a).

Similarly, backward masking disrupts figure-ground modulation. In monkeys, the visibility of texture orientation defined figure-ground targets was manipulated by masking with a stimulus consisting of randomly-positioned texture-defined figures (figure 8). The animals were at chance in detecting the location of the target figure for stimulus-onset asynchronie (SOA) of up to 50 ms (i.e., 50 ms between the onset of the target figure and the mask). At larger SOA's, behaviour quickly rose to ceiling. Figure-ground contextual modulation followed the same pattern: absent up to and including SOA's of 50 ms, and increasingly present at longer latencies. At the shorter latencies, however, V1 neurons still responded vigorously to the texture patterns in an orientation-selective manner,

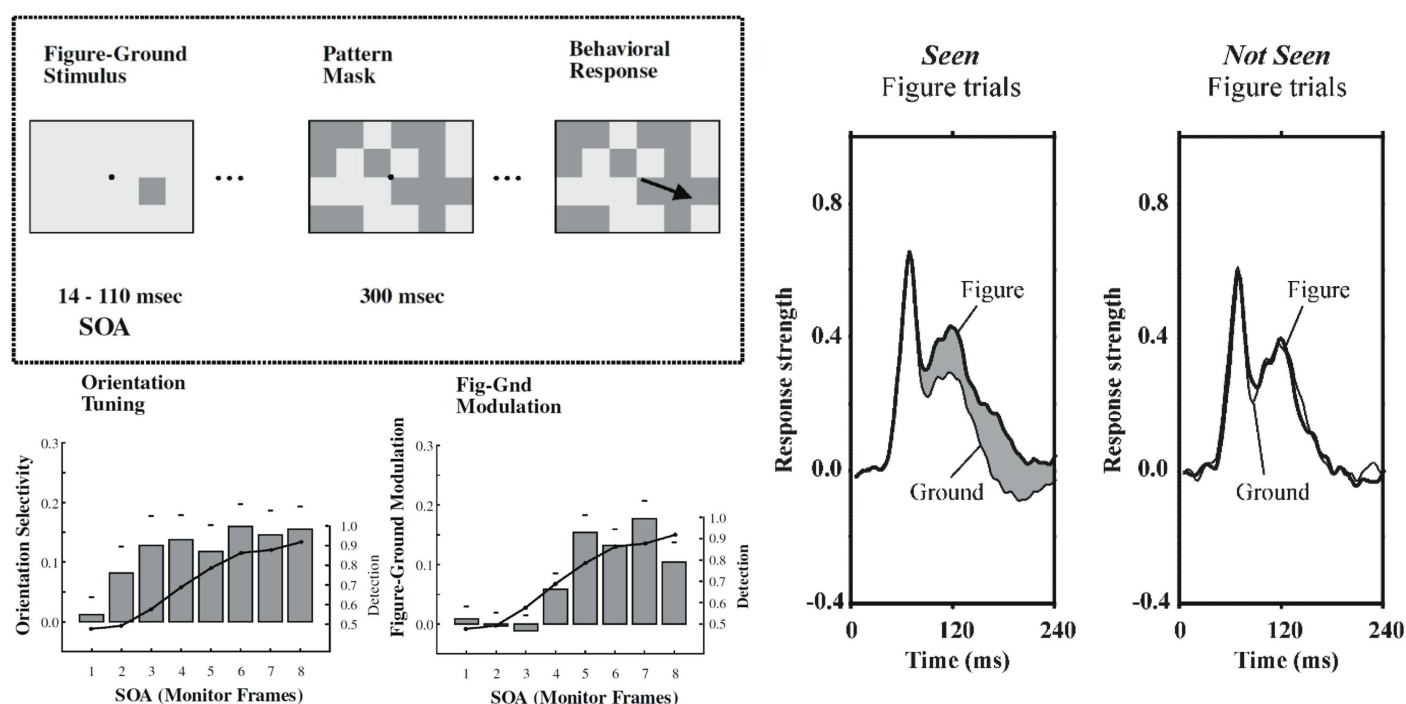

Figure 8: Left, above: textured figure-ground squares (like shown in figure 5) were presented either left or right of the fixation spot, and monkeys had to indicate their position with an eye movement. The figure targets were masked with a pattern of randomly-positioned texture squares. Left, below: the graphs show—for different SOA's—the ability of monkeys to correctly identify the position of the squares (line graph) versus the strength of either orientation-selective responses or figure-ground modulation (bars). Monkeys do not see the figures at SOA's of up to 3 frames (~50ms), and likewise, contextual modulation is absent in those cases, whereas orientation selectivity is not (Lamme et al. 2002). Right: monkeys had to indicate the presence or absence of textured figure targets by making an eye movement or deliberately maintaining fixation. When figures were not seen, contextual modulation was absent (Supér et al. 2001).

showing that lower level classification was still present for unseen orientations (Lamme et al. 2002). Similar results were obtained in human subjects using EEG responses (Fahrenfort et al. 2007).

Contour grouping, as displayed in figure 7, is particularly susceptible to masking. When these displays are temporally alternated, so that each element rotates 90° in successive displays, a strong masking effect is observed.²⁴ Depending on the angle between elements forming a contour, visibility drops to chance at alternation frequencies between 12 and 1Hz. This implies that the integration of these contours takes between 80 to 1000 ms (Hess et al. 2001).

Zipser used dichoptic masking to render orientation-defined figures invisible. Figure-

ground stimuli like those of figure 5 were shown to the two eyes of awake and fixating monkeys, yet with opposite orientations in either eye. As a result, the dichoptically-fused image consisted of cross-like elements, in which a figure was no longer visible.²⁵ Figure-ground modulation was absent in this case (Zipser et al. 1996). In a similar experiment in human subjects, Fahrenfort used face stimuli that were defined by oriented texture differences. A face was present in each image presented to the two eyes. Yet when binocularly combined, the face disappeared in the fused percept. He compared the neural signals obtained for such stimuli to responses to similar stimuli where binocular fusion resulted in a vis-

²⁴ This manipulation is a combination of backward and forward masking, and also somewhat reminiscent of dichoptic masking, in that in subsequent displays images with the opposite orientation contrast are shown. See the two images of figure 9, but then not presented to the two eyes but in rapid alternation.

²⁵ A similar setup was used in the curious case of alleged "blindsight in normal observers". In one of the experiments in that paper, target figures were made invisible using the same manipulation of dichoptic presentation of orthogonally-oriented elements. It was claimed that despite their subjective invisibility, subjects were able to localize the targets above chance, just as blindsight patients do for unseen stimuli (Kolb & Braun 1995). The findings were not replicated, however (Robichaud & Stelmach 2003).

ible face (figure 9) (Fahrenfort et al. 2012). A striking finding was that visibility (although rigorously checked behaviourally) had no effect on the ability of the Fusiform face area to distinguish between face and non-face stimuli, once more corroborating the independence of categorization responses and consciousness. In addition, invisible face stimuli could be classified from neural responses when training the classifier on visible stimuli and vice versa. The difference between visible and invisible binocular faces was found in the fact that visible faces evoked strong recurrent interactions between the FFA and earlier visual areas, both expressed in the fMRI signal (assessed using psychophysiological interaction analysis with the FFA as a seed), as well as in the EEG signal (showing a larger amount of theta, beta and gamma synchronization, and the presence of figure-ground modulation only in the visible condition).

The most direct relation between contextual modulation and consciousness was perhaps demonstrated by Supér et al. (2001). Monkeys were shown oriented texture figure-ground targets at different locations, and had to signal their presence by making an eye movement towards their positions. Importantly, however, in 20% of the trials, no figure was presented at all, and the monkeys had to maintain fixation on those catch trials for the duration of the stimulus.²⁶ Indeed the monkeys refrained from making eye movements on catch trials (as they were trained to do). But also on some 8% of trials in which a figure *was* presented they maintained fixation, as if to say “I did not see a stimulus here”. There was a striking difference in the level of contextual modulation for seen versus not-seen figure targets: modulation was fully absent for not-seen figures (figure 8). Seemingly, on some trials contextual interactions spontan-

eously fail to develop, and the result is that figure targets were invisible.²⁷

That brings us to the question of neural mechanisms. Seemingly, the visual functions of perceptual organization, grouping according to Gestalt laws, and figure-ground segregation all depend strongly on the conscious state, and on the objective (or subjective) visibility and perceptual interpretation of the stimulus. Do these functions have similar neural mechanisms? There has been much debate on the neural connections underlying contextual modulation effects. Given the latency of the effects (typically several milliseconds after the initial categorization or feature response) it was originally hypothesized that they depended on feedback signals from higher-level visual areas (e.g., V4, IT, MT, etc.) toward lower levels (e.g., V1, Zipser et al. 1996). Experiments using cooling or lesioning of higher-level areas gave mixed results. Local inactivation of V2 using GABA injections had no effect on short- to medium-range contextual effects in V1 (Hupé et al. 2001). Cooling area V5/MT, on the other hand, had effects on figure-ground signals in V1, V2, and V3 (Hupé et al. 1998). These effects, however, worked on the early part of the response, and were evoked using stimuli where segregation depended more on contrast differences than on the long-range integration of information (Bullier et al. 2001). Others also found figure-ground effects that were faster than those discussed here (Sugihara et al. 2011). There is thus a whole range of contextual effects, some of which are faster than others, and some of which may depend on feedback while others do not.

There is one counterintuitive aspect of interpreting these results in this way: in fact, feedback connections are not slow, but just as fast as feedforward connections, where both are at about 3.5 m/s (Girard et al. 2001). Horizontal connections that run via unmyelinated fibres in layers 2 and 3 of the cortex are about 10 times slower (Sugihara et al. 2011). Many of the Gestalt principles of perceptual organization

²⁶ This paradigm has been shown to distinguish between seen and not-seen stimuli in monkeys with a V1 lesion in one hemi-field, and was used to differentiate between “conscious” visual responses and unconscious blindsight behaviour: without catch trials (i.e., when in forced choice mode), monkeys react to both stimuli in the intact and in the lesioned field, expressing blindsight capabilities. In catch trials, however, monkeys only respond to stimuli in the intact and not in the lesioned hemi-field, as if expressing conscious sensation instead of a mere reflex (Moore et al. 1995). Supér et al. used the same paradigm in intact monkeys to assess conscious percepts of figure-ground stimuli.

²⁷ A later investigation into neural activity preceding either seen or not-seen figure trials showed that not-seen trials are preceded by somewhat lower level of spontaneous activity, and also express less inter-neuronal synchrony (Supér et al. 2003; Van der Togt et al. 2006).

Invisible fusion

Faces > Houses & Nonsense

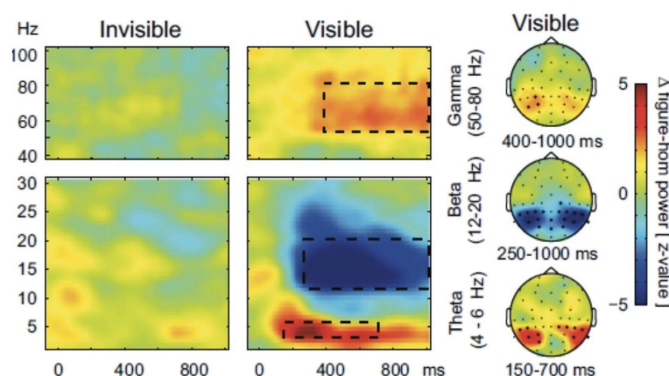

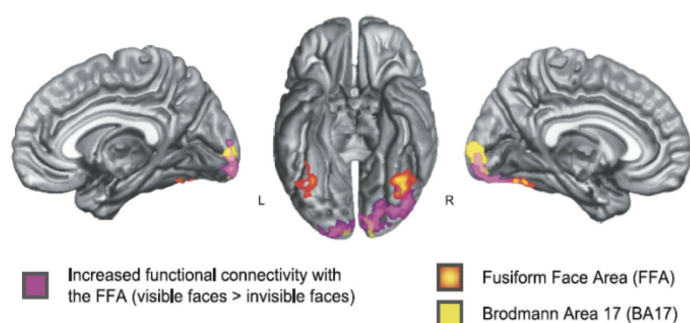

Figure 9: Top left: texture-defined faces were presented in either eye of subjects, yet with different orientations of line segments. As a result, the face was not visible in the fused percept (compare manipulation of figure 1). By using other orientation combinations, the same design could also result in a visible face (not shown). Top right: category-specific responses in the FFA did not differ for visible or invisible faces. Below: visible faces are characterized by strong recurrent interactions between FFA and earlier visual areas (left), and by strong synchronous activity in the theta, beta, and gamma bands (right). From: [Fahrenfort et al. \(2012\)](#).

are, however, embedded in these slow horizontal connections: V1 cells with a similar orientation preference are selectively interconnected via so-called patchy horizontal fibres. Moreover, these interconnections are strongest for oriented cells that have their receptive fields aligned along their orientation preference. Horizontal connections are also strongest between nearby cells ([Gilbert & Wiesel 1989](#); [Malach et al. 1993](#); [Bosking et al. 1997](#)). As such, these horizontal connections thus form the neural substrate of the well known Gestalt rules of “similarity”, “collinearity”, and “proximity”. A similar arrangement of preferred interconnectivity has been found for motion-direction selective cells in MT ([Ahmed et al. 2012](#)), potentially forming the substrate of the grouping principle of “common fate”. Neurophysiological correlates of these

grouping principles are relatively fast, however ([Knierim & Van Essen 1992](#); [Kapadia et al. 1995](#)).

The figure-ground segregation effects of figures 5, 6, 7, and 8 are among the longest latency contextual effects reported. That may be because they depend on both horizontal and feedback connections. Figure 10 shows the result of an experiment where the complete peristriate belt of visual cortex surrounding V1 and V2 was subjected to suction lesioning, removing (parts of) areas V3, V3A, V4, V4t, MT, MST, FST, PM, DP, and 7a ([Lamme et al. 1998b](#); [Supér & Lamme 2007](#)). Before the lesion, an oriented texture figure-ground stimulus evoked elevated activity in all neurons responding to the figure elements. Response modulation was even somewhat stronger, and occurred earlier at

Figure 10: Contextual modulation (i.e., figure-ground responses, see figure 5) for various positions of the receptive field of V1 neurons (vertical axis), and extending over time (horizontal axis). In an intact monkey, modulation arises first at the figure-ground boundary, followed by a “filling-in” of the boundaries. After a lesion to the peri-striate belt of the visual cortex, only the boundary modulation remains, while filling-in has been abolished (Lamme et al. 1998a).

the boundary between figure and background. This was followed by a sort of “filling in” of enhanced activity between the boundary regions. We thus see an incremental process, starting with boundary segmentation and followed by surface segmentation. Similar findings have been reported in humans using combined EEG and TMS (Wokke et al. 2012).

After the lesion, the boundary enhancement remained, which may indicate that texture boundary detection mechanisms do not depend on feedback from higher visual areas and hence are mediated by horizontal connections within V1, or by recurrent interaction with V2. The centre modulation, where the figure elements are “neurally elevated” from the background elements, was completely abolished after the lesion, indicating that these figure-ground signals do depend on recurrent interactions between V1 and higher-tier areas. This finding was modelled on a realistic neural network of spiking neurons, indeed formalizing the idea that local orientation contrast—and hence the boundary between figure and ground—is mediated by inhibitory horizontal interactions between oriented receptive fields, whereas the figure-ground signal depended on excitatory feedback interactions trickling down from higher to lower areas (Roelfsema et al. 2002). Recently, laminar recording of figure-ground signals in V1 confirmed this idea (Self et al. 2013). These results show

that the long-latency figure-ground segregation effects depend on incremental interactions mediated by both horizontal and feedback connections. That may be the reason why they are most vulnerable to anaesthesia, masking, and other manipulations of consciousness.

Tononi modelled several neural architectures in order to find the connection parameters that fulfil the requirements for achieving maximally-integrated information. The optimal architecture consists of neurons that each have specific and different connections patterns, yet are sufficiently interconnected for each neuron to be able to connect to another via a few steps. Uniformly, or strictly modularly organized networks are less optimal. The thalamo-cortical system fits these requirements very well. On the one hand, neurons should be interconnected, otherwise information is not integrated. On the other hand, too much interconnection leads to a loss of specific information, as all neurons start doing the same thing, which happens in epilepsy or deep sleep—states that are indeed accompanied by a loss of consciousness (Tononi 2004, 2008, 2012). The contextual modulations that have been explored here seem to exactly express these properties: on the one hand, the neural responses are very specific, in that the major part of the response is driven by the features that are within the (small) receptive field. But on the other hand, the integration of these

Function is Present
 Conflicting Results
 Function is Absent
 Unknown

Figure 11: Table summarizing the influence of consciousness manipulation on various visual functions. Colours indicate whether functions (rows) still operate under a particular manipulation (columns). In the case of conflicting or uncertain evidence (yellow), the cases or conditions where the function still seems present is written in green; the cases where the function is absent are written in red. All functions are assumed to be present in conscious vision. For each visual function, an icon depicts its most prominent example. See text for explanation.

features ride on top of that response as a moderate modulation, expressing perceptual integration that may cover a large spatial extent, yet never even beginning to fully override the information carried by the neuron. In other words, visual neurons have categorization as their main priority, yet they also integrate these categories at some point in their response. That is the moment in time where the seed for conscious perception is laid (Lamme 2003, 2006, 2010a, 2010b).

8 Is there a functional boundary between unconscious and conscious vision?

I have taken the two extreme ends of consciousness manipulation: clear-cut visible and above-threshold items in awake subjects veridically reporting their visual experiences versus visual processing in anaesthesia, blindsight, or during profound masking or suppression (figure 11). If we don't accept conscious vision in the former, and the absence of it in the latter, there is no use arguing about the phenomenon of con-

sciousness. Even so, it has been surprisingly hard to find fundamental differences in the workings of many visual functions in the two conditions. Categorization of visual stimuli, even up to high levels, clearly stands independent of conscious visibility. It is unclear whether interference—i.e., the fact that features are no longer treated independently—depends on consciousness: shifts in brightness perception do not depend on consciousness, while it is uncertain whether the transition from wavelength to colour perception (and colour constancy) marks the conscious-unconscious divide.²⁸ Similarly, the status of inference phenomena like those observed in the Kanizsa triangle is uncertain.

This is all the more surprising given that many of these functions have traditionally been viewed as expressing the transition from merely physical features detected by sensor arrays towards the perceptual interpretation of this in-

²⁸ Yet this transition may be the “Holy Grail” for those willing to understand qualia—or at least for those believing in “soft qualia”, i.e., phenomenal properties that are not entirely detached from visual functioning, and having some sort of neural substrate (Block 1996, 2005, 2007).

formation. Moreover, they mark the integration of stimulus-driven input with our knowledge of the world, such that we arrive at visual “meaning”. Recently, there has been quite some interest in so called predictive coding frameworks of vision (Rao & Ballard 1999; Panichello et al. 2012). In these frameworks, vision is seen as a type of Bayesian inference, where our prediction (prior) of the outside world is continuously matched with our sensory input, and where the difference is propagated through the network as an “error signal”, which then results in an updating of the model (posterior). Indeed, expectations bias our perception of the world, most strongly in the face of ambiguous stimuli, but also in the case of unambiguous stimuli (Panichello et al. 2012). Although it has been suggested that either the matching process, the prior, or the posterior in this type of inference have some relation to consciousness,²⁹ this is questionable given the automaticity of many expectation effects. For example, the mere statistical dominance of a particular stimulus type is sufficient to bias perceptual interpretations (Chopin & Mamassian 2012). Also, expected words break from continuous flash suppression sooner than unexpected words (Costello et al. 2009).³⁰

All in all, the relation between consciousness on the one hand and categorization, interference, and inference processes on the other hand ranges from non-existent to weak. A much stronger case seems possible for functions like the grouping of image elements according to Gestalt laws and figure-ground segregation. These operations seem to depend strongly on the conscious state, and on conscious perception of the stimuli involved (figure 11). This is surprising, given their relative “simplicity”. For example, the grouping of similarly-oriented or col-linear line segments may be achieved by horizontal connections in the primary visual cortex (Bosking et al. 1997, see above). Figure-ground

segregation—and its neurophysiological correlate—has been successfully modelled in a recurrent network architecture consisting of orientation-selective visual neurons in three hierarchically-organized visual areas, combined with some inhibitory horizontal interactions and excitatory feedback (Roelfsema et al. 2002). Regardless, the experimental data clearly show that if we want to identify visual functions that mark the transition from unconscious processing to conscious vision, grouping according to Gestalt laws (incremental grouping) and figure-ground segregation³¹ (or perceptual organization in general) are our best bets.³²

9 Is it all about distance, or time?

So why do Gestalt grouping and segregation bear such a close relation to consciousness? From a neural perspective, they differ from most other functions in that they depend on interactions between neurons at rather large distances. For example, for a neuron to “know” whether it sits on the figure or the background of the stimulus in figure 5, information has to travel over a distance of about 20 millimetres in the visual cortex.³³ Moreover, the modulations of neural activity that accompany this “knowing” depend on the incremental push-pull interactions between horizontal and feedback connections (Lamme & Roelfsema 2000; Roelfsema et al. 2002; Roelfsema 2006). These require quite extensive processing steps, given that the con-

³¹ Of course one could argue that in the case of a face on a blank background there also is figure-ground segregation. This type of segregation clearly does not depend on consciousness. This touches on the debate on whether categorization is possible without segregation (Wagemans et al. 2012).

³² A promising theory of consciousness holds that conscious representations and states are characterized by the integration of information, or more precisely, on the formation of complexes of integrated information (Tononi 2004, 2008, 2012). That integrated information characterizes consciousness is, however, mainly derived from a set of axioms and introspective or intuitive thought experiments, most of which have already been discussed in the previous text or footnotes (Tononi 2012). What this review of experimental findings however shows is that the “integration of information” comes in many guises, not all of which are equally strongly related to consciousness. A somewhat more precise definition of “integrated information” may be guided by these experimental findings.

³³ The figure is 4 degrees of visual angle wide. Neurons in human V1 with receptive fields at that distance are about 20 mm apart, given a cortical magnification factor of 0.2 degrees per millimetre at 2.0 degrees eccentricity (Duncan & Boynton 2003).

²⁹ In my reading, the predictive coding models are sometimes rather vague about exactly which signal mediates conscious experience. It is often seen to be a combination of the matching process and the posterior, e.g., Seth et al. (2011).

³⁰ But note that this is in fact nothing more than a semantic priming experiment. The results primarily show that if a semantic category has been activated, this category will then break earlier from CFS.

textual Gestalt effects typically manifest themselves at long latency.

Intuitively, seeing an illusion like the Kanizsa triangle, or the contextual shifts in brightness or colour perception discussed above, also seems to depend on “long range” interactions: information travels over large distances in the visual field. But distance travelled over the visual field does not always equal distance travelled in the brain. These phenomena may depend on fairly hardwired and feedforward mechanisms, and their neural correlates typically have relatively short temporal latencies (Von der Heydt et al. 1984). Seemingly, these phenomena tap into mechanisms that have high ecological relevance to the visual system, and are hence solved in a few processing steps, using dedicated feedforward mechanisms. The same holds for all categorization responses in the brain, regardless of their apparent complexity: the progression from low-level to high-level feature detection (including categorization of faces or other complex stimuli) proceeds in a feedforward “sweep” that lasts 100 ms or less (Lamme & Roelfsema 2000).

What emerges is the nagging feeling that consciousness has nothing to do with the seeming complexity or “high-levelness” of a visual function. Whether a visual function depends on consciousness may simply be related to the amount of space that has to be travelled in the brain, how many processing steps have to be taken in between, and hence how much time it takes to complete. This converges onto a thesis that we may call:

The STERP-property of phenomenal representations $=_{\text{DF}}$ conscious representations depend on the spatio-temporally extended neural processing mediated by recurrent interactions.

What that extent is remains to be specified, but has been studied directly by Faivre & Koch (2014), who measured the effects of stimuli made invisible using CFS on the perception of subsequent visible stimuli. Both for apparent motion and for biological motion walkers, it was found that unconscious motion integration only

occurred for relatively short (100 ms) and not for longer (400, 800, 1200ms) temporal intervals. Meng et al. (2007) observed that neural signals representing the spatial filling-in of a grating over a gap in the visual field depended on conscious experience of the grating.³⁴ This suggests that for visual information to literally “bridge a distance” across the visual field, consciousness is required.

The importance of the spatial and temporal extent of neural processing in consciousness also emerges from an entirely different field: that of disorders of consciousness. It is generally believed that there is a gradual decrease of consciousness from the healthy awake state towards minimally conscious, vegetative state and coma. These states also show a gradual decrease in the extent of neural interactions, in both space (Casali et al. 2013) and time (Bekinschtein et al. 2009). Particularly striking is the finding that the presence or absence of consciousness (in this case: the difference between minimally conscious and vegetative state patients) could be classified by simply looking at the amount of “shared symbolic information” in the EEG³⁵ at various distances in the brain. Shared symbolic information at distances of 10 cm and beyond signalled the presence of consciousness, and moreover was indicative of the prognosis of vegetative state patients (whether they would eventually awaken or not). Strikingly, this measure hardly depended on the location of the interactions (King et al. 2013). In other words, whenever and wherever neurons share information at distances of 10 cm or more, there is consciousness.³⁶

Both distance and time are continuous. Arguing that consciousness is related to the temporal or spatial extent of neural processing therefore almost automatically seems to imply that the transition from unconscious to con-

³⁴ It did not depend on attending the grating, however, which is of relevance to the discussion on the relation between attention and consciousness. See below (Lamme 2003, 2004, 2006, 2010a, 2010b).

³⁵ At each electrode, EEG signals were first transformed into symbolic shapes (e.g., up-down-up) for various temporal intervals. Then it was determined to what extent these EEG “symbols” covaried between electrode pairs of various distances, after the exclusion of covariance that was caused by simple volume conduction.

³⁶ Which made me wonder whether any piece of cortex of 10 cm or larger that is held on life support in a petri-dish might have consciousness.

scious processing is gradual rather than discrete. This is not necessarily so, however. Recurrent processing is mediated by highly non-linear interactions, and in such interactions, rather discrete phase transitions are possible (Steyn-Ross et al. 1999; Del Cul et al. 2007; Hwang et al. 2012). It could thus very well be that there is a discrete transition from a phase where information integration is rather limited to a phase that is characterized by extensive information integration, and that this transition depends on the temporal or spatial extent of recurrent interactions.³⁷

Whether the transition from unconscious to conscious processing is discrete or continuous has been argued on different grounds, such as on the distribution of behavioral responses (“seen” versus “not seen”) in relation to manipulations of stimulus variables (Sergent & Dehaene 2004; Overgaard et al. 2006). In signal detection theory, the strength of perceptual information is considered to be continuous, while the decision criterion imposes a discrete boundary between what is reported as “seen” or “not seen”. In its classic form, however, signal detection theory is agnostic about whether consciousness is pre- or post-decisional. Recently, many attempts have been made to incorporate consciousness into the framework of signal detection theory, and in many of these models consciousness is considered post- rather than pre-decisional (Maniscalco & Lau 2012; King & Dehaene 2014)—thus the boundary between the conscious and unconscious is taken to be discrete. Based on neurophysiological findings in the monkey visual cortex, a signal-detection model was devised in which consciousness was considered pre-decisional. In this model, the distribution of sensory information was considered bi-modal, reflecting either a conscious or an unconscious state. The model could explain both the behavioral and neurophysiological findings in the monkey visual cortex, obtained using a variety of stimulus strengths and decision cri-

teria (Supèr et al. 2001). Note that also in this pre-decisional model the conscious–unconscious divide is discrete (or at least bi-modal), rather than gradual.

10 The function of conscious vision

Could it be that Gestalt grouping and figure-ground segregation (of textured images) only happen to go along with consciousness because they take more time; because they require more elaborate computations, not provided by the many dedicated feedforward pathways and modules of the brain? Normally, vision proceeds in a fast and feedforward fashion, where dedicated neurons detect features and categories. Using its hardwired connections, the visual system can swiftly detect the most relevant objects: food, mates, or dangerous animals. Some objects are more difficult to discern, and require prior knowledge or the computation of neighbourhood relations between image elements: food behind a leaf, a sweet versus a sour apple. That takes slightly more—but not too much more—time, because many of the required interactions are hardwired as well. They are hardwired because the visual system has been exposed to these “visual problems” very often, either during evolution or during visual experience. Then there are visual problems that are even more difficult: a camouflaged animal in a crowded forest (figure 7), only visible via subtle differences in overall texture or motion. In this case, all visual resources and mechanisms have to come to the rescue. Only by combining the input from many neurons in a versatile way can the visual “solution” be found. That may be the function of consciousness in the visual domain: to combine the otherwise unconscious modules and mechanisms in a flexible way so as to solve otherwise unresolvable visual problems leading to a second thesis that we may call:

The SUPER-property of phenomenal representations =_{Df} neural representations require consciousness and invoke phenomenality as soon as what needs to be represented can no longer be represented by a single dedicated module or mechanism, yet

³⁷ It could even be that the mere fact that information exchange extends over a particular time and space is critical for that exchange to be accompanied by a conscious sensation. When the same amount of information would be exchanged much slower — as in plants — or much faster — as in a supercomputer — or over a smaller or larger space (as in a microchip or over the internet) no conscious sensation ensues.

requires the interaction of these modules so that a super-positioned representation emerges.

From the point of view of consciousness, a hierarchy of visual functions can then be made. This starts with largely unconscious feature detection and object categorization. These features start to influence each other, and are no longer treated independently, so that categories form that are about the relations between image items (base groupings, short range incremental grouping). With this, there is a transition from the physical properties of the visual input as they are presented to the sensor array to the meaning³⁸ of these properties (e.g., wavelength to colour). During these operations, features and categories are matched with our knowledge and expectations of the world, embedded in the anatomical organization of the visual cortex, aiding in the transformation from visual input towards meaning (inference). Finally, all this information is combined into an organized percept. The longer these operations take, the more distance has to be travelled in the brain, and the more conscious these operations become.³⁹

If nothing interferes, the visual system will always strive towards optimally integrating the available information, so that the richest interpretation of all available information is achieved, and all features have been detected, all inferences have been made, all image elements are combined and all potential ambiguities have been resolved. If this process is cut short, for example by masking or a TMS pulse (Pascual-Leone & Walsh 2001; Silvanto et al. 2005), there is no integrated end-result. And seemingly there is no conscious sensation either. Regardless of this, many features have still been detected, many inferences have been made, and

the brain can use this information to achieve its goals. Behaviour may be influenced, or set into motion (Dehaene et al. 1998). Priming will occur, as well as all sorts of unconscious cognition (Van Gaal & Lamme 2012). Without consciousness, and without maximal integration, the visual system is far from helpless. It can do less, but it can still do a lot.

From this perspective, the function of consciousness in vision is just to enable that last push. That is, to resolve the visual issues that cannot be dealt with otherwise.⁴⁰ And with that, visual functions grow more complex, and evolve from their basic form into more sophisticated versions. A good example comes—once again—from the processing of faces. The core property of face-selective neurons is to respond in a category-selective manner: they distinguish between faces and other objects. They do so from the very first action-potentials that are fired. At that moment, however, category specificity is still very basic, in the sense that all types of faces evoke a similar response (Rolls 1992). At a later moment in time, however, responses typically become more and more specific. In the monkey visual cortex, face cells distinguish between different viewpoints and different emotional expressions of faces with a delay of about 50 milliseconds relative to the categorical face/non-face response (Sugase et al. 1999). View invariant identity representations arise even later, with a delay of about 200 ms (Freiwald & Tsao 2010). At these delays, the face-selective neurons will have established recurrent interactions with lower (and higher) level neurons across the brain, allowing for these more sophisticated classifications to be expressed in the response.

We may thus conclude that face recognition “as we know it”—i.e., not just categorizing face versus non-face, but seeing that face, knowing what it looks like, who it is, and what emo-

³⁸ Note that “meaning” in this context refers to the meaning information has to the organism, shaped by and in accordance with its evolutionary history and ontogenesis (like colour has the “meaning” of the edibility of fruit). It does not refer to “meaning” in any linguistic sense.

³⁹ That may explain why two seemingly similar phenomena like the brightness and colour shifts of figure 2, and the arrival at colour constancy in figure 3 are depend on consciousness in different ways. Colour constancy requires the computation of the full distribution of wavelengths over the entire image, which takes more time than the computations required to compute brightness of adjacent patches.

⁴⁰ Maybe that is the reason why the transition from unconscious to conscious processing also marks the transition between veridical and inferred representations (e.g., from wavelength to colour). Dedicated modules can do their thing in isolation, and therefore have no need to compromise towards a non-veridical representation of the outside world. When modules interact, the necessity may arise to compromise veridical representations to achieve global coherence into the combined super-positioned representation that cannot be represented otherwise.

tion it carries—is a visual function tightly linked to conscious rather than unconscious vision. The main reason for this lies in the fact that in conscious recognition we go beyond simple categorization, and move towards a function where the integration of all possible information about that face (its viewpoint, colour, identity, emotional expression, etc.) is required.

This may raise the question of how we then become conscious of an extremely simple stimulus, such as an oriented black line on a completely white background. With such a simple stimulus, there seems to be no need for any elaborate binding, incremental grouping, or inference. Neurons in the primary visual cortex can detect the line and its orientation within a few action potentials. There seems to be no need to call in the functions that are enabled by conscious processing. So why is it, then, that we still see the black line on the white background?

First, it should be noted that the notion of “simple” stimuli is more complex than one would expect. For example, it was shown that subjects can rapidly detect animals or vehicles in complex natural scenes, even when their attention is simultaneously focused on another task. Discriminating large T’s from L’s, or bisected colour disks from their mirror images was impossible under the same dual task paradigm. Apparently, seemingly simple letter or disk stimuli require more attentive processing than seemingly complex natural scenes (Li et al. 2002), suggesting that they take longer and more elaborate processing. In blindsight, subjects can discriminate lines of different orientations, suggesting that conscious processing is not required for these simple stimuli. However, discrimination performance—although above chance—is typically worse than for consciously-seen line segments, suggesting that something is “missing” from the neural representations formed in blindsight compared to those in conscious vision.

So what might the more elaborate processing steps that lift the unconscious representation of a black line towards a conscious representation of that line be? First, it is known that neurons in many visual areas beyond V1 respond to orientated line segments. At each level,

receptive fields, and hence spatial frequency preferences, differ. This means that (the orientation of) the line segment is represented at many different spatial scales across the visual cortex. Only the integration of these differently-scaled representations, via recurrent interactions, yields a precise and conscious representation. The same holds for other properties of the “simple” line segment, such as its colour, its depth, and its relation to the background.⁴¹ Indeed, oriented lines are fairly easy to mask (in fact easier than faces), indicating that their conscious percept depends on more elaborate processing steps than expected for such a simple stimulus.

11 The impact of conscious vision on the brain

If a particular visual problem has to be dealt with often, the brain will start to build connections so that the problem can be resolved more rapidly. Visual problems that require long and elaborate processing will eventually be resolved in milliseconds. By building new and dedicated connections, elaborate processing steps may be simplified into a fast and short set of interactions. Conscious processing will turn into unconscious processing, because conscious processing has triggered perceptual learning that in turn evokes synaptic changes that create new “dedicated modules” that can do the job unconsciously. This leads to a third thesis:⁴²

The LEARN-property of phenomenal representations =_{Df} neural representations that require consciousness and invoke phenomenality, at the same time evoke synaptic plasticity mechanisms and learning,

⁴¹ Even something as simple as a white background will give the black line another visual “meaning” than a yellow background, a green background, or a textured background. The same point has been formulated by Giulio Tononi (2004, 2008, 2012): a conscious representation is conscious because it differentiates from the endless other potential representations that could have been. In this case: the oriented black line on the white background is one of the endless possible configurations of lines on backgrounds, and only by integrating the information of line and background is it known which of these configurations is actually present.

⁴² Similar ideas exist in the context of motor learning: a task that first requires extensive conscious practice will gradually become more and more automatic, up to the point where it can be executed fully unconsciously.

in an attempt to make these representations less dependent on consciousness and invoking less phenomenality.

Indeed, there are several arguments for linking consciousness to perceptual learning. Plasticity in the visual cortex comes in many temporal and spatial scales. There are fast- and short-range adaptations or recalibrations, expressed in altered stimulus-response dependencies (e.g., contrast normalization). But receptive fields may also change in size or feature selectivity when exposed to repeated stimulation. Receptive fields literally grow or shift position when their surrounds are stimulated but the receptive field is not (Gilbert & Wiesel 1992). Prolonged depletion of input leads to the induction of new connectivity via fast axonal sprouting of horizontal connections (Yamahachi et al. 2009). Horizontal connections in particular play an important role in both immediate and longer term plasticity of the visual cortex (Gilbert et al. 1996). The repeated execution of Gestalt grouping via the same connections may therefore induce learning (Gilbert et al. 2001), as, for example, is observed in the learning of texture segregation (Karni & Sagi 1991) or in the gradual improvement of contour integration during childhood development (Kovács et al. 1999). In addition, perceptual learning induces a reorganization of the areas involved in encoding the learned object—a process that is mediated by feedback connections (Sigman & Gilbert 2000; Sigman et al. 2005). It seems that the neural machinery that mediates Gestalt grouping and segregation is also the machinery that mediates perceptual learning.

Furthermore, feedback and horizontal connections have been linked to the molecular mechanisms of neural plasticity. A key component in neural plasticity is the NMDA receptor pathway, and in the monkey, NMDA receptor blocking using APV reduces contextual figure-ground modulation (Self et al. 2012). Similarly, in humans, figure-ground segregation is impaired using Ketamine, an anaesthetic which selectively blocks the NMDA receptor at low doses (Meuwese et al. 2013). Also, it was found that Ketamine at sub-anaesthetic doses inter-

feres with the learning of Mooney figures. Mooney figures are high-contrast versions of images that are hard to recognize when you don't know what the image is about. Once you have seen its original natural contrast version, however, the Mooney image is readily recognizable. It was found that the neural representation of Mooney images starts to resemble that of their natural versions once they are learned. Ketamine disrupts this rapid learning process, but only in V1, and not in higher visual areas, indicating that feedback from higher areas to V1 is selectively disrupted by Ketamine (Van Loon et al. submitted).

In sum, there are strong indications that link conscious visual processing and its neural machinery—horizontal and feedback connection—are linked to perceptual learning and the molecular mechanisms involved. This may open up a path to a more molecular understanding of consciousness. In addition, it provides us with a clear idea about the function of consciousness: that of building a new repertoire of visual functions, so that eventually conscious processing is no longer necessary.

It must be noted however, that the link between consciousness and learning is controversial. Many instances of “unconscious” perceptual learning exist (e.g., Gutnisky et al. 2009; Seitz et al. 2009; Seitz & Watanabe 2003; Schwiedrzik et al. 2011). An important issue here, however, is whether these are cases of learning without conscious experience of the stimuli that induce the learning, or whether they are instances of learning without cognitive access or attention to these stimuli (see Meuwese et al. 2013). A further clarification of the role of consciousness in learning is required.

12 The dolphins of consciousness research

I have examined the defining characteristics of conscious versus unconscious vision. Incremental grouping and segregation according to Gestalt laws seems to be a defining characteristic of conscious vision. Other visual phenomena and functions, like interference or inference, are less

strongly linked. Feature detection and higher-level categorization clearly do not mark the transition from unconscious to conscious vision. From a neural perspective, it can be argued that conscious processing is linked to those operations that require spatially and temporally extended processing, where neurons engage in incremental interactions involving many steps. These processes are selectively dependent on horizontal and feedback connections. Moreover, these interactions induce learning, as they operate along highly plastic neural pathways, and use the molecular machinery that is directly involved in neural plasticity.

We can now start using these defining characteristics to answer more difficult questions. Is there consciousness in the right half-brain of a split brain patient (Sperry 1984)? Is there consciousness without attention (Koch & Tsuchiya 2012)? Is there consciousness in neglect or extinction (Lamme 2003)? Is it appropriate to talk about inattentional “blindness”, where people do not remember having seen something while their attention was engaged elsewhere? What exactly happens during change blindness (Simons & Rensink 2005)? Is there consciousness in animals (Edelman & Seth 2009), or in a vegetative state (Owen et al. 2006)? These are the “dolphins” of consciousness research, situations that are hard to position in the current taxonomy of conscious versus unconscious, because much controversy exists about the presence or absence of conscious experience in those conditions. With this, I hope to have given some usable arguments that can settle such controversies. My claim would simply be that whenever we see the defining properties of conscious vision that have been laid out here (i.e., incremental Gestalt grouping and segregation), there is conscious vision, regardless of whether there is conscious access or report (e.g., Scholte et al. 2006). More in general, the more fruitful stance towards consciousness would be to let all the available evidence converge into general theses, such as those derived here, and then take these as the defining characteristics of conscious processing and consciousness, regardless of whether they fit our introspective intuition of

what consciousness is or should be. Defining consciousness as the process that builds on spatio-temporally extended neural processing (**STERP property**), that enables the building of super-positioned representations that individual modules cannot provide (**SUPER property**), and that evokes synaptic plasticity and learning (**LEARN property**) yields clear defining characteristics. These characteristics go a great length towards elucidating important features of phenomenality (its integrated nature, Gestalt properties), towards explaining the nature of conscious experience (perceptual organization, interference, inference), and are hinting towards a potential function of consciousness (learning) and its molecular basis. What I consider irrelevant characteristics (such as the ability to report about an experience, see Lamme 2010a, 2010b) generally do no such explaining. It is better to build a taxonomy of conscious versus unconscious processing on defining characteristics than on irrelevant ones. That has helped a lot in positioning dolphins in the taxonomy of species. It will also help a lot in positioning the wild amalgam of phenomena that the field of consciousness research has produced so far. And it will enable us to give consciousness its proper ontological status. But I have already contributed to that discussion extensively elsewhere (Lamme 2003, 2004, 2006, 2010a, 2010b), so I will lay that to rest here.

At the crack of dawn, something magical happens. Night turns into day, life springs, vibrations fill the air. We know, it is just the earth rotating. But a very fundamental transition it remains. Unconscious or conscious processing, it's all neurons doing their job, firing action potentials, exchanging chemicals, transferring information. But somehow, suddenly, they “turn on the light”. You see. You have a conscious sensation of that dawn. Isn't it beautiful? You should take a picture of it.

Consciousness as Inference in Time

A Commentary on Victor Lamme

Lucia Melloni

Unraveling the neural correlates of conscious remains one of the great challenges of our time. Victor Lamme proposes that neural integration through feedback loops is what differentiates conscious from unconscious processing. Here, I review his hypothesis, focusing on the spatial scale of integration as well as the possible neural mechanisms involved. I go on to show that any theory of the neural correlates of consciousness is incomplete if it cannot account for how prior knowledge shapes perception and how this form of integration occurs. Finally, I propose that integration across moments in time is a crucial but hitherto neglected aspect of conscious perception, which creates the “flow” of conscious experience.

1 Qualia 2.1: Integration is key but is it all?

Why do we see the way we *see*? How is our perception different from the way a photograph is acquired on the sensor chip of a digital camera? It seems obvious that we do not see an image made of individual pixels but an integrated, smooth, colourful, and vivid image. What is the neural substrate of this marvellous capacity that makes us feel and experience the way we do? These are the central questions that Victor Lamme sets out to address in his paper *The Crack of Dawn: Perceptual Functions and Neural Mechanisms that Mark the Transition from Unconscious Processing to Conscious Vision*.

This is by no means an easy task, even when one stays away from the difficult problem of qualia or “what it is like to be” (Nagel 1974). The question of how awareness arises has preoccupied philosophers and scientists for centuries, and while significant progress has been made in recent decades we are still far from reaching a conclusion (Dehaene 2014; Koch 2004). One thing is clear however: success in understanding the neural machinery that instantiates consciousness rests on identifying the fundamental features that characterise a state as conscious and that distinguish it from unconscious states.

A remarkable discovery of the past century is that a significant portion of all mental operations, including fairly complex ones such as decision-making and perceptual categorisation, can be carried out unconsciously. Take the case of language: while it seems effortless to understand the words that you are currently reading, you do not have conscious access to the syntactic processes that ultimately allow you to grasp the relations between the elements of this sentence and thus its meaning. These complex mental operations occur “behind the scene” of consciousness. Given that so many intricate processes can operate unconsciously, one cannot but wonder what consciousness is good for. Which mental processes *require* consciousness, if any? And if so, what really distinguishes conscious from unconscious cognition? Victor Lamme offers a stimulating and comprehensive review of processes in vision that can be performed outside the realm of awareness. The list is long and may be surprising (also see Kouider & Dehaene 2007), ranging from detection of simple (e.g., oriented lines) and complex features (e.g., faces; Almeida et al. 2013; de Gardelle et al. 2011; Del Zotto et al. 2013), to mathematical operations such as abstract comparisons between quantities (Greenwald et al. 2003), to triggering of motor plans (Dehaene et al. 1998), and even error-related responses to stimuli that fully escape our consciousness (Cohen et al. 2009).

What do we need consciousness for, then? Lamme proposes that consciousness is required when all sources of information need to be integrated. For instance, when we see a face, we can not only *detect* that is a face, a process that can be performed unconsciously, but also *identify* it as that of our friend Billy, whom we have not seen in ten years and that we *remember* warmly from our childhood. Consciousness brings this *unified* moment in which all comes together: previous experiences are retrieved from memory (e.g., do we have reason to like Billy?) and unified with the context of the current experience (e.g., where are we now?), but also intertwined with predictions for future actions (e.g., would we like to engage in a conversation?). Thus, in one single moment, past,

present and future come together and form a unified conscious experience. Many scientists nowadays agree that conscious experience provides an abstract summary of all available sources of information, from which many features are filtered out and reinterpreted in a format that is most useful for further actions, thoughts, deliberations, and chain operations that cannot be processed by non-conscious processors (Lamme this collection; Baars 2002; Dehaene 2014; Melloni & Singer 2010). Hence, what reaches our perception is a highly processed, “interpreted” version of the world. One key intuition is that the unification and “interpretation” of the experience that reaches our consciousness is achieved through the activation of myriads of neurons that signal individual features, but that it is by virtue of *integrating* their information through dynamic interactions (for example via synchronous coordination of their activity or via feedback processes) that a coherent experience across senses, space, and time comes about.

An important caveat is that integration of information *per se* is unlikely to distinguish conscious from unconscious processing as integration of many features can also proceed unconsciously (Dehaene et al. 1998; Gaillard et al. 2009; Lin & He 2009; Melloni et al. 2007; Melloni & Rodriguez 2007; Mudrik et al. 2014). In fact, integration through convergence is a key principle of the wiring of the brain, which explains the mere existence of feature-selective neurons that respond to motion, shape, or complex stimuli such as faces, and that process information in an unconscious manner. If it is not integration *per se*, then what kind of integration are we talking about?¹ We and others (Melloni & Singer 2010; Thompson & Varela 2001;

¹ Giulio Tononi (2004; Tononi & Koch 2008) argues that not only integration but also differentiation/segregation (e.g., distinguishing a particular state from all possible other states) is characteristic of conscious states. However, even when both conditions are met, say integration through convergence is observed in FFA and differentiated from other states, e.g., there is no activation in PPA, an area selective to processing places, and thus there is no guarantee that this would constitute a conscious state. In fact, experimental evidence suggests that such feature-selective processing can indeed proceed unconsciously, for example in the case of face processing under conditions of masking (de Gardelle et al. 2011), continuous flash suppression (Almeida et al. 2013), and in blindsight patients (Del Zotto et al. 2013).

Varela et al. 2001) have previously argued for a distinction between *local* and *global* integration, and proposed that the spatial scale of integration differentiates between unconscious and conscious states: unconscious processing is observed when local integration occurs within the divergent-convergent feedforward architecture; conscious processing however requires long-range integration through neural synchronization, which integrates information across the various levels of the cortical processing hierarchy.

Indeed, in recent years, a wealth of experimental studies (Aru et al. 2012; Gaillard et al. 2009; Hipp et al. 2011; Melloni et al. 2007; Melloni & Rodriguez 2007) have provided support to the idea that long-range integration through synchronous coupling is a mechanism for conscious perception, and that the spatial scale of synchronisation strongly correlates with the perceptual outcome. For example, we have shown that masked words are only consciously perceived when accompanied by a burst of long-distance synchronization in the gamma band, while unconscious processing, even up to a semantic level, elicits only local gamma oscillations (Melloni et al. 2007; Melloni & Rodriguez 2007). Although controversy still persists as to whether long-range integration necessitates the involvement of particular brain areas (Dehaene 2014; Edelman & Tononi 2000) or not (Lamme this collection; Melloni & Singer 2010), it is reassuring to witness some convergence on the results that have even led to clinical applications (e.g., coma classification, King et al. 2013). In his most recent work, Victor Lamme now also assigns a central role to the spatial scale of the integration for consciousness, joining an ever-increasing number of researchers proposing long-range integration as key to consciousness (Dehaene & Changeux 2011; Edelman & Tononi 2000; Melloni & Singer 2010; Thompson & Varela 2001). An interesting point of divergence from other theories is that while Lamme assigns a particular role to feedback and horizontal connections in the integration of information for consciousness, other theories, including our own, hypothesise that it is the synchronisation of neural populations that glues all experiences into one, thereby instantiating con-

sciousness. As empirical data and theoretical considerations continue to accumulate, we expect that this and other pressing challenges such as identifying how far is “long” in the brain, or whether “long” involves the activation of specific neural cell populations, specific areas, and/or a specified number of nodes will become addressable.

However, imagine those questions have been addressed and we know that integration on a particular spatial scale is key to consciousness; would we have understood what consciousness is or how it comes about? Here I propose that we would not, as any theory that does not account for two fundamental, hitherto neglected aspects of conscious experience will fall short of explaining consciousness. In particular, our experience is never an island in isolation, but instead is shaped by previous knowledge, by priors that stem from the preceding context or from our history of learning. These priors determine our perception; and thus understanding how they become integrated is paramount to explaining consciousness. However, an even more pressing problem is that conscious experience unfolds over time, whereby the recent past moulds the current moment, which in turn creates predictions for moments to come, i.e., the future. How all those temporal processes intertwine and define our experience (the flow of consciousness) is something that most research has neglected. In the following sections I will review current research that we and others have undertaken with the purpose of raising awareness of these overlooked integrative properties of conscious experience and the challenges that they entail for the study of consciousness.

2 Consciousness as an inferential process and the consequences for the neural mechanism of conscious perception

One central and characteristic feature of conscious perception is its constructive nature. In contrast to unconscious cognition, which is directly driven by sensory stimulation, the images that reach consciousness often bear little resemblance to reality. Indeed, percepts in our

mind can be understood as useful distortions of reality in which only specific parts of the physical input are represented while being enriched with a model of the world that has been learned and that provides context to the current moment. In the words of [Heinz von Foerster \(1984\)](#), “the world, as we perceive it, is our own invention”. To provide a striking example of this, consider the image on the right (Figure 1) and try to figure out what it shows. Most people at first see a collection of black and white blobs, much like the input that strikes our retina—a raw, uninterpreted signal. Now, rotate the page upside down. Voila! You will clearly see a face (do you recognize whose face it is?). Remarkably, you can turn the page back and you will continue seeing the face. Once you have recognized the image, the visual system has created a *prior*, an expectation that enriches perception. This example is not mere curiosity. Most of our behaviour and perceptions are based on predictions: we do not wait for visual input to impinge our eyes, we *actively* look for it. We cannot, however, initiate a rational search for an object without making *predictions* about “what” it is, “where” it is likely to be, and even “when” it is likely to be there. The brain’s ability to make predictions and to mould its data gathering accordingly is thus essential for its ability to evaluate options, make life-critical decisions, and generate adaptive behaviour.

While the constructive nature of perception is undeniable and may even appear as one of its defining features, surprisingly little research has been carried out to understand how previous experience interacts with consciousness. Most importantly, the scientific community has not embraced an understanding of consciousness in the context of a flow of experience in which every moment is integrated with past moments and interfaced with expectations about what will happen in the future (but see [Varela 1999](#)). A possible reason for neglecting the contribution of previous experience is that this integration of past with present moments has been understood as a process of “unconscious inference” (following [von Helmholtz 1866/1962](#)), or, in Victor Lamme’s words, in the context of the “automaticity of the many ex-

pectation effects.” However, this inferential process is carried out in the backstage of consciousness, and it is only the result that we consciously experience. This bears resemblance to syntactic analysis, which is also carried out automatically and unconsciously, but is paramount to conscious access to meaning. Without unconscious syntactic analysis we would not be able to “consciously” understand text; nor is its automatic activation under our control. In the same vein, our conscious perception would be totally different if prior knowledge did not help us enrich or even construct our experience, endowing it with meaning. In fact, it has been proposed that alterations in perception, i.e., the defragmented sensory experience observed in schizophrenics and autistic people can be the result of a deficit in this inferential process ([Jardri & Deneve 2013](#); [Pellicano & Burr 2012](#)), underscoring the fundamental role that perceptual inference plays in conscious perception.

One promising framework within which the influence of previous experience through unconscious inference can be understood is the Bayesian framework. When applied to perception, each mathematically-formulated ingredient of this framework can be assigned a perceptual counterpart, with previous experience referring to the prior, the current moment referring to the likelihood, unconscious inference referring to Bayes rule (which combines the prior with the likelihood in an optimal way), and the result—our perception—referring to (the peak of) the posterior distribution. This idea has recently proven to be a powerful tool for understanding perception not only in terms of modelling behaviour, but also as a theoretical framework for understanding how perception arises in the brain. A prominent implementation of the latter is Predictive Coding ([Friston 2010](#)). This theory postulates that the brain builds models (priors) of the world based on previous experience, which are used to explain the current inputs. This occurs iteratively *across all levels in the cortical hierarchy* with the goal of minimising predictions errors, i.e., the difference between what is expected and the incoming sensory input, which are energetically costly. This minimization process can either be achieved by chan-

ging the way the system samples its environment, or by changing its models. Relevant for this discussion is the idea that perceptual inference, in the Predictive Coding framework, implies that all levels in the hierarchy reach an agreement, i.e., minimise all prediction errors, much like the idea of a unified/integrative moment as proposed by Victor Lamme and others (Dehaene 2014; Edelman & Tononi 2000; Melloni & Singer 2010). While Predictive Coding by itself is currently agnostic as to whether such unified agreement represents a conscious state, the central tenet that integration across all levels is what the system strives for still holds. This allows for the formulation of interesting, testable predictions about the Neural Correlates of Consciousness (NCC).

In recent years research in my lab has focused on understanding how previous experience enriches perception, how expectations alter the NCC, and how this can be understood within the Predictive Coding framework. The central idea that motivated these studies was to test whether or not the NCC are context independent, i.e., impervious to the influence of expectations, as many theories implicitly postulate. To test this hypothesis we presented subjects with illusory letters, that is letters whose borders were not explicitly defined but instead required the activation of figure-ground segregation cues. We reasoned that providing subjects with a prior, i.e., knowing which letter would be presented next, would facilitate the figure-ground segregation process, making an initially invisible letter clearly visible. In line with our expectations, we observed that the threshold of conscious perception is not fixed but instead changes depending on the availability of previous knowledge: subjects are able to perceive a stimulus on the basis of minimal sensory information when they have a clear expectation. We were able to confirm this result in a series of different paradigms in which expectations could be generated online from recent experience as in the example of the letter given above (Melloni et al. 2011; Schwiedrzik et al. 2014), drawn from memory based on prior exposure to clearly visible natural images (Aru et al. 2012), stem from a life-long history of association between letters

and colour as in grapheme-colour synaesthesia (van Leeuwen et al. 2013), or result from systematic training as in perceptual learning (Schwiedrzik et al. 2009, 2011). These studies allowed us to test not only whether the behavioural threshold of conscious perception is fixed, but also how previous knowledge would affect the neural “construction” of conscious percepts.

Figure 1: Can you recognize what this is? If not, rotate the image. Note that once you turn it back around the object is now clear.

A first hypothesis we derived from the Predictive Coding framework was that the presence of strong priors should have an effect of how quickly content reaches awareness. If conscious perception is the result of a process that iterates until information is consistent between the different levels of the hierarchy (Di Lollo et al. 2000), i.e., until all prediction errors are minimised, then having a better model of the input based on prior knowledge may speed up this process. Indeed and contrary to the com-

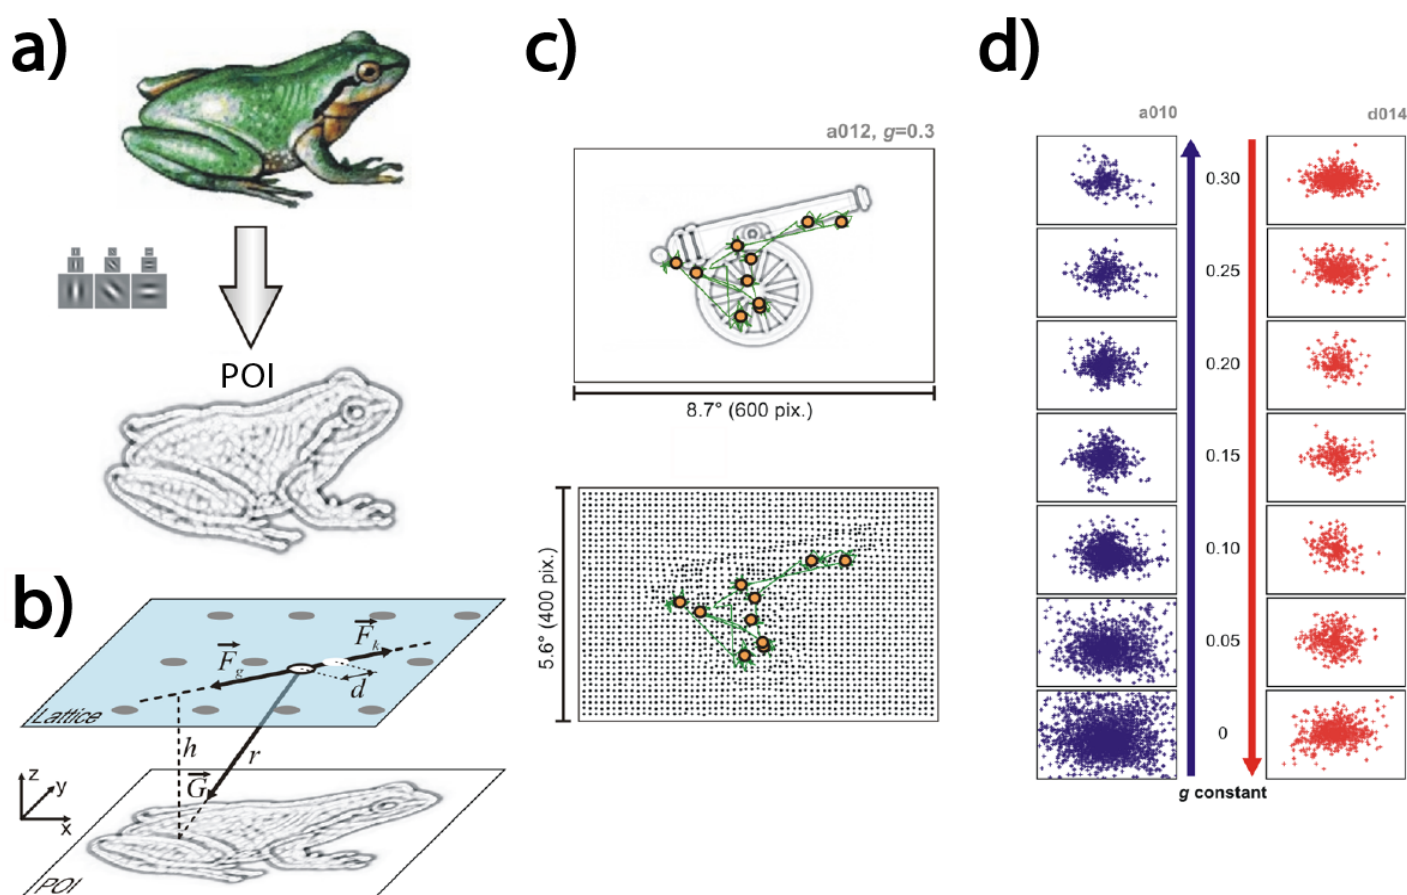

Figure 2: (a) Original images are filtered through a series of gabor wavelets, which allows the estimation of the points of maximal local information (Points of Maximal Information, POI) in the source image. (b) Dots of an elastic lattice are created by mapping the POI in the projection plane, and attracting them by the projection F_0 of a gravitational force G . (c) Pattern of saccades/fixations when subjects recognise a stimulus and its underlying POI map. (d) Pattern of fixations for stimuli of different degradation levels from high degradation (0) to low degradation (0.30). Dots in blue correspond to fixations when subjects do not have an expectation of the stimuli, dots in red correspond to patterns of fixation observed in the presence of expectations. Note that in the presence of expectations, the distribution of fixations are much less scattered. From [Moca et al. \(2011\)](#).

mon belief that information processing in the brain has a fixed latency, we observed that the NCC shifts in time when a prior is available. While the electrophysiological difference between seen and unseen letters occurred around 300ms when it exclusively depended on sensory evidence, it occurred as early as 200ms when priors were available ([Melloni et al. 2011](#)). Thus, priors sped up information processing by 100ms. These results have important implications for the search for the NCC as they show that conscious processing is not bound to a particular time, but can flexibly adjust its timing depending on the task at hand, the readiness of the system, or the presence of expectations.

They also pose a challenge to theories that postulate that the NCC always occur late, as proposed by [Victor Lamme \(this collection\)](#) or [Stanislas Dehaene \(2014\)](#).

A second prediction that follows from the principle of minimising prediction errors is that in the presence of priors, activity in lower areas can be “explained away” by priors in higher brain areas ([Murray et al. 2004](#)); this entails that when inputs can be fully predicted based on previous experience, they do not elicit prediction errors. To test this hypothesis, we took the same study to the MEG and performed source localisation. Here, we found that priors sparsify the networks involved in processing the

stimulus, such that when a prior is present only the brain areas that are most diagnostic to the stimulus features are activated (Mayer et al. in preparation). All alternative interpretations of the stimulus are thus “explained away”. Thus, consciousness and its neural correlates appear as mobile targets, which adjust their locus in the presence of expectations. This poses a further challenge to the search for the NCC, as not only the timing, but also the location of neural activation does not appear as a diagnostic feature for the NCC.

Finally, Predictive Coding also suggests that priors may be used to change the way information is sampled, as the models derived from previous experience can be used to optimise the search for the most relevant information (Friston et al. 2012). Only rarely do we keep our gaze still and wait for the world to bring novel information; instead, we scan images through rhythmic patterns of eye movements accompanied by fixations. This active sensing view implies that perception is not a passive phenomenon in which the system waits for information to hit the sensory transducers, but instead an active process that seeks information through exploratory routines (Melloni et al. 2009; Schroeder et al. 2010). To test whether and how priors affect the sampling of information we developed stimuli for which we could quantify the local information content at each point (Figure 2) and determined the efficiency of information extraction based on eye movements in the presence or absence of expectations. Figure 2 shows that when subjects have prior knowledge of the object they are trying to perceive, they can immediately orient their eyes to areas of most diagnostic information for the perception of an object. At the same time, the sampling of information becomes sparser, concentrating eye movements to maximally informative areas (Moca et al. 2011). This implies that priors direct our exploratory motor routines, thus optimising perception.

Overall, these studies show that previous experience enriches the contents of consciousness and fundamentally changes the way information is processed in our brain, enhancing speed and efficiency. This raises questions for

theories that propose a fixed latency or neural locus for conscious access, but also complicates the quest for the NCC, as they turn out to differ in time and location depending on the precision and accuracy of expectations. Although current formulations of Predictive Coding do not make specific predictions about consciousness, this framework may nevertheless prove to be an important starting point in trying to understand these effects. In fact, more explicit theoretical links between Predictive Coding and consciousness are now being worked out (e.g., Clark 2013; Hohwy 2013; Seth et al. 2011)—after all, Predictive Coding has been framed as a unifying theory of the brain (Friston 2010), which would fall short if consciousness was left unexplained.

3 The neglected dimension of consciousness: Time and the flow of consciousness

But is that all? One dimension of our experience that is often neglected is time. Of course, time is an implicit component of previous experience, however, it may also be revealing to consider time by itself. In fact, living organisms seldom encounter a static image in isolation, but are instead confronted with a flow of temporally-correlated sensory inputs (Schwartz et al. 2007). Imagine for instance a tennis match, and picture the tennis ball flying over the field. If queried, you could easily estimate where the ball is, but also where it was a second ago and where it will be in a few milliseconds. Event-objects of the conscious mind² thus per definition unfold in time and we also act in time: we make use of current and previous input to figure out the most appropriate response predicting their consequences. There is thus a continuum of interdependencies along the time dimension whereby every past moment is *integrated* with the present and projected into the future, giving rise to the flow of consciousness. The same way

² We are usually conscious of objects, and become so by virtue of their being differentiated from the background, but also because their internal features are linked or bound in some way. Objects and their internal features do not need to be static entities but can have temporal dynamics, i.e., they develop or change in time. In this case, they become events (and thus event-objects of the conscious mind).

we have been thinking about the integration of multiple source of information *within* a given moment of time, such as multiple features of a single object, there is thus integration *across* time. A case in point is strikingly vivid perceptual aftereffects, such as the waterfall illusion, where viewing motion in one direction for several seconds causes a subsequently presented static image to move in the opposite direction (Purkinje 1820). Such effects are not limited to basic perceptual features such as motion direction, colour, or orientation, but also affect high-level percepts such as the perceived gender of faces (Webster et al. 2004), numerosity (Burr & Ross 2008), or gaze direction (Jenkins et al. 2006); and they are not limited to fleeting illusions that vanish almost instantaneously, but may persist for days or even weeks (Jones & Holding 1975). This indicates that our current experience is embedded into a continuous flow of previous experience at multiple time scales, ranging from lifelong experience with our environment to short-term, moment-by-moment effects that arise from our most recent encounters, even if just milliseconds ago.

The past thus leaves traces (predictions) that determine the current contents of consciousness. This has the consequence that the contents of consciousness represent an aggregate of imprints from the past and the present moment that jointly promote a sense of *stability over time*. However, through which mechanism these interdependencies affect our perception is currently unclear. Experimentally, the multiple time-scales of previous experience are particularly evident when subjects are confronted with sequences of multistable stimuli such as the Necker cube.³ Because the sensory information these stimuli provide by themselves is insufficient to determine perception, they are particularly susceptible to the effects of previous experience. Under these conditions, one can observe two different effects that temporal dependencies entail: on the one hand, an *attractive* effect, which increases the likelihood of continuing to perceive the same stimulus, and on the other hand a *repulsive* effect, which increases the like-

lihood of perceiving something different. The former is often referred to as hysteresis, priming, stabilisation, or perceptual memory, while the latter is commonly known as perceptual adaptation.

Recently, Chopin & Mamassian (2012) studied the temporal dynamics of these serial dependencies, addressing the question of which part of the perceptual history the system retains and how remote and recent experiences differentially determine perception. They observed a remarkable dissociation between long stretches of time that occurred in the remote past (in their case several minutes) and short stretches of time that had just recently occurred (a few seconds ago): while the former had a positive correlation with perception, and thus ensured stability over time (hysteresis), the latter had a negative correlation to perception, that is, it promoted alternative interpretations (adaptation). These two timescales indicate that previous experience can act along at least two separate timescales and hence, that there may be several mechanisms at work. Using functional magnetic resonance imaging, we set out to further elucidate how these effects are implemented in the brain, how the brain entertains these two opposing processes without mutual interference, and what determines their direction (Schwiedrzik et al. 2014). Presenting multistable visual stimuli sequentially, we found that although affecting our perception concurrently, hysteresis and adaptation map into distinct cortical networks: a widespread network of higher-order visual and fronto-parietal areas was involved in hysteresis, while adaptation was confined to early visual areas (areas V2/V3). Importantly, hysteresis and adaptation bear a differential relation with whether or not the stimuli were consciously perceived: while adaptation was present even if the adapting interpretation was not consciously perceived (in agreement with previous reports, e.g., Hock et al. 1996), hysteresis depended on what was previously consciously perceived. Hence, conscious experiences in the past affected the present experience, preserving continuity in time, while unconscious processing had the opposite effect, bringing change and novelty to perception.

³ But they are by no means limited to ambiguous stimuli (Fischer & Whitney 2014; Treisman 1984).

This brings us back to the question of neural integration, indicating that even in the case of *integration over time*, the spatial scale at which neuronal processing occurs determines whether content enters awareness or not: in the case of hysteresis, a conscious moment is integrated in time with another conscious moment, which involves a widespread cortical network, while in the case of adaptation, prior information is only integrated within a local module, which happens irrespective of whether this prior information is consciously experienced or not, similar to Lamme's "base grouping". This interpretation fits with results that have been obtained in the auditory domain in which short temporal regularities can be detected unconsciously eliciting a locally generated event-related potential (ERP), termed mismatch negativity (MMN), while detection of long-term regularities depends on conscious perception, which elicits an electrophysiological response known as P300 from a widespread network of brain areas (Bekinschtein et al. 2009; Faugeras et al. 2011).

Together, I propose that these results mesh well with the idea that one of the functions of consciousness is to interpret the world in *long timescales*, bringing together the *now* with the past beyond the simple and automatic input-output relations rooted in unconscious processors, thus allowing for the extraction of more complex and abstract regularities. Brain areas with longer time constants such as the prefrontal cortex (Fuster 1973) would extract the world's statistics from the remote past, creating a model of the world that keeps a stable picture. In contrast, early sensory areas with short time constants act on shorter timescales, sampling the world for alternative interpretations, thus allowing the system to stay tuned to deviations from the long-term statistics (Clifford 2012; Snyder et al. under review).⁴

While previous studies and established experimental paradigms have mostly focused on the "nowness" of conscious perception, it ap-

pears that much remains to be learned about consciousness and its fundamental phenomenological characteristics such as its flow and our sense of stability over time. In fact, considering that much of what we currently know about the NCC stems from "static" paradigms, and by those I mean paradigms that do not take the temporal context in which the stimuli unravel into account and thus only inform us about what has "changed" in consciousness, we in fact only have access to the neural processes related to the *update* of contents in consciousness, while the mechanisms at play in the *maintenance* or continuity of our experience remain obscure (but see Kleinschmidt et al. 2002). The *present* might be known, but the *flow* is still a mystery!

Thus I propose that a full account of consciousness requires a reappraisal of our object of study in which we incorporate the temporal flow of consciousness as another fundamental property that needs to be explained. This calls for a dynamic view in which a train of conscious states (the flow) would be captured as successions of neuronal meta-assemblies, each with a particular relaxation time, followed by phase transitions, which determine the time of emergence, dominance, and dissolution of a state that leads to another perceptual cycle (Melloni & Singer 2010; Varela 1999). In this framework, the rate-limiting factor for the formation of a new meta-assembly would correspond to the time needed to establish stable phase relations; while the different time constants promoting stability vs. change may be implemented by different oscillatory frequency bands, in addition to the intrinsic time window of integration of a given area (Chaudhuri et al. 2014).

In summary, much remains to be discovered about consciousness and its neural correlates, but significant progress has already been made since the seminal paper by Crick & Koch (1990) that got the field going about twenty-five years ago. Victor Lamme's experimental work and theoretical proposals on the role of feedback connections and reentrant activity in conscious perception have been central to bringing us closer to an understanding of the neural processes that allow us to "see". His paper in this volume contains an erudite review

⁴ Similarly, higher areas have larger receptive fields than lower areas, allowing integration over larger regions of space, and are often more broadly tuned (i.e., allow for more variability in the stimulus, e.g., different views of the same object). This resonates well with psychophysical evidence that hysteresis is spatially less specific and more broadly tuned than adaptation (Gepshtein & Kubovy 2005; Knapen et al. 2009).

of the present knowledge against a background of thought provoking hypotheses, e.g., that the function of consciousness is to solve difficult perceptual problems. In Lamme's view, consciousness is there to create, while unconscious processes are there to utilise. In close analogy to any creative process, consciousness in Lamme's framework is slow and takes time and resources to develop. In a way, his proposal is that it is all about distance, or time. This is a powerful intuition, and an idea worth exploring, yet its contribution does not end there—more than that, it serves as a reminder of a central characteristic of consciousness that is not yet fully explored, namely that conscious experience unfolds at a characteristic spatio-temporal scale, and that it is this flow in space/time that brings the strong sense of experiential stability and continuity. The interwoven temporal scales of the flow of consciousness that bring about the “unity of experience” remain the next challenge, and maybe the one that will finally unlock the mystery of consciousness.

Predictive Coding Is Unconscious, so that Consciousness Happens *Now*

A Reply to Lucia Melloni

Victor Lamme

Conscious percepts depend strongly on past events. Expectations, primes, and prior experiences all shape the percept we have at any moment in time. Yet does this imply that conscious experience should be viewed as extended in time—as “flowing”—instead of as just happening now?

Keywords

Bayesian framework | Inference | Predictive coding | Snapshot vision | Spatial integration | Stream of consciousness | Temporal integration

1 To infer or to integrate, that is the question

In her commentary, Lucia Melloni argues that consciousness unfolds in time: there is a stream of consciousness. What I see now is intricately linked to what I have seen before. And what I see now is what I expect to see—much along the lines of predictive coding. A full understanding of consciousness should not neglect this point. There is even a stronger claim that somehow the process of inference over time is crucial to understanding consciousness.

I appreciate the boldness of linking the framework of Bayesian predictive coding to specific stages in the process of generating consciousness:

One promising framework within which the influence of previous experience can be understood is the Bayesian framework. When applied to perception, each mathematically-formulated ingredient of this framework can be assigned a percep-

tual counterpart, with previous experience referring to the prior, the current moment referring to the likelihood, unconscious inference referring to Bayes rule (which combines the prior with the likelihood in an optimal way), and the result—our perception—referring to (the peak of) the posterior distribution. ([Melloni this collection](#), p. 4)

To my knowledge, this is the first time this has been so explicitly laid out—writers on predictive coding thus far have always stayed a little vague on where exactly consciousness sits in the Bayesian framework.

Yet at the same time, there is the suggestion of long temporal range integration being the key ingredient of consciousness:

Event-objects of the conscious mind thus per definition unfold in time and we also act in time: we make use of current and previous input to figure out the most appropriate response predicting their consequences. There is thus a continuum of interdependencies along the time dimension whereby every past moment is integrated with the present and projected into the future, giving rise to the flow of consciousness. The same way we have been thinking about the integration of multiple sources of information within a given moment of time, such as multiple features of a single object, there is thus integration across time. ([Melloni this collection](#), pp. 7-8)

This makes intuitive sense, particularly in the case of moving objects, such as the tennis ball Melloni uses as an example. Indeed it is hard—if not impossible—to pinpoint the exact *now* of conscious experience of such a ball.¹

Yet the two points seem contradictory. In the Bayesian predictive coding framework, consciousness is the *result* of the unconscious inferential processes. Previous knowledge and

experience (the priors) play an important role, but they are combined with current input to produce the posterior, which is conscious sensation. In the second account, however, consciousness seems to be something that is stretched out over time, so that both prior and posterior are smelted into a “flow” of consciousness. I find it hard to reconcile these two views.

2 The latency of visual consciousness is variable

Melloni discusses some impressive experiments that show the crucial importance of prior information and expectation in shaping or simply altering conscious experience (and her example, figure 1, is enlightening and flattering at the same time). In all these cases, however, consciousness is portrayed as the *outcome* or *result* of an otherwise unconscious inferential process. The result may come earlier or later, as in the experiment on letter priming that Melloni describes, resulting in earlier (200ms) or later (300ms) electrophysiological correlates of conscious recognition depending on the presence or absence of appropriate priors. Further experiments are discussed, showing that neural correlates of consciousness may shift (neural) location, depending on expectation and priors. Yet still, the end result—consciousness—occurs at the end of a cascade of neural operations. Consciousness, in this account, may occur at variable moments and locations, but *moments* they are.

These results complement earlier findings that the latency of recurrent processing—and hence the emergence of a conscious sensation—may vary. [Super et al. \(2001\)](#) showed that degrading stimulus quality may increase the latency of recurrent signals to V1 in the monkey visual cortex (see figure 5c of [Supèr et al. 2001](#)), and that this affects the latency of behavioral responses of animals that are consciously reporting the presence or absence of the stimuli. Latency of recurrent signals may also vary spontaneously between trials, which correlates with the latency of memory-guided—but not reflexive—saccades to the targets

¹ Although some have argued that consciousness unfolds in time as a succession of static frames, more or less like the single frames of a movie—even at specific frequencies, namely 10Hz and 40Hz ([Van Rullen & Koch 2003](#)).

that elicit these recurrent signals (Supèr et al. 2004). In humans, the latencies of electrophysiological correlates of recurrent processing also vary, either spontaneously or depending on stimulus properties (Jolij et al. 2011), or depending on the IQ of the subject (Jolij et al. 2007). Likewise, this has consequences for the latency of conscious sensations. The Jolij 2011 study, for example, found that variations in the latency of recurrent EEG signals covary with variations in subjective simultaneity of the stimuli evoking these signals.² These results invariably imply that consciousness arises at a particular *moment* in time. That moment may vary from stimulus to stimulus, from trial to trial, from person to person, from prior to prior. But nothing is flowing or stretched out over time.

3 Consciousness is not streaming, but taking snapshots

One may argue that these findings are all obtained with stimuli that are presented *de novo*, using the classic stimulus-onset paradigms. In normal vision, things don't suddenly appear out of nowhere. Or do they? We naturally make about three saccadic eye movements per second, and each time the eye lands on a "new" scene which is—from a retinotopic point of view—radically different from the previous one. In between, we are blind due to saccadic suppression. Moreover, little information seems to be transferred from one view to the next, although some (attended) neural representations seem to be *remapped* across saccades (see Bays & Husain 2007, for an overview of trans-saccadic memory and neural remapping). Such a remapping may allow for a more efficient saccade from one object to the next, when both were already present before the first saccade was made. The predictive coding framework seems to re-emerge in this context: objects that were present or attended on a first fixa-

tion form a sort of prior for the representation that is built during the second fixation (which may then arise more rapidly).

Melloni further claims that previous experience has different effects on what is perceived now depending on the temporal interval between prior and current experience. Bistable percepts show hysteresis or adaptation depending on these temporal intervals, or depending on whether the previous experience was conscious or not. But again, I fail to see how these findings support the idea that consciousness is stretched out over time instead of just happening *now*.³

So I appreciate the importance of the predictive coding framework. Previous experience plays a very important role in the conscious sensations we have, and the why and how of this is extremely important for fully understanding vision. But these contributions are unconscious. Consciousness happens now, and its neural correlates are likewise limited in time. Consciousness of the past we call memory.

This work was supported by an advanced investigator grant from the ERC.

² For this reason, I don't quite understand why Melloni suggests that I am claiming that consciousness arises at a particular and *fixed* moment in time. My claim is only that it comes *after* feedforward processing, and as soon as recurrent processing emerges—which may vary.

³ Of course there are visual percepts that are more or less defined by their temporal sequence, the prime example being motion. But this does not imply that the perception of motion is flowing. The first thing the brain does in detecting motion is to convert the flow of motion into a discrete and momentary signal, indistinguishable from how the brain represents other features such as orientation, color, or shape. As a result we see motion now, and instantaneously, which is also crucial for our survival: perceiving something moving in the shadows of a bush (e.g., a snake) needs to be translated into action as soon as possible (e.g., running away). No time for any flow there.

Vestibular Contributions to the Sense of Body, Self, and Others

Bigna Lenggenhager & Christophe Lopez

There is increasing evidence that vestibular signals and the vestibular cortex are not only involved in oculomotor and postural control, but also contribute to higher-level cognition. Yet, despite the effort that has recently been made in the field, the exact location of the human vestibular cortex and its implications in various perceptual, emotional, and cognitive processes remain debated. Here, we argue for a vestibular contribution to what is thought to fundamentally underlie human consciousness, i.e., the bodily self. We will present empirical evidence from various research fields to support our hypothesis of a vestibular contribution to aspects of the bodily self, such as basic multisensory integration, body schema, body ownership, agency, and self-location. We will argue that the vestibular system is especially important for global aspects of the self, most crucially for implicit and explicit spatiotemporal self-location. Furthermore, we propose a novel model on how vestibular signals could not only underlie the perception of the self but also the perception of others, thereby playing an important role in embodied social cognition.

1 Introduction

There is an increasing interest from both theoretical and empirical perspectives in how the central nervous system dynamically represents the body and how integrating bodily signals arguably gives rise to a stable sense of self and self-consciousness (e.g., [Blanke & Metzinger 2009](#); [Blanke 2012](#); [Gallagher 2005](#); [Legrand 2007](#); [Metzinger 2007](#); [Seth 2013](#)). Discussion of the “bodily self”—which is thought to be largely pre-reflective and thus independent of

higher-level aspects such as language and cognition—has played an important role in various theoretical views (e.g., [Alsmith 2012](#); [Blanke 2012](#); [Legrand 2007](#); [Metzinger 2003](#); [Metzinger 2013](#); [Serino et al. 2013](#)). For example in the conceptualisation of minimal phenomenal selfhood (MPS), which constitutes the simplest form of self-consciousness, [Blanke & Metzinger \(2009\)](#) suggested three key features of the MPS: a globalized form of identification with the body

as a whole (as opposed to ownership for body parts), self-location—by which one’s self seems to occupy a certain volume in space at a given time—and a first-person perspective that normally originates from this volume of space.¹ In recent years, an increasing number of studies has tried to manipulate and investigate these aspects of the minimal self as well as other aspects of the bodily self empirically. This chapter aims to show that including the oft-neglected vestibular sense of balance (Macpherson 2011) into this research might enable us to enrich and refine such empirical research as well as its theoretical models and thus gain further insights into the nature of the bodily self. We agree with Blanke & Metzinger (2009) that self-identification, self-location, and perspective are fundamental for the sense of a bodily self and argue that exactly these components are most strongly influenced by the vestibular system. Yet, we additionally want to stress that the phenomenological sense of a bodily self is—at least in a normal conscious waking state—much richer and involves various fine-graded and often fluctuating bodily sensations. We will thus also describe how the vestibular system might contribute to these (maybe not minimal) aspects of bodily self (e.g., the feeling of agency).

The aim of this book chapter is thus to combine findings from human and non-human animal vestibular research with the newest insights from neuroscientific investigations of the sensorimotor foundations of the sense of self. We present several new experimentally testable hypotheses out of this convergence, especially regarding the relation between vestibular coding and the sense of self-location. We first describe the newest advances in the field of experimental studies of the bodily self (section 2) and give a short overview of vestibular processing and multisensory integration along the vestibulo-

thalamo-cortical pathways (section 3). In section 4, we present several lines of evidence and hypotheses on how the vestibular system contributes to various bodily experiences thought to underpin our sense of bodily self. We conclude this section by suggesting that the vestibular system not only contributes to the sense of self, but may also play a significant role in self-other interactions and social cognition.

2 Multisensory mechanisms underlying the sense of the body and self

How the body shapes human conscious experience is an old and controversial philosophical debate. Yet, recent theories converge on the importance of sensory and motor bodily signals for the experience of a coherent sense of self and hence for self-consciousness in general (Berlucchi & Aglioti 2010; Bermúdez 1998; Blanke & Metzinger 2009; Carruthers 2008; Gallagher 2000; Legrand 2007; Metzinger 2007; Tsakiris 2010). Even the emergence of self-consciousness in infants has been linked to their ability to progressively detect intermodal congruence (e.g., Bahrick & Watson 1985; Filippetti et al. 2013; Rochat 1998).² The assumption that multisensory integration of bodily signals underpins the sense of a bodily self has opened up—next to clinical research—a broad and exciting avenue of experimental investigations in psychology and cognitive neuroscience as well as interdisciplinary projects integrating philosophy and neuroscience. Experiments in these fields typically provided participants with conflicting information about certain aspects of their body and assessed how it affected implicit and explicit aspects of the body and self. The first anecdotal evidence of an altered sense of self through exposure to a multisensory conflict dates back at least to the nineteenth century with the work of Stratton (1899). More systematic, well-controlled paradigms from experimental psychology have gained tremendous influence since the first description of the *rubber*

1 Jennifer Windt (2010) suggested, based on dream research, an even more basic form of minimal phenomenal selfhood, which she defined as a “sense of immersion or of (unstable) location in a spatiotemporal frame of reference”, thus not needing a global full-body representation (see also Metzinger 2013, 2014 for an interesting discussion of this view). We believe that for this more basic sense of a self especially, the vestibular system should be of importance, as a vestibular signal unambiguously tells us that our self was moving (i.e., change in self-location and perspective) without an actual sensation from the body (i.e., a specific body location as it is the case in touch, proprioception, or pain).

2 It is interesting to note for the frame of this chapter that these authors describe the importance of the detection of coherence of all self-motion specific information (including the vestibular system), despite the fact that their experimental setup involved only proprioceptive and visual information (leg movements in a sitting position).

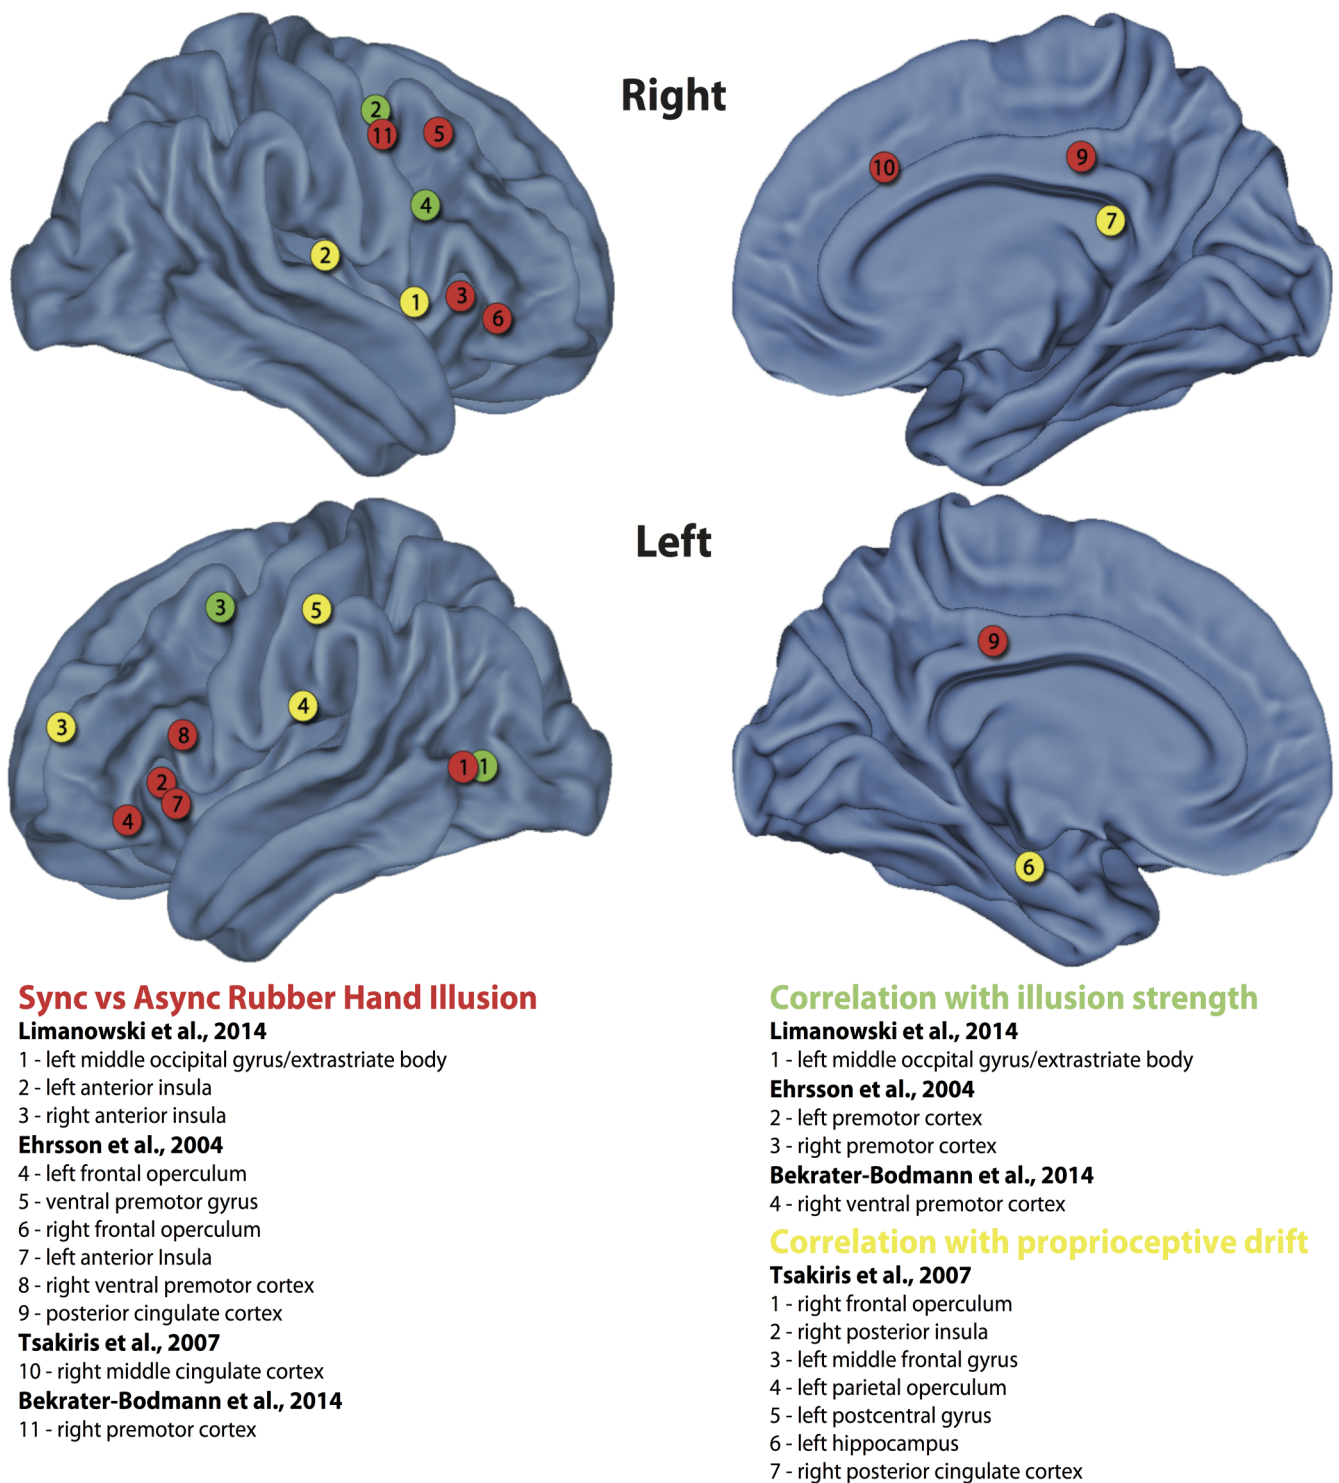

Figure 1: An overview of brain imaging studies of the rubber hand illusion (Bekrater-Bodmann et al. 2014; Ehrsson et al. 2004; Limanowski et al. 2014; Tsakiris et al. 2006). Red circles indicate significant brain activation in the comparison of synchronous visuo-tactile stimulation (illusion condition) to the control asynchronous visuo-tactile stimulation. Green circles indicate brain areas where the hemodynamic response correlates with the strength of the rubber hand illusion. Yellow circles indicate areas that significantly correlate with the proprioceptive drift. For the generation of the figure, MNI coordinates were extracted from the original studies and mapped onto a template with caret (<http://www.nitrc.org/projects/caret/> (van Essen et al. 2001)).

hand illusion seventeen years ago (Botvinick & Cohen 1998). Since then, different important components underlying the bodily self have been identified, described, and experimentally modified. Most prominently: *self-location*—the feeling of being situated at a single location in space; *first-person perspective*—the centeredness of the subjective multidimensional and multimodal experiential space upon one's own body (Vogeley & Fink 2003); *body ownership*—the sense of ownership of the body (Blanke & Metzinger 2009; Serino et al. 2013); and *agency*—the sense of being the agent of one's own actions (Jeannerod 2006). In this section, we briefly describe these components of the bodily self as well as experimental paradigms that allow their systematic manipulation and investigation of their underlying neural mechanisms. Later, in section 4, we will describe how and to what extent vestibular signals might influence these components as well as their underlying multisensory integration.

2.1 Ownership, self-location, and the first-person perspective

2.1.1 Body part illusions

Both ownership and self-location³ have traditionally been investigated in healthy participants using the rubber hand illusion paradigm (Botvinick & Cohen 1998). Synchronous stroking of a hidden real hand and a seen fake hand in front of a participant causes the fake hand to be self-attributed (i.e., quantifiable subjective change in ownership) and the real hand to be mis-localized towards the rubber hand (i.e., objectively quantifiable change in self-location). During the last ten years, various other correlates of the illusion have been described. For example, illusory ownership for a rubber hand is accompanied by a reduction of the skin temperature of the real hand (Moseley et al. 2008), an increased skin conductance and activity in pain-related neural networks in response to a threat toward the rubber hand (Armel &

Ramachandran 2003; Ehrsson et al. 2007), and increased immune response to histamine applied on the skin of the real hand (Barnsley et al. 2011). Several variants of the illusion have been established using conflicts between tactile and *proprioceptive information*,⁴ between visual and nociceptive information (Capelari et al. 2009), between visual and *interoceptive information*, and between visual and motor information (Tsakiris et al. 2007). All these multisensory manipulations have in common that they can induce predictable changes in the implicit and explicit sense of a bodily self. Yet, the question of what components of the bodily self are really altered during such illusions and how the various measures relate to them is still under debate. Longo et al. (2008) used a psychometric analysis of an extended questionnaire presented after the induction of the rubber hand illusion to identify three components of the illusion: (1) *ownership*, i.e., the perception of the rubber hand as part of oneself; (2) *location*, i.e., the localization of one's own hand or of touch applied to one's own hand in the position of the rubber hand; and (3) *sense of agency*, i.e., the experience of control over the rubber hand. These different components seem also to be reflected in differential neural activity as revealed by recent functional neuroimaging studies.⁵

Figure 2 summarizes the main brain regions found to be involved in the rubber hand illusion during functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) studies (Bekrater-Bodmann et al. 2014; Ehrsson et al. 2004; Limanowski et al. 2014; Tsakiris et al. 2006). The activation patterns depend on how the illusion was quantified. The pure contrast of the illusion condition (i.e., synchronous stroking) to the control condition reveals a network including the insular, cingulate, premotor, and lateral occipital (extrastriate body area) cortex. Areas in which haemodynamic responses correlate with the strength of illusory ownership include the premotor cortex

³ This component is in such context usually termed self-location, but a more accurate formulation is “body part location with respect to the self” (Blanke & Metzinger 2009; Lenggenhager et al. 2007).

⁴ Proprioception classically refers to information about the position of body segments originating from muscle spindles, articular receptors, and Golgi tendon organs, while interoception refers to information originating from internal organs such as the heart, gastrointestinal tract, and bladder.

⁵ The sense of agency has not yet been investigated using neuroimaging studies in the context of the rubber hand illusion.

Figure 2: A comparison of brain activity associated with two illusions targeting the manipulation of more global aspects of the bodily self, i.e., the full body illusion (Lenggenhager et al. 2007, setup in orange frame) and the body swap illusion (Petkova & Ehrsson 2008, setup in green frame). In both variants of the illusion, synchronous stroking of one's own body and the seen mannequin led to self-identification with the latter (locus of self-identification is indicated in red colour). Two recent fMRI studies using either the full body illusion (Ionta et al. 2011 in orange circles) or the body swap illusion (Petkova et al. 2011, in green circles) are compared and plotted. Only areas significantly more activated during synchronous visuo-tactile stimulation (illusion condition), as compared to control conditions, are shown. For the generation of the figure, MNI coordinates were extracted from the original studies and mapped onto a template with caret (<http://www.nitrc.org/projects/caret/>). Adapted from Serino et al. 2013, Figure 2.

and extrastriate body area, whereas illusory mis-localization of the physical hand (referred to as “proprioceptive drift”) correlates particularly with responses in the right posterior insula, right frontal operculum, and left middle frontal gyrus (see figure 1 for the detailed list). The fact that different brain regions are involved in illusory ownership and mis-localization of the physical hand provides further evidence for distinct sub-components underlying the bodily self.

2.1.2 Full-body illusions

Several authors claimed that research on body part illusions is unable to provide insight into the mechanisms of global aspects of the bodily self, such as self-identification with a body as a whole, self-location in space, and first-person perspective (e.g., Blanke & Metzinger 2009; Blanke 2012; Lenggenhager et al. 2007). Thus, empirical studies have more recently adapted

the rubber hand illusion paradigm to a *full-body illusion* paradigm where the whole body (instead of just a body part) is seen using video-based techniques and virtual reality.

Two main versions of multisensory illusions targeting more global aspects of the self have been used (but see also Ehrsson 2007), one in which the participants saw the back-view of their own body (or a fake body) in front of them as if it were seen from a third-person perspective (full-body illusion [see figure 2, orange frame]; Lenggenhager et al. 2007) and one in which a fake body was seen from a first-person perspective (body swap illusion [see figure 2 green frame; Petkova & Ehrsson 2008]). In both versions of the illusion, synchronous visuo-tactile stroking of the fake and the real body increased self-identification (i.e., full-body ownership)⁶ with a virtual or fake body as compared

⁶ While these experiments are targeting illusory full-body ownership, it has recently been criticized (Smith 2010; see also Metzinger 2013) that it has not empirically been shown that it really

to asynchronous stroking. Importantly, it has been argued that only the former is associated with a change in self-location⁷ (Aspell et al. 2009; Lenggenhager et al. 2007; Lenggenhager et al. 2009) and in some cases with a change in the direction of the first-person visuo-spatial perspective (Ionta et al. 2011; Pfeiffer et al. 2013).

A recent psychometric approach identified three components of the bodily self in a full-body illusion set up: bodily self-identification, space-related self-perception, which is closely linked to the feeling of presence in a virtual environment (see section 4.5.1.3), and agency (Dobricki & de la Rosa 2013). Again, these sub-components seem to rely on different brain mechanisms. Figure 2 contrasts two recent brain imaging studies using full-body illusions (see Serino et al. 2013, for a more thorough comparison). While self-identification with a fake body seen from a first-person perspective is associated with activity in premotor areas (Petkova et al. 2011), changes in self-location and visuo-spatial perspective are associated with activity in the temporo-parietal junction (TPJ) (Ionta et al. 2011). The TPJ is a region located close to the parieto-insular vestibular cortex (see section 3.2.3), suggesting that the vestibular cortex might play a role in the experienced self-location and visuo-spatial perspective, as we will elaborate on in the following sections.

2.2 Agency

Agency, the feeling that one is initiating, executing, and controlling one's own volitional actions, has been described as another key aspect of the bodily self and self-other discrimination (Gallagher 2000; Jeannerod 2006; Tsakiris et al. 2007). Experimental investigations of the sense of agency started in the 1960s with a study by Nielsen (1963). In this seminal study,

affects the full body (as opposed to just certain body parts). We agree that this argument is justified and that further experiments are needed to address this issue (see also Lenggenhager et al. 2009).

⁷ Similarly to the rubber hand illusion, changes in self-location and self-identification have been associated with physiological changes such as increased pain thresholds, decreased electrodermal response to pain (Romano et al. 2014), and decreased body temperature (Salmom et al. 2013).

as well as in follow-up studies, a spatial or a temporal bias was introduced between a physical action (e.g., reaching movement toward a target) and the visual feedback from this action (Farrer et al. 2003b; Fournier & Jeannerod 1998). These studies measured the degree of discrepancy for which the movement is still self-attributed. Theories of the sense of agency have mostly been based on a “forward model,” which has been defined in a predictive coding framework (Friston 2012). The forward model uses the principle of the *efference motor copy*, which is a copy from the motor commands predicting the sensory consequences of an action. Such efference copies allow the brain to distinguish self-generated actions from externally generated actions (Wolpert & Miall 1996). This idea is supported by a large body of empirical evidence showing that the sense of agency increases with increasing congruence of predicted and actual sensory input (e.g., Farrer et al. 2003a; Fournier et al. 2001). Neurophysiological and brain imaging studies showed a reduction of activation in sensory areas in response to self-generated, as compared to externally generated, movements (e.g., Gentsch & Schütz-Bosbach 2011). As well as suppression of activity in specific sensory areas, agency has also been linked to activity in a large network including the ventral premotor cortex, supplementary motor area, cerebellum, dorsolateral prefrontal cortex, posterior parietal cortex, posterior superior temporal sulcus, angular gyrus, and the insula (David et al. 2006; Farrer et al. 2008; Farrer et al. 2003a).

While studies on agency have almost exclusively investigated agency for arm and hand movements, a recent study has addressed “full-body agency” during locomotion using full-body tracking and virtual reality (Kannape et al. 2010). As the vestibular system is importantly involved in locomotion, we will argue for a strong implication of the vestibular system in full-body agency during locomotion (see section 4.4).

3 The vestibular system

In this section, we describe the basic mechanisms of the peripheral and central vestibular

system for coding self-motion and self-orientation, as we believe that these aspects are crucial bases for a sense of the bodily self. It is, however, beyond the scope of this paper to provide a comprehensive description of the vestibular system anatomy and physiology, and the reader is referred to recent review articles (e.g., Angelaki & Cullen 2008; Lopez & Blanke 2011).

3.1 Peripheral mechanisms

The peripheral vestibular organs in the inner ear contain sensors detecting three-dimensional linear motions (two otolith organs) and angular motions (three semicircular canals). The characteristic of these sensors is that they are *inertial sensors*, a type of accelerometers and gyroscopes found in inertial navigation systems. When an individual turns actively his or her head, or when the head is moved passively (e.g., in a train moving forward), the head acceleration is transmitted to the vestibular organs. Head movements create inertial forces—due to the inertia of the otoconia, the small crystals of calcium carbonate above the otolith organs, and to the inertia of the endolymphatic fluid in the semicircular canals—inducing an activation or inactivation of the vestibular sensory hair cells.

It is important to note here that the neural responses of the vestibular sensory hair cells depend on the direction of head movements with respect to head-centred inertial sensors and not with respect to any external reference. For this reason, the vestibular system enables the coding of *absolute* head motion in a *head-centred reference frame* (Berthoz 2000). This way of coding body motion differs from the motion coding done by other sensory systems. The coding by the visual, somatosensory, and auditory system is ambiguous because these sensory systems detect a body motion *relative to* an external reference, or the motion of an external object with respect to the body. For example, the movement of an image on the retina can be interpreted either as a motion of the body with respect to the visual surrounding, or as a motion of the visual scene in front of a static observer (e.g., Dichgans & Brandt 1978), leading to an am-

biguous sense of ownership for the movement. Similarly, if a subject detects changes of pressures applied to his skin (e.g., under his foot soles), this can be related either to a body movement, with respect to the surface on which he is standing, or to the movement of this surface on his skin (Kavounoudias et al. 1998; Lackner & DiZio 2005). Similar observations have been made in the auditory system and illusory sensations of body motion have been evoked by rotating sounds (Väljamäe 2009). By contrast, a vestibular signal is a non-ambiguous neural signal that the head moved or has been moved; thus there is no ambiguity regarding whether the own body moved or the environment moved. It should, however, be noted that the vestibular information on its own does not distinguish between passive or active movements of the subject's whole body (i.e., the self-motion associated with the feeling of agency; see also section 4.4).⁸

The otolith organs are not only activated by head translations, such as those produced by a train moving forward or by an elevator moving upward, but also by Earth's gravitational pull. Otolith receptors are sensitive to *gravito-inertial forces* (Angelaki et al. 2004; Fernández & Goldberg 1976) and thus provide the brain with signals about head orientation with respect to gravity. Such information is crucial to maintain one's body in a vertical orientation and to orient oneself in the physical world (Barra et al. 2010).

3.2 Central mechanisms

The vestibulo-thalamo-cortical pathways that transmit vestibular information from the peripheral vestibular organs to the cortex involve several structures relaying and processing vestibular sensory signals. We describe below vestibular sensory processing in the vestibular nuclei complex, thalamus, and cerebral cortex.

⁸ As we will see below, the neural signal provided by the peripheral vestibular organs does not allow us to distinguish whether the self is (active motion) or is not (passive motion) the agent of the action. Therefore, peripheral vestibular signals are ambiguous regarding the sense of agency. Yet, comparisons with motor efference copy in several vestibular neural structures allow such distinction and provide a sense of agency.

3.2.1 The vestibular nuclei complex and thalamus

The eighth cranial nerve transmits vestibular signals from the vestibular end organs to the vestibular nuclei complex and cerebellum (Barmack 2003). The vestibular nuclei complex is located in the brainstem and is the main relay station for vestibular signals. From the vestibular nuclei, descending projections to the spinal cord are responsible for vestibulo-spinal reflexes and postural control. Ascending projections to the oculomotor nuclei support eye movement control, while ascending projections to the thalamus and subsequently to the neocortex support the vestibular contribution to higher brain functions. Vestibular nuclei are also strongly interconnected with several nuclei in the brainstem and limbic structures, enabling the control of autonomic functions and emotion (see section 4.1.3) (Balaban 2004; Taube 2007).

The role of the vestibular nuclei is not limited to a relay station for vestibular signals. Complex sensory processing takes place in vestibular nuclei neurons, involving, for example, the distinction between active, self-generated head movements and passive, externally imposed head movements (Cullen et al. 2003; Roy & Cullen 2004). As we will argue in section 4.4, this processing is likely to play a crucial role in the sense of agency, especially concerning full-body agency during locomotion. Another characteristic of the vestibular nuclei complex is the large extent of *multisensory convergence* that occurs within it (Roy & Cullen 2004; Tomlinson & Robinson 1984; Waespe & Henn 1978), which leads to the perceptual “disappearance” of vestibular signals as they are merged with eye movement, visual, tactile, and proprioceptive signals. Because there is “no overt, readily recognizable, localizable, conscious sensation” from the vestibular organs during active head movements, excluding artificial passive movements and pathological rotatory vertigo, the vestibular sense has been termed a “silent sense” (Day & Fitzpatrick 2005).

Ascending projections from the vestibular nuclei complex reach the thalamus. These projections are bilateral and very distributed as

there is no thalamic nucleus specifically dedicated to vestibular processing, as compared to visual, auditory, or tactile processing.⁹ Anatomical and electrophysiological studies in rodents and primates identified vestibular neurons in many thalamic nuclei (review in Lopez & Blanke 2011). Important vestibular projections have been noted in the ventroposterior complex of the thalamus, a group of nuclei typically involved in somatosensory processing (Marlinski & McCrea 2008a; Meng et al. 2007). Other vestibular projections have been identified in the ventroanterior and ventrolateral nuclear complex, intralaminar nuclei, as well as in the lateral and medial geniculate nuclei (Kotchabhakdi et al. 1980; Lai et al. 2000; Meng et al. 2001). Electrophysiological studies revealed that similarly to vestibular nuclei neurons, thalamic vestibular neurons can distinguish active, self-generated head movements from passive head movements, showing a convergence of vestibular and motor signals in the thalamus (Marlinski & McCrea 2008b).

3.2.2 Vestibular projections to the cortex

Vestibular processing occurs in several cortical areas as demonstrated as early as the 1940s in the cat neocortex and later in the primate neocortex (reviews in Berthoz 1996; Fukushima 1997; Grüsser et al. 1994; Guldin & Grüsser 1998; Lopez & Blanke 2011). Figure 3 summarizes the main vestibular areas found in the monkey and human cerebral cortex. More than ten vestibular areas have been identified to date.

Electrophysiological and anatomical studies in animals have revealed important vestibular projections to a region covering the posterior parts of the insula and lateral sulcus, an area referred to as the parieto-insular vestibular cortex (PIVC) (Grüsser et al. 1990a; Guldin et al. 1992; Liu et al. 2011). Other vestibular regions include the primary somatosensory cortex (the hand and neck somatosensory representations of postcentral areas 2 and 3 [Ödkvist et al. 1974;

⁹ Olfactory processing in the thalamus seems also to be different from processing of the main senses as there is no direct relay between sensory neurons and primary cortex, and olfactory thalamic nuclei have been identified only recently (Courtillot & Wilson 2014).

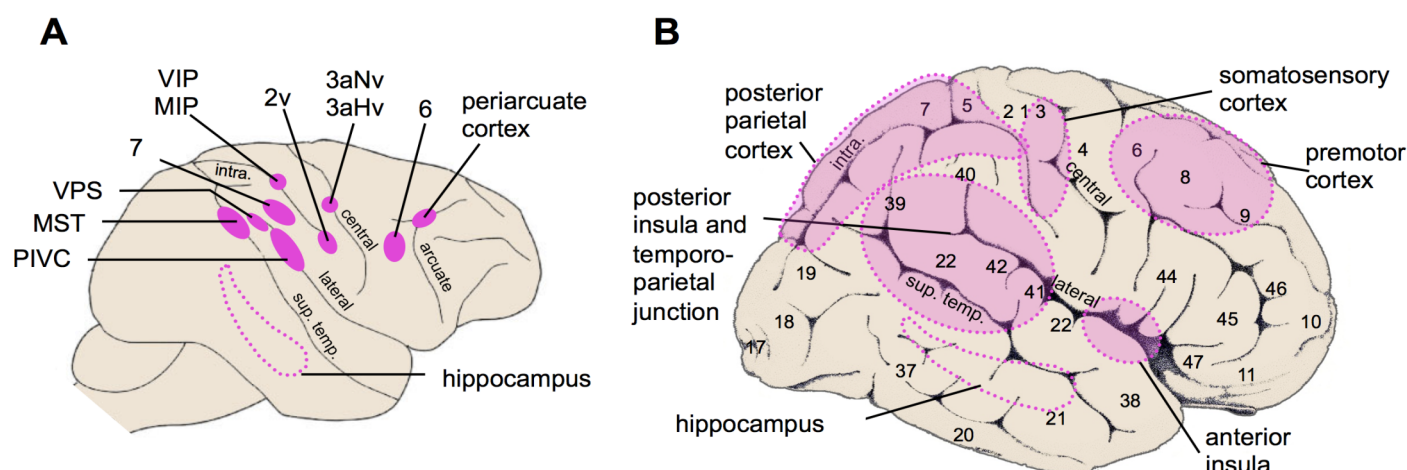

Figure 3: Schematic representation of the main cortical vestibular areas. (A) Main vestibular areas in monkeys are somatosensory areas 2v and 3av (3aHv (3a-hand-vestibular region), 3aNv (3a-neck-vestibular region)) in the postcentral gyrus, frontal area 6v and the periarculate cortex, parietal area 7, MIP (medial intraparietal area) and VIP (ventral intraparietal area), extrastriate area MST (medial superior temporal area), PIVC (parieto-insular vestibular cortex), VPS (visual posterior sylvian area), and the hippocampus. Major sulci are represented: arcuate sulcus (arcuate), central sulcus (central), lateral sulcus (lateral), intraparietal sulcus (intra.), and superior temporal sulcus (sup. temp.). Adapted from Lopez and Blanke after Sugiuchi et al. (2005). (B) Main vestibular areas in the human brain identified by noninvasive functional neuroimaging techniques. Numbers on the cortex refer to the cytoarchitectonic areas defined by Brodmann. Adapted from Lopez & Blanke (2011) after Sugiuchi et al. (2005).

Schwarz et al. 1973; Schwarz & Fredrickson 1971]); ventral and medial areas of the intraparietal sulcus (Bremmer et al. 2001; Chen et al. 2011; Schlack et al. 2005); visual motion sensitive area MST (Bremmer et al. 1999; Gu et al. 2007); frontal cortex (motor and premotor cortex and the frontal eye fields [Ebata et al. 2004; Fukushima et al. 2006]); cingulate cortex (Guldin et al. 1992) and hippocampus (O'Mara et al. 1994). These findings indicate that vestibular processing in the animal cortex relies on a highly distributed cortical network.

A similar conclusion has been drawn from neuroimaging studies conducted in humans. These studies have used fMRI and PET during caloric and galvanic vestibular stimulation¹⁰ and

revealed that the human vestibular cortex closely matches the vestibular regions found in animals. Vestibular responses were found in the insular cortex and parietal operculum as well as in several regions of the temporo-parietal junction (superior temporal gyrus, angular and supramarginal gyri). Other vestibular activations are located in the primary and secondary somatosensory cortex, precuneus, cingulate cortex, frontal cortex, and hippocampus (Bense et al. 2001; Bottini et al. 1994; Bottini et al. 1995; Dieterich et al. 2003; Eickhoff et al. 2006; Indovina et al. 2005; Lobel et al. 1998; Suzuki et al. 2001).

It is of note that the non-human animal and human vestibular cortex differs from other sensory cortices as there is apparently no *primary vestibular cortex*; that is, there is no koniocortex dedicated to vestibular processing and containing only or mainly vestibular responding neurons (Grüsser et al. 1994; Guldin et al. 1992; Guldin & Grüsser 1998), stressing again the multisensory character of the vestibular

behind one ear, and the cathode on the opposite side. The cathodal current increases the firing rate in the ipsilateral vestibular afferents.

¹⁰ Caloric and galvanic vestibular stimulations are the two most common techniques to artificially (i.e., without any head or full-body movements) stimulate the vestibular receptors. Caloric vestibular stimulation was developed by Robert Bárány and consists of irrigating the auditory canal with warm (e.g., 45°C) or cold (e.g., 20°C) water (or air), creating convective movements of the endolymphatic fluid mainly in the horizontal semicircular canals. This stimulation evokes a vestibular signal close to that produced during head rotations. Galvanic vestibular stimulation consists of the application of a transcutaneous electrical current through electrodes placed on the skin over the mastoid processes (i.e., behind the ears). Galvanic vestibular stimulation is often applied binaurally, with the anode fixed

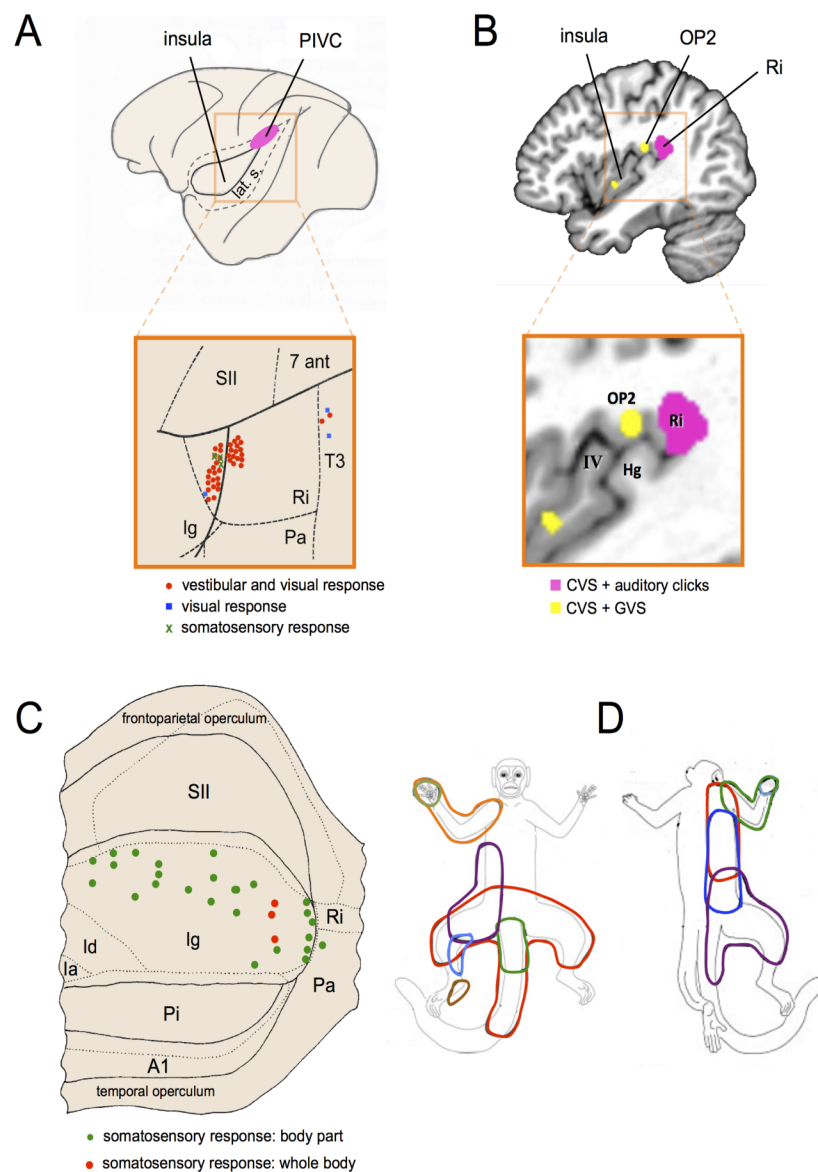

Figure 4: Anatomical location and functional properties of the parieto-insular vestibular cortex (PIVC). (A) Schematic representation of the macaque brain showing the location of the PIVC. For the purpose of illustration, the lateral sulcus (lat. s.) is shown unfolded. The macaque PIVC is located in the parietal operculum at the posterior end of the insula and retroinsular cortex. Modified from Grüsser et al. (1994). The insert illustrates the location of vestibular neurons in different regions of the lateral sulcus in a squirrel monkey (*Saimiri sciureus*). The lateral sulcus is shown unfolded to visualize the retroinsular cortex (Ri), secondary somatosensory cortex (SII), granular insular cortex (Ig), and auditory cortex (PA). Vestibular neurons (red dots) were mostly located in Ri and Ig. Adapted from Guldin et al. (1992). (B) Vestibular activations found in the human PIVC using meta-analysis of functional neuroimaging data. The Ri showed a convergence of activations evoked by caloric vestibular stimulation (CVS) of the semicircular canals and auditory activation of the otolith organs (pink). The parietal operculum (OP2) and posterior insula showed a convergence of activations evoked by CVS and galvanic vestibular stimulation (GVS) of all primary vestibular afferents (yellow). Hg (Heschl's gyrus). Adapted from Lopez et al. (2012). (C) View of the unfolded lateral sulcus of the rhesus monkey (*Macaca mulatta*) showing somatosensory neurons (green dots) in the granular insula, of which some have large somatosensory receptive fields covering the whole body (red dots). Ia (agranular insular field); Id (dysgranular insular field); A1 (first auditory field); Pa (postauditory field); Pi (parainsular field). Modified from Schneider et al. (1993). (D) Representation of the size of the receptive fields of neurons recorded in somatosensory representations of the body found in the dorsal part of the insula (ventral somatosensory area) of the titi monkey (*Callicebus moloch*). Modified from Coq et al. (2004).

lar system. All areas processing vestibular signals are multimodal, integrating visual, tactile, and proprioceptive signals. The PIVC has been shown to occupy a key role in the cortical vestibular network and is the only vestibular area that is connected to all other vestibular regions described above. The PIVC also receives signals from the primary somatosensory cortex, premotor cortex, posterior parietal cortex, and the cingulate cortex (Grüsser et al. 1994; Guldin et al. 1992), and it integrates signals from personal and extrapersonal spaces. Given these characteristics, we believe that the PIVC should be importantly involved in a coherent representation of the bodily self and the body embedded in the world.

3.2.3 The PIVC as a core, multimodal, vestibular cortex

The group of Grüsser was the first to describe vestibular responses in the monkey PIVC. Vestibular neurons were located in several regions of the posterior end of the lateral sulcus “in the upper bank of the lateral sulcus around the posterior end of the insula, sometimes also within the upper posterior end of the insula [... and] more posteriorly in the retroinsular region or more anteriorly in the parietal operculum” (Grüsser et al. 1990a, pp. 543-544; Grüsser et al. 1990b; Guldin et al. 1992; Guldin & Grüsser 1998). Figure 4A illustrates the location of PIVC in the macaque brain. Recent investigations of PIVC in rhesus monkeys revealed that vestibular neurons were mostly located in the retroinsular cortex and at the junction between the secondary somatosensory cortex, retroinsular cortex, and granular insular cortex (area Ig) (Chen et al. 2010; Liu et al. 2011).

In humans, functional neuroimaging studies used caloric and galvanic vestibular stimulation and showed activations in and around the posterior insula and temporo-parietal junction (Bense et al. 2001; Bottini et al. 1994; Dieterich et al. 2003; Eickhoff et al. 2006; Lobel et al. 1998; Suzuki et al. 2001). Because these activations also extend to the superior temporal gyrus, posterior and anterior insula, and inferior parietal lobule, the exact location of human

PIVC is still debated (review in Lopez & Blanke 2011). Recent meta-analyses of vestibular activations suggest that the core vestibular cortex is in the *parietal operculum*, *retroinsular cortex*, and/or *posterior insula* (Lopez et al. 2012; zu Eulenburg et al. 2012) (figure 4B). Of note, several neuroimaging studies have also implicated the anterior insula in vestibular processing (Bense et al. 2001; Bottini et al. 2001; Fasold et al. 2002). The insula is crucial for interoceptive awareness (Craig 2009) and could provide the neural substrate for vestibulo-interoceptive interactions that impact several aspects of the bodily self (see section 4.1.3).

4 Vestibular contributions to various aspects of the bodily self

The aim of this section is to describe several mechanisms by which the vestibular system might influence multisensory mechanisms underlying the bodily self. Again, we would like to stress that the vestibular system seems of utter importance for the most minimal aspects of self-consciousness (i.e., the sense of location in a spatial reference frame) (Windt 2010; Metzinger 2013, 2014) but at the same time also contributes to our rich sense of a bodily self in daily life. We will try to include both aspects in the following section. We further point out that while some mechanisms of a vestibular contribution to the sense of a self are now accepted, others are still largely speculative. We start by pinpointing the influence of the vestibular system on basic bodily senses such as touch and pain (section 4.1, which are subjectively experienced as bodily, i.e., as coming from within one's own bodily borders, and thus importantly contribute to a sense of bodily self. We then outline evidence for a vestibular contribution to several previously identified and experimentally modified components of the multisensory bodily self: body schema and body image, body ownership, agency, and self-location (sections 4.2–4.5). On the basis of recent data on self-motion perception in a social context and on the existence of shared sensorimotor representations between one's own body and others' bodies, we propose a vestibular contribution to the socially embedded self (section 4.6).

4.1 The sensory self

4.1.1 Touch

The feeling of touch, as its subjective perception is confined within the bodily borders, is considered as crucial for the feeling of ownership and other aspects of the bodily self (Makin et al. 2008) and a loss of somatosensory signals has been associated with a disturbed sense of the bodily self (e.g., Lenggenhager et al. 2012). Vestibular processes have been shown to interact with the perception and location of tactile stimulation. Clinical studies in brain-damaged patients suffering from altered somatosensory perceptions showed transient improvement of somatosensory perception during artificial vestibular stimulation (Kerkhoff et al. 2011; Vallar et al. 1990). Furthermore, studies in healthy participants showed that caloric vestibular stimulation can alter conscious perception of touch (Ferrè et al. 2011), probably due to interfering effects in the parietal operculum (Ferrè et al. 2012). A recent study further suggests that vestibular stimulations not only modify tactile perception thresholds, but also the perceived location of stimuli applied to the skin (Ferrè et al. 2013), a finding likely related to a vestibular influence on the body schema (see section 4.2).

Behavioural evidence of vestibulo-tactile interactions is in line with both human and animal physiological and anatomical data. Human neuroimaging studies identified areas responding to tactile, proprioceptive, and caloric vestibular stimulation in the posterior insula, retroinsular cortex, and parietal operculum (Bottini et al. 1995; Bottini et al. 2001; Bottini et al. 2005; zu Eulenburg 2013). Electrophysiological recordings in monkeys revealed a *vestibulo-somesthetic convergence* in most of the PIVC neurons. Bimodal neurons in the PIVC have large somatosensory receptive fields often located in the region of the neck and respond to muscle pressure, vibrations, and rotations applied to the neck (Grüsser et al. 1990b).

To date, the influence of caloric vestibular stimulation on somatosensory perception has been measured at the level of peripheral body parts only (e.g., the capacity to detect

touch applied to the hand, or to locate touch on the hand), but not on more central body parts or *the entire body*. Here, we propose that vestibular signals are not only important for sensory processes and awareness of body parts, but even more for *full-body awareness*. This hypothesis is supported by findings from mapping of the posterior end of the lateral sulcus in rhesus monkey that revealed neurons in the granular field of the posterior insula with *large* and *bilateral* tactile receptive fields (Schneider et al. 1993). The range of stimuli used included brushing and stroking the hair, touching the skin, muscles and other deep structures, and manipulating the joints. Importantly, the authors noted that some neurons had receptive fields covering the entire surface of the animal body, excluding the face. As can be seen in figure 4C, those neurons (red dots) were located in the most posterior part of the insula. Functional mapping conducted in the dorsal part of the insula in other monkey species has also identified neurons with large and sometimes bilateral tactile receptive fields (Coq et al. 2004) (figure 4D). So far, there is no direct evidence that neurons with full-body receptive fields receive vestibular inputs, probably because to date few electrophysiological studies have directly investigated the convergence of vestibular and somatosensory signals in the lateral sulcus (Grüsser et al. 1990a; Grüsser et al. 1990b; Guldin et al. 1992). We hypothesize that caloric and galvanic vestibular stimulation, as well as physical head rotations and translations, are likely to interfere with populations of neurons with whole-body somatosensory receptive fields and therefore may strongly impact full-body awareness. Indeed, in daily life the basic sense of touch, especially regarding large body segments, should be crucial to experience a bodily self. While full-body tactile perception hasn't been directly assessed during vestibular stimulation, the fact that caloric vestibular stimulation in healthy participants as well as acute vestibular dysfunction can evoke the feeling of strangeness and numbness for the entire body might point in this direction (see Lopez 2013, for a review).

4.1.2 Pain

Similar to touch, the experience of pain has been described as crucial to self-consciousness and the feeling of an embodied self. In his book “Still Lives—Narratives of Spinal Cord Injury” (Cole 2004), the neurophysiologist Jonathan Cole reports the case of a patient with a spinal cord lesion who described that “the pain is almost comfortable. Almost my friend. I know it is there, it puts me in contact with my body” (p. 89). This citation impressively illustrates how important the experience of pain might be in some instances for the sense of a bodily self. Reciprocal relations between pain and the sense of self are further supported by observations of altered pain perception and thresholds during dissociative states of bodily self-consciousness, such as depersonalization (Röder et al. 2007), dissociative hypnosis (Patterson & Jensen 2003) and out-of-body experiences (Green 1968). Similarly, acting in an immersive virtual environment is also associated with an increase in pain thresholds (Hoffman et al. 2004), a fact that is now increasingly exploited in virtual reality based pain therapies. This increase in pain threshold depends on the strength of *feeling of presence* in the virtual environment, i.e., the sense of “being there,” located in the virtual environment (Gutiérrez-Martínez et al. 2011; see also section 4.5.2.1). These analgesic effects of immersion and presence in virtual realities are usually explained by attentional resource mechanisms (i.e., attention is directed to the virtual environment rather than the painful event). Yet, all described instances involve also illusory self-location which has shown in full-body illusions to be accompanied by an increasing in pain thresholds or altered arousal response to painful stimuli (Hänsel et al. 2011; Romano et al. 2014). We thus speculate that analgesic effects of immersion could also be linked to disintegrated multisensory signals and a related illusory change in self-location and global self-identification. Since the vestibular system is crucially involved in self-location (see section 4.5), we suggest that some interaction effects between altered self-location and pain may be

mediated by the vestibular system.¹¹ Interestingly, galvanic and caloric stimulation, which also induce illusory changes in self-location, increase pain thresholds in healthy participants (Ferrè et al. 2013). This result and several clinical observations suggest an interplay between vestibular processes, nociceptive processes, and the sense of the bodily self (André et al. 2001; Balaban 2011; Gilbert et al. 2014; McGeoch et al. 2008; Ramachandran et al. 2007).

These interactions are likely to rely on multimodal areas in the insular cortex. Intracranial electrical stimulations of the posterior insula in conscious epileptic patients revealed nociceptive representations with a somatotopic organization (Mazzola et al. 2009; Ostrowsky et al. 2002). Functional neuroimaging studies in healthy participants also demonstrated that painful stimuli (usually applied to the hand or foot) activate the operculo-insular complex (Baumgartner et al. 2010; Craig 2009; Kurth et al. 2010; Mazzola et al. 2012; zu Eulenburg et al. 2013). It has to be noted that vestibulo-somesthetic convergence may also exist in thalamic nuclei such as the ventroposterior lateral nucleus, known to receive both somatosensory and vestibular signals (Lopez & Blanke 2011). The parabrachial nucleus of the brainstem is also a region where vestibular and nociceptive signals converge, as shown by noxious mechanical and thermal cutaneous stimulations (Balaban 2004; Bester et al. 1995). The parabrachial nucleus is further strongly interconnected with the insula and amygdala and may control some autonomic manifestations of pain (Herbert et al. 1990). Furthermore, a recent fMRI study revealed an overlap between brain activations caused by painful stimuli and by artificial vestibular stimulation in the anterior insula (zu Eulenburg et al. 2013), a structure that has been proposed to link the homeostatic evaluation of the current state of the bodily self to broader social and motivational aspects (Craig 2009). We speculate that such association could explain why illusory changes in

¹¹ A recent study investigating pain thresholds during the rubber hand illusion did not show any change in pain threshold or perception (Mohan et al. 2012), suggesting that pain perception is linked more to global aspects of the bodily self, e.g., self-location.

self-location during vestibular stimulation or during full-body illusions decrease pain thresholds.

4.1.3 Interoception

Visceral signals and their cortical representation—often referred to as *interoception*—are thought to play a core role in giving rise to a sense of self (e.g., [Seth 2013](#)). It has been proposed that visceral signals influence various aspects of emotional and cognitive processes (e.g., [Furman et al. 2013](#); [Lenggenhager et al. 2013](#); [Werner et al. 2014](#); [van Elk et al. 2014](#)) and anchor the self to the physical body ([Maister & Tsakiris 2014](#); [Tsakiris et al. 2011](#)). For this reason, various clinical conditions involving disturbed self-representation and dissociative states have been related to abnormal interoceptive processing ([Seth 2013](#), but see also [Michal et al. 2014](#) for an exception). Further evidence that interactions of exteroceptive with interoceptive signals play a role in building a self-representation comes again from research using bodily illusions in healthy participants. Two recent studies introduced an interoceptive version of the rubber hand illusion ([Suzuki et al. 2013](#)) and the full-body illusion ([Aspell et al. 2013](#)). In both cases, a visual cue on the body part/full body was presented in synchrony/asynchrony with the participant's own heartbeat. Synchrony increased self-identification with the virtual hand or body and modified the experience of self-location, thus suggesting a modulation of these components through interoceptive signals.

Vestibular processing in the context of such interoceptive bodily illusions has not yet been studied. Yet, we would like to emphasize the important interactions between the vestibular system and the regulation of visceral and autonomic functions at both functional and neuroanatomical levels (review in [Balaban 1999](#)). As mentioned earlier, the coding of body orientation in space relies on otolithic information signaling the head orientation with respect to gravity. Self-orientation with respect to gravity also requires that the brain integrates these vestibular signals with information

from gravity receptors in the trunk (e.g., visceral signals from kidneys and blood vessels) ([Mittelstaedt 1992](#); [Mittelstaedt 1996](#); [Vaitl et al. 2002](#)). Other examples of interactions between the vestibular system and autonomic regulation come from the vestibular control of blood pressure, heart rate, and respiration ([Balaban 1999](#); [Jauregui-Renaud et al. 2005](#); [Yates & Bronstein 2005](#)). Blood pressure, for instance, needs to be adapted as a function of body position in space and the vestibular signals are crucially used to regulate the baroreflex. Vestibular-mediated symptoms of motion sickness such as pallor, sweating, nausea, salivation, and vomiting are also very well-known and striking examples of the vestibular influence on autonomic functions.

At the anatomical level, there is a large body of data showing that vestibular information projects to several brain structures involved in autonomic regulation, including the *parabrachial nucleus*, nucleus of the solitary tract, paraventricular nucleus of the hypothalamus, and the central nucleus of the amygdala. Important research has been conducted in the monkey and rat parabrachial nucleus as this nucleus contains neurons responding to natural vestibular stimulation ([McCandless & Balaban 2010](#)) and is involved in the ascending pain pathways and cardiovascular pathways to the cortex and amygdala ([Bester et al. 1995](#); [Feil & Herbert 1995](#); [Herbert et al. 1990](#); [Jasmin et al. 1997](#); [Moga et al. 1990](#)). The parabrachial nucleus receives projections from several cortical regions, including the insula, as well as from the hypothalamus and amygdala ([Herbert et al. 1990](#); [Moga et al. 1990](#)). Accordingly, the parabrachial nucleus should be a crucial brainstem structure for basic aspects of the self as it is a place of convergence for nociceptive, visceral, and vestibular signals.

While research on the effects of vestibular stimulation on interoceptive awareness is still missing, we propose that artificial vestibular stimulation might be a particularly interesting means to manipulate interoception and investigate its influence on the sense of a bodily self.

4.2 Body schema and body image

Here, we propose that vestibular signals are not only important for the interpretation of basic somatosensory (tactile, nociceptive, interoceptive) processes, but as a consequence also contribute to *body schema* and *body image*. Body schema and body image are different types of models of motor configurations and body metric properties, including the size and shape of body segments (e.g., [Gallagher 2005](#); [de Vignemont 2010](#); [Berlucchi & Aglioti 2010](#); [Longo & Hag-gard 2010](#)). Although body schema and body image are traditionally thought to be of mostly proprioceptive and visual origin, respectively, a vestibular contribution was already postulated over a century ago (review in [Lopez 2013](#)). [Pierre Bonnier \(1905\)](#) described several cases of distorted bodily perceptions in vestibular patients and coined the term “*aschématie*” (meaning a “loss” of the *schema*) to describe these distorted perceptions of the volume, shape, and position of the body. [Paul Schilder \(1935\)](#) also noted distorted body schema and image in vestibular patients claiming for example that their “neck swells during dizziness,” “extremities had become larger,” or “feet seem to elongate.” The contribution of vestibular signals to mental body representations has been recognized more recently by Jacques Paillard. He proposed that “the ubiquitous geotropic constraint [i.e., gravitational acceleration, which is detected and coded by vestibular receptors] dominates the [body-, world-, object- and retina-centered] reference frames that are used in the visuomotor control of actions and perceptions, and thereby becomes a crucial factor in linking them together” ([Paillard 1991](#), p. 472). According to Paillard, gravity signals would help merge and give coherence to the various reference frames underpinning action and perception.

Because humans have evolved under a constant gravitational field, human body representations are strongly shaped by this physical constraint. In particular, grasping and reaching movements are constrained by gravito-inertial forces and internal models of gravity ([Indovina et al. 2005](#); [Lacquaniti et al. 2013](#); [McIntyre et al. 2001](#)). Thus, the body schema and action

potentialities must take into account signals from the otolithic sensors. For example, when a subject is instructed to reach a target while his entire body is rotated on a chair, the body rotation generates Coriolis and centrifugal forces deviating the hand. Behavioural studies demonstrate that vestibular signals generated during whole-body rotations are used to correct the hand trajectory ([Guillaud et al. 2011](#)). Other studies demonstrate that vestibular signals continuously update the body schema during hand actions. [Bresciani et al. \(2002\)](#) asked participants to point to previously memorized targets located in front of them ([figure 5A](#)). At the same time, participants received bilateral galvanic vestibular stimulation, with the anode on one side and the cathode on the other side. The data indicate that the hand was systematically deviated toward the side of anodal stimulation ([figure 5B](#)). It is important to note that galvanic vestibular stimulation is known to evoke illusory body displacements in the frontal plane and thus modifies the perceived self-location ([Fitzpatrick et al. 2002](#); see also section 4.5). One possible interpretation of the change in hand trajectory during the pointing movement was that it compensated for an “apparent change in the spatial relationship between the target and the hand,” evoked by the vestibular stimulation ([Bresciani et al. 2002](#)). Thus, vestibular signals are used to control the way we act and interact with objects in the environment.

After having established the contribution of vestibular signals to hand location and motion, we shall describe the role of vestibular signals in the perception of the body’s metric properties (the perceived shape and size of body segments). During parabolic flights, known to create temporary weightlessness and thus mimic a deafferentation of the otolithic vestibular sensors, [Lackner \(1992\)](#) reported cases of participants experiencing a “telescoping motion of the feet down and the head up internally through the body,” that is, an inversion of their body orientation. Experiments conducted on animals born and raised in hypergravity confirm an influence of vestibular signals on body representations. In these animals, changes in the strength of the gravita-

Figure 5: Influence of vestibular signals on motor control and perceived body size. (A) Pointing task toward memorized targets. Participants received binaural galvanic vestibular stimulation as soon as they initiated the hand movement (with eyes closed). (B) Deviation of the hand trajectory towards the anode (modified after [Bresciani et al. 2002](#)). (C) Proprioceptive judgment task used to estimate the perceived size of the left hand. Participants were tested blindfolded and used a stylus held in their right hand to localize on a digitizing tablet four anatomical landmarks corresponding to the left hand under the tablet. (D) Illustration of the perception of an enlarged hand during caloric stimulation activating the right cerebral hemisphere (modified after [Lopez et al. 2012](#)).

tional field permanently disorganized the somatosensory maps recorded in their primary somatosensory cortex ([Zennou-Azogui et al. 2011](#)).

Experimental evidence of a vestibular contribution to the coding of body metric properties comes from the application of stimulation in healthy participants. In a recent study, [Lopez et al. \(2012\)](#) showed that caloric vestibular stimulation modified the perceived size of the body during a proprioceptive judg-

ment task ([figure 5C](#)). Participants had their left hand palm down on a table. Above the left hand, there was a digitizing tablet on which participants were instructed to localize four anatomical targets enabling the calculation of the perceived width and length of the left hand. While participants pointed repeatedly to these targets, they received bilateral caloric vestibular stimulation known to stimulate the right cerebral hemisphere in which the left hand is mostly represented

(e.g., warm air in the right ear and cold air in the left ear). The results showed that in comparison to a control stimulation (injection of air at 37°C in both ears), in the stimulation condition the left hand appeared significantly enlarged (figure 5D), showing that vestibular signals can modulate internal models of the body.

4.3 Body ownership

Correct self-attribution of body parts and self-identification with the entire body relies on successful integration of multisensory information as evidenced by various bodily illusions in healthy participants (e.g., Botvinick & Cohen 1998; Lenggenhager et al. 2007; Petkova & Ehrsson 2008). So far there is only little evidence of a vestibular contribution to the sense of body ownership. Bisiach et al. (1991) described a patient with a lesion of the right parieto-temporal cortex who suffered from somatoparaphrenia, claiming that her left hand did not belong to her. In this patient, caloric vestibular stimulation transiently restored normal ownership for her left hand. Similarly, Lopez et al. (2010) applied galvanic vestibular stimulation to participants experiencing the rubber hand illusion and showed that the vestibular stimulation increased the feeling of ownership for the fake hand. The authors have linked such interaction between the vestibular system, multisensory integration, and body ownership to overlapping cortical areas in temporo-parietal areas and the posterior insula. No study has so far investigated the effect of vestibular stimulation on full-body ownership. Yet, reports from patients with acute vestibular disturbances as well as reports from healthy participants during caloric vestibular stimulation (Lopez 2013; Sang et al. 2006) suggest that full-body ownership might also be modified by artificial vestibular stimulation or vestibular dysfunctions. Given the importance of the vestibular system in more global aspects of the bodily self, we predict that vestibular stimulation would influence ownership even stronger in a full-body illusion than in a body-part illusion set-up.

4.4 The acting self: Sense of agency

As mentioned earlier, the sense of being the agent of one's own actions is another crucial aspect of the sense of self. Agency relies on sensorimotor mechanisms comparing the motor efference copy with the sensory feedback from the movement, and on other cognitive mechanisms such as the expectation of a self-generated movement (Cullen 2012; Jeannerod 2003, 2006). While no study so far has directly investigated vestibular mechanisms of the sense of agency, recent progress in this direction has been made in a study investigating full-body agency during a goal-directed locomotion task (Kannape et al. 2010). Participants walked toward a target and observed their motion-tracked walking patterns applied to a virtual body projected on a large screen in front of them. Various angular biases were introduced between their real locomotor trajectory and that projected on the screen. Comparable to the classical experiments assessing agency for a body part (Fournieret & Jeannerod 1998), these authors investigated the discrepancy up to which the motion of the avatar showed on the screen was still perceived as their own. During this task, the brain does not only detect visuo-motor coherence but also vestibulo-visual coherence, and self-attribution of the seen movements is thus likely to depend on vestibular signal processing. In the following we present an example of neural coding underlying an aspect of the sense of agency in several structures of the vestibulo-thalamo-cortical pathways.

In the vestibular system, peripheral organs encode in a similar way head motions for which the subject is or is not the agent.¹² Thus, vestibular organs generate similar signals during an active rotation of the head (i.e., the person is the agent of the action) or during a passive, externally imposed, rotation of the head (i.e., the person is passively moved while sitting on a rotating chair). It is important for the central

¹² Although the coding of movements by the peripheral vestibular organs is ambiguous regarding the sense of agency, the coding is not ambiguous regarding the sense of ownership for the movements and self-other distinction. Indeed, because vestibular sensors are inertial sensors, vestibular signals are necessarily related to one's own motion and are the basis of the perception that I have (been) moved, irrespective of whether the "self" is or is not the agent of this movement.

nervous system to establish whether afferent vestibular signals are generated by active or passive head movements, and this is done at various levels. Electrophysiological studies conducted in monkeys have revealed that some vestibular nuclei neurons were silent, or had a strongly reduced firing rate, during active head rotations, whereas their firing rate was significantly modulated by passive head rotations. This indicates that vestibular signals generated by active head rotations were suppressed or attenuated. This suppression of neural responses was found in the vestibular nuclei complex (Cullen 2011; Roy & Cullen 2004), thalamus (Marlinski & McCrea 2008b) and cerebral cortex, for example in areas of the intraparietal sulcus (Klam & Graf 2003, 2006). Several studies were conducted to determine which signal might induce such suppression. Roy & Cullen (2004) suggested that a *motor efference copy* was used. They showed that the suppression occurred “only in conditions in which the activation of neck proprioceptors matched that expected on the basis of the neck motor command”, suggesting that “vestibular signals that arise from self-generated head movements are inhibited by a mechanism that compares the internal prediction of the sensory consequences by the brain to the actual resultant sensory feedback” (p. 2102). In conclusion, as early as the first relay along the vestibulo-thalamo-cortical pathways, neural mechanisms have the capacity to distinguish between the consequences of active and passive movements on vestibular sensors. Given this evidence, we suggest an important contribution of the vestibular system to the sense of agency in general and to full-body agency in particular.

4.5 The spatial self: Self-location

4.5.1 Behavioural studies in humans

Self-location is the experience of where “I” am located in space and is one of the (if not the) crucial aspects of the bodily self (Blanke 2012). Recently, self-location has been systematically investigated in human behavioural and neuroimaging studies using multisensory conflicts (Ionta et al. 2011; Lenggenhager et al.

2007; Lenggenhager et al. 2009; Pfeiffer et al. 2013). While we usually experience ourselves as located within our own bodily borders at one single location in space, the sense of self-location can be profoundly disturbed in psychiatric and neurological conditions, most prominently during *out-of-body experiences* (Bunning & Blanke 2005). Based on findings in neurological patients that revealed a frequent association between vestibular illusions (floating in the room, sensation of lightness or levitation) and out-of-body experiences, Blanke and colleagues proposed that the illusory disembodied self-location was due to a dis-integration of vestibular signals with signals from the personal (tactile and proprioceptive signals) and extrapersonal (visual) space (Blanke et al. 2004; Blanke & Mohr 2005; Blanke 2012; Lopez et al. 2008). The authors proposed that this multisensory disintegration is mostly a result of abnormal neural activity in the temporo-parietal junction (Blanke et al. 2005; Blanke et al. 2002; Heydrich & Blanke 2013; Ionta et al. 2011). In this section, we review experimental data in healthy participants that may account for the tight link between vestibular disorders and illusory or simulated changes in self-location. While the most direct evidence of such a link comes from the finding that artificial stimulation of the vestibular organs induces an illusory change in self-location¹³ (Fitzpatrick & Day 2004; Fitzpatrick et al. 2002; Lenggenhager et al. 2008), we focus on three experimental set-ups that have been used to alter the experience of self-location in healthy participants.

4.5.1.1 Illusory change in self-location during full-body illusions

Full-body illusions have increasingly been used to study the mechanisms underlying self-location (see Blanke 2012, for a review). No study has so far investigated the influence of artificial vestibular stimulation on such illusions. Nevertheless, there is some experimental evidence suggesting a vestibular involvement in illusory changes in self-location. While the initial full-

¹³ Depending on the stimulation parameters and method, participants describe various sensations of movements and change in position.

body illusion was described in a standing position (Lenggenhager et al. 2007), the paradigm has later been adapted to a lying position (Ionta et al. 2011; Lenggenhager et al. 2009; Pfeiffer et al. 2013), mainly because the frequency of spontaneous out-of-body experiences is higher in lying position than in standing or sitting positions (Green 1968). It has been speculated that this influence of the body position on the sense of embodiment is related to the decreased sensitivity of otolithic vestibular receptors and decreased motor and somatosensory signals in the lying position (Pfeiffer et al. 2013). We hypothesized that under such conditions of reduced vestibular (and proprioceptive) information, visual capture is enhanced in situations of multisensory conflict, thus resulting in a stronger change in self-location during the full-body illusion. So far, the full-body illusion has not been directly compared in standing versus lying positions. However, the application of visuo-tactile conflicts in a lying position not only alters self-location but also evokes sensations of floating (Ionta et al. 2011; Lenggenhager et al. 2007). This finding hints toward a reweighting of visual, tactile, proprioceptive, and vestibular information during the illusion, plausibly in the temporo-parietal junction and human PIVC. In line with this finding, the changes in self-location and perspective have been associated with individual perceptual styles of visual-field dependence (Pfeiffer et al. 2013), i.e., weighting of visual as compared to vestibular information in a subjective visual vertical task, suggesting an individually different contribution and weighting of the various senses for the construction of the bodily self (for a similar finding regarding the rubber hand illusion, see David et al. 2014).

4.5.1.2 Mental own-body transformation and perspective taking

Another way to investigate bodily self-consciousness has been to use experimental paradigms requiring participants to put themselves “into the shoes” of another individual, that is to mentally simulate an external self-location (own-body, egocentric, mental trans-

formation tasks) and a third-person visuo-spatial perspective. Typically, participants are instructed to make left-right judgments about a body, for example, to judge whether this other shown person is wearing a glove on his right or left hand (Blanke et al. 2005; Lenggenhager et al. 2008; Parsons 1987; Schwabe et al. 2009). Other tasks require that participants adopt the visual perspective of another person to decide whether a visual object is to the right or left of the other person (David et al. 2006; Lambrey et al. 2012; Vogeley & Fink 2003). Early studies have shown that the time needed for own-body mental transformations correlates with the distance or angle between the participant’s position in the physical space and the position to be simulated (Parsons 1987). It is largely admitted that own-body mental transformation is an “embodied” mental simulation that can be influenced by various sensorimotor signals from the body (e.g., Kessler & Thomson 2010). In line with this view, various experiments demonstrated that the actual body position influences mental own-body transformation of body parts (e.g., Ionta et al. 2012). Importantly, next to proprioceptive and motor mechanisms, visuo-spatial perspective taking and own-body mental transformation also require the integration of vestibular information (active or passive body motion). Thus, while most of this research looked at how body parts’ posture (e.g., of the hand) influences mental own-body (part) transformation, some recent research investigated how mental own-body transformation is influenced by vestibular cues (Candidi et al. 2013; Dilda et al. 2012; Falconer & Mast 2012; Lenggenhager et al. 2008; van Elk & Blanke 2014). All these studies revealed that vestibular signals influence mental (full) own-body transformation, confirming again the influence of the vestibular system in the sense of self-location and perspective taking.¹⁴

¹⁴ Visuo-spatial perspective-taking has not only been used in the field of spatial cognition but also in the field of social cognition. Perspective taking is a very crucial aspect of human cognition, which allows us to understand other people’s actions and emotions. The fact that the vestibular system is importantly involved in such simulations might further suggest that the vestibular system is important for social cognition (see also section 5 and Deroualle & Lopez 2014).

4.5.1.3 Change in self-location and the feeling of presence

The development of immersive virtual environments has launched a powerful research area where the mechanisms of self-location can be investigated and manipulated by the *feeling of presence*. The term “presence” stems from virtual reality technologies and commonly refers to the feeling of being immersed (“being there”) in the virtual environment. Yet, it has been argued that “presence” also reflects a more general and basic state of consciousness (Riva et al. 2011). The study of presence has thus been suggested to provide useful tools to study (self-)consciousness, with the advantage of precise experimental control (Sanchez-Vives & Slater 2005).

Similar to previously mentioned full-body illusions, a participant who is immersed in a virtual environment receives contradicting multisensory information about his or her self-location: while visual information suggests that s/he is located in a virtual world, proprioceptive information suggests that s/he is located in the real world, for example, by indicating a different body position between the physical body and the avatar. Furthermore, and contrary to the full-body illusion, the visual information often indicates that the participant is moving, whereas the proprioceptive and vestibular information suggests that he or she is sitting still. The compelling feeling of presence in virtual environments indicates that participants rely strongly on visual cues. Of note, some authors have proposed that a sort of bi-location is possible in such a situation, by which one feels to a certain degree being localized simultaneously in both the real and virtual environments (Furlanetto et al. 2013; Wissmath et al. 2011), which has also been described in a clinical condition called heautoscopy (e.g., Blanke & Mohr 2005; Brugger et al. 1994).

Neuroimaging studies in healthy participants showed that self-identification with—and self-localization at—a position of a virtual avatar seen from a third-person perspective activates the left inferior parietal lobe (Corradi-Dell’acqua et al. 2008; Ganesh et al. 2012). Corroboratively, people who are addicted to video-

games show altered processing in a left posterior area of the middle temporal gyrus (Kim et al. 2012). These studies converge in their conclusion that multimodal areas in the temporo-parietal junction are involved in altered self-localization in virtual reality. As mentioned before, the temporo-parietal junction is a main region for vestibular processing. We thus hypothesize that the feeling of presence might be mediated by vestibular signals, which should be directly tested by assessing whether the feeling of presence can be modified by caloric and galvanic vestibular stimulation.

4.5.2 Physiological and vestibular mechanisms of self-location

4.5.2.1 Categories of cells coding self-location and self-orientation

Electrophysiological investigations in rodents have identified three categories of neurons encoding specifically where the animal is located, how its head is oriented, and how the animal moves in its environment (see Barry & Burgess 2014, for a recent review). These neurons are referred to in the literature as “place cells,” “head-direction cells,” and “grid cells”. In rats, *place cells* have been recorded as early as the 1970s in the hippocampus, and later in the subiculum and entorhinal cortex (O’Keefe & Conway 1978; O’Keefe & Dostrovsky 1971; Poucet et al. 2003). The firing rate of these neurons increases when the animal is located at a specific position within the environment. This activity is strongly modulated by allocentric signals (visual references in the environment) and vestibular signals (Wiener et al. 2002). Place cells have later been identified in several other animal species including mice (McHugh et al. 1996), bats (Ulanovsky & Moss 2007), monkeys (Furuya et al. 2014; Ludvig et al. 2004; Matsumura et al. 1999; Ono et al. 1993) and humans (Ekstrom et al. 2003; Miller et al. 2013). *Head-direction cells* were first recorded in the rat postsubiculum and later in several nuclei constituting the Papez circuit, such as the dorsal thalamic nucleus and lateral mammillary nuclei (Taube 2007). They were also found in

the retrosplenial and entorhinal cortex. Electrophysiological recordings revealed that head-direction cells “discharge allocentrically as a function of the animal’s directional heading, independent of the animal’s location and ongoing behavior” (Taube 2007). Head-direction cells have also been identified in the monkey hippocampus (Robertson et al. 1999). Finally, *grid cells* have been identified in the rat medial entorhinal cortex, but also in the pre- and parasubiculum (Boccaro et al. 2010; Sargolini et al. 2006). Grid cells fire for multiple locations of the animal within its environment. Altogether, these locations form a periodic pattern, or “grid,” spanning the entire surface of the environment. More recently, electrophysiological recordings have shown grid cells in mice (Fyhn et al. 2008), bats (Yartsev et al. 2011) and monkeys (Killian et al. 2012), and even probable homologues of grid cells in the human hippocampus (Doeller et al. 2010; Jacobs et al. 2013).

4.5.2.2 Place cells in the human hippocampus and “virtual” self-location

We can only speculate about the neural mechanisms of place and head-direction specific coding in the human brain. With the non-invasive neuroimaging techniques available to date (fMRI, PET, scalp electroencephalography (EEG), near-infrared spectroscopy (NIRS)), it remains difficult to investigate neural activity of potential human homologues of place cells, head-direction cells and grid cells (for fMRI identification of grid cells, see Doeller et al. 2010). Single-unit recordings can only be achieved during rather rare intracranial EEG carried out for presurgical evaluations of drug refractory epilepsy.

In a seminal intracranial EEG study conducted in 7 epileptic patients, Ekstrom et al. (2003) identified neurons with place selectivity in the *hippocampus*. Patients were immersed in a virtual environment and played a taxi driver computer game, picking up customers at one location in the virtual town and delivering them to another location of the town. As illustrated in figure 6, a neuron recorded in the right hip-

pocampus had a significantly stronger firing rate when the patient was virtually “located” in the upper left corner than in any other location of the virtual town, showing its place selectivity. The authors found that 24% of neurons recorded in the hippocampus displayed a pattern of place selectivity, a proportion that was significantly larger than in the other brain structures they explored. Using a very similar procedure in a virtual environment in patients with intracranial electrodes, a recent study identified probable grid-like cells in humans (Jacobs et al. 2013). They were predominantly located in the entorhinal cortex and anterior cingulate cortex.

Interestingly, in both studies, patients did not physically move but moved virtually using button presses on a keyboard or a joystick. Nevertheless, the firing rate of these neurons changed as a function of the “virtual” location of the participants within the virtual environment. This observation indicates that both hippocampal “place cells” as well as entorhinal and cingulate “grid-cells” were coding the patient’s location in the virtual world on the basis of allocentric visual signals, rather than the patient’s position in the real world. Although the findings about these properties of the hippocampus have been mostly interpreted in the research field of spatial navigation and memory (Burgess & O’Keefe 2003), we make a new proposition that they can also shed light on the neural underpinnings of bodily self-consciousness, especially on how the brain localizes the self both in everyday life as well as in situations of multisensory conflicts.

As mentioned earlier, the experience of self-location can be manipulated by creating conflicts between visual cues about the location of one’s own body (or an avatar) in the external world and tactile or other somatosensory signals (Ehrsson 2007; Lenggenhager et al. 2011; Lenggenhager et al. 2009; Lenggenhager et al. 2007). These visuo-tactile conflicts can induce the perception of being located closer to the avatar. The recent use of these visual-tactile conflicts during fMRI recordings showed that the apparent changes in self-location and visuo-spatial perspective were related to signal changes in the temporo-parietal junction, not in the hippocampus (Ionta et al. 2011). It is not clear whether

hippocampal place cells' activity can be recorded with the large-scale, non-invasive functional neuroimaging techniques available. Yet, we predict that visuo-tactile conflicts, by modifying the experienced self-location, should also modify the neural activity of place cells and grid cells and their vestibular modulation (see next section), as showed during navigation in immersive virtual environments (Ekstrom et al. 2003; Jacobs et al. 2013). Future research using intracranial EEG recordings in epileptic patients should endeavour to study directly the relation between place cell activity and the experience of human self-location in situations of conflicting multisensory information.

Figure 6: Map illustrating the firing rate of one cell in the right hippocampal showing a pattern of place selectivity. The rectangular map represents the virtual town explored by the participant using key presses on a keyboard and the red line represents the participant's trajectory within the virtual town. The nine white boxes indicate the location of buildings in the virtual town (SA, SB, and SC represent three shops that were "visited" by the participant). Colors from blue to red in the background represent the firing rate of the hippocampal cell as a function of the participant's location in the virtual town. This neuron displays a significantly higher firing rate when the participant was located in the left upper part of the virtual environment (location showed by a black square). Reproduced from Ekstrom et al. (2003).

4.5.2.3 Vestibular signals and place cells

In this section, we emphasize the contribution of vestibular signals to the neural coding of self-

location in the hippocampus. As mentioned above, the firing rate of place cells is strongly modulated by allocentric signals, a finding replicated in several studies in rodents (Wiener et al. 2002). Vestibular signals have also been shown to modulate the firing pattern of the hippocampal place cells, which is necessary when animals navigate in darkness (O'Mara et al. 1994).

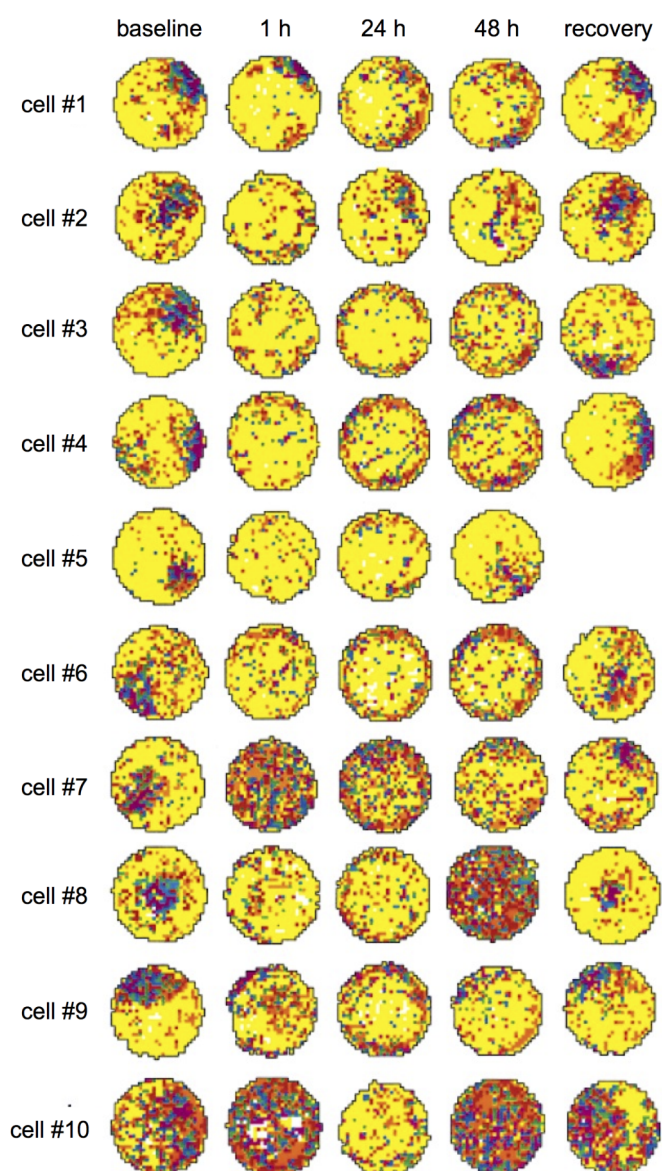

Figure 7: Modification of spatial selectivity of ten hippocampal place cells before and after inactivation of the vestibular apparatus with TTX injection. The colors ranging from yellow to purple represent the increase in firing rate of the place cells as a function of the location of the rat in the circular arena. From Stackman et al. (2002).

For example, [Stackman et al. \(2002\)](#) temporarily inactivated the vestibular system of rats using bilateral transtympanic injections of tetrodotoxin (TTX). TTX abolishes almost immediately neural activity in the vestibular nerve, producing a temporary vestibular deafferentation, mimicking the situation of patients with a bilateral vestibular loss. [Figure 7](#) illustrates changes in the firing rate of ten hippocampal neurons before and after TTX injection. Before TTX injection, hippocampal neurons displayed a typical pattern of place selectivity when the animal explored the circular environment. A major finding of this study was that as early as one hour after vestibular deafferentation, the location-specific activity of the same hippocampal neurons was strongly disturbed. In particular, the vestibular deafferentation reduced the spatial coherence and spatial information content that usually characterize the place cells. These disorders remained between thirty-six and seventy-two hours after TTX injection, despite the fact that the rats continued to explore their circular environment and had normal locomotor activity twelve hours after TTX injection. These results indicate that place cells are continuously integrating vestibular signals to estimate one's location within the physical environment and that vestibular signals strongly contribute to one of the most important neural mechanisms of self-location.

The activity of place cells or grid cells has not been recorded after vestibular deafferentation in humans. Nevertheless the neural consequences of vestibular lesions on place cells ([Stackman et al. 2002](#)) and head-direction cells ([Stackman & Taube 1997](#)) in animal models corroborate the effects of unilateral and bilateral vestibular lesions in humans. Patients with vestibular disorders may experience spatial disorientation as measured during path completion tasks ([Glasauer et al. 1994](#)) and navigation in virtual environments ([Hüfner et al. 2007](#); [Péruch et al. 1999](#)). We propose that vestibular disorders, by disorganizing the firing pattern of place cells in the human hippocampus (and in other brain regions containing place cells) may strongly disturb the sense of self-location and thus the coherent sense of self, which could

eventually even lead to disturbance of the usually very stable feeling of being located at a single place at a given time (see the strong disorganization of the place cells activity in [figure 7](#)). Another striking consequence of a bilateral vestibular loss is the induced atrophy of the hippocampus, whose volume is decreased by about seventeen percent ([Brandt et al. 2005](#)). Altogether, these data show that one neural mechanism of bodily self-location (place cells encoding of the body location in the environment) strongly relies on vestibular signals.

4.6 The socially embedded self

An important branch of research suggests that the neural mechanisms that dynamically represent multisensory bodily signals not only give rise to a sense of self, but also to the sense of others. The emerging field of social neuroscience has investigated both in animals and humans how the perception of another person modifies neural activity in body-related, sensorimotor neural processing and vice versa.¹⁵ “Sensorimotor sharing” and related mechanisms such as emotional contagion, sensorimotor resonance, or mimicry are thought to enable individuals to understand others' emotions, intentions, and actions and are thus fundamental for our social functioning. This line of research has evolved from an influential electrophysiological study that identified *mirror neurons* activated both when a monkey was performing a (body part) action and when observing someone else executing the same action ([Gallese et al. 1996](#); [Rizzolatti et al. 1996](#)). A human mirror-neuron-like system has been suggested based on neuroimaging studies that revealed similar brain activations when acting and when observing the same action being executed by another person (e.g., [Rizzolatti & Craighero 2004](#)). Importantly, similar mechanisms were found in various sensory systems as further experiments have shown common neural activity when experiencing and

¹⁵ The research on bodily illusions has recently extended to social neuroscience by investigating how sensorimotor self-other confusion (during the rubber hand, full-body, and enfacement illusions) affects the perception of another person and, vice versa, how the perception of another person influences illusory self-other confusion (e.g., [Bufalari et al. 2014](#); [Paladino et al. 2010](#); [Tajadura-Jiménez et al. 2012](#)).

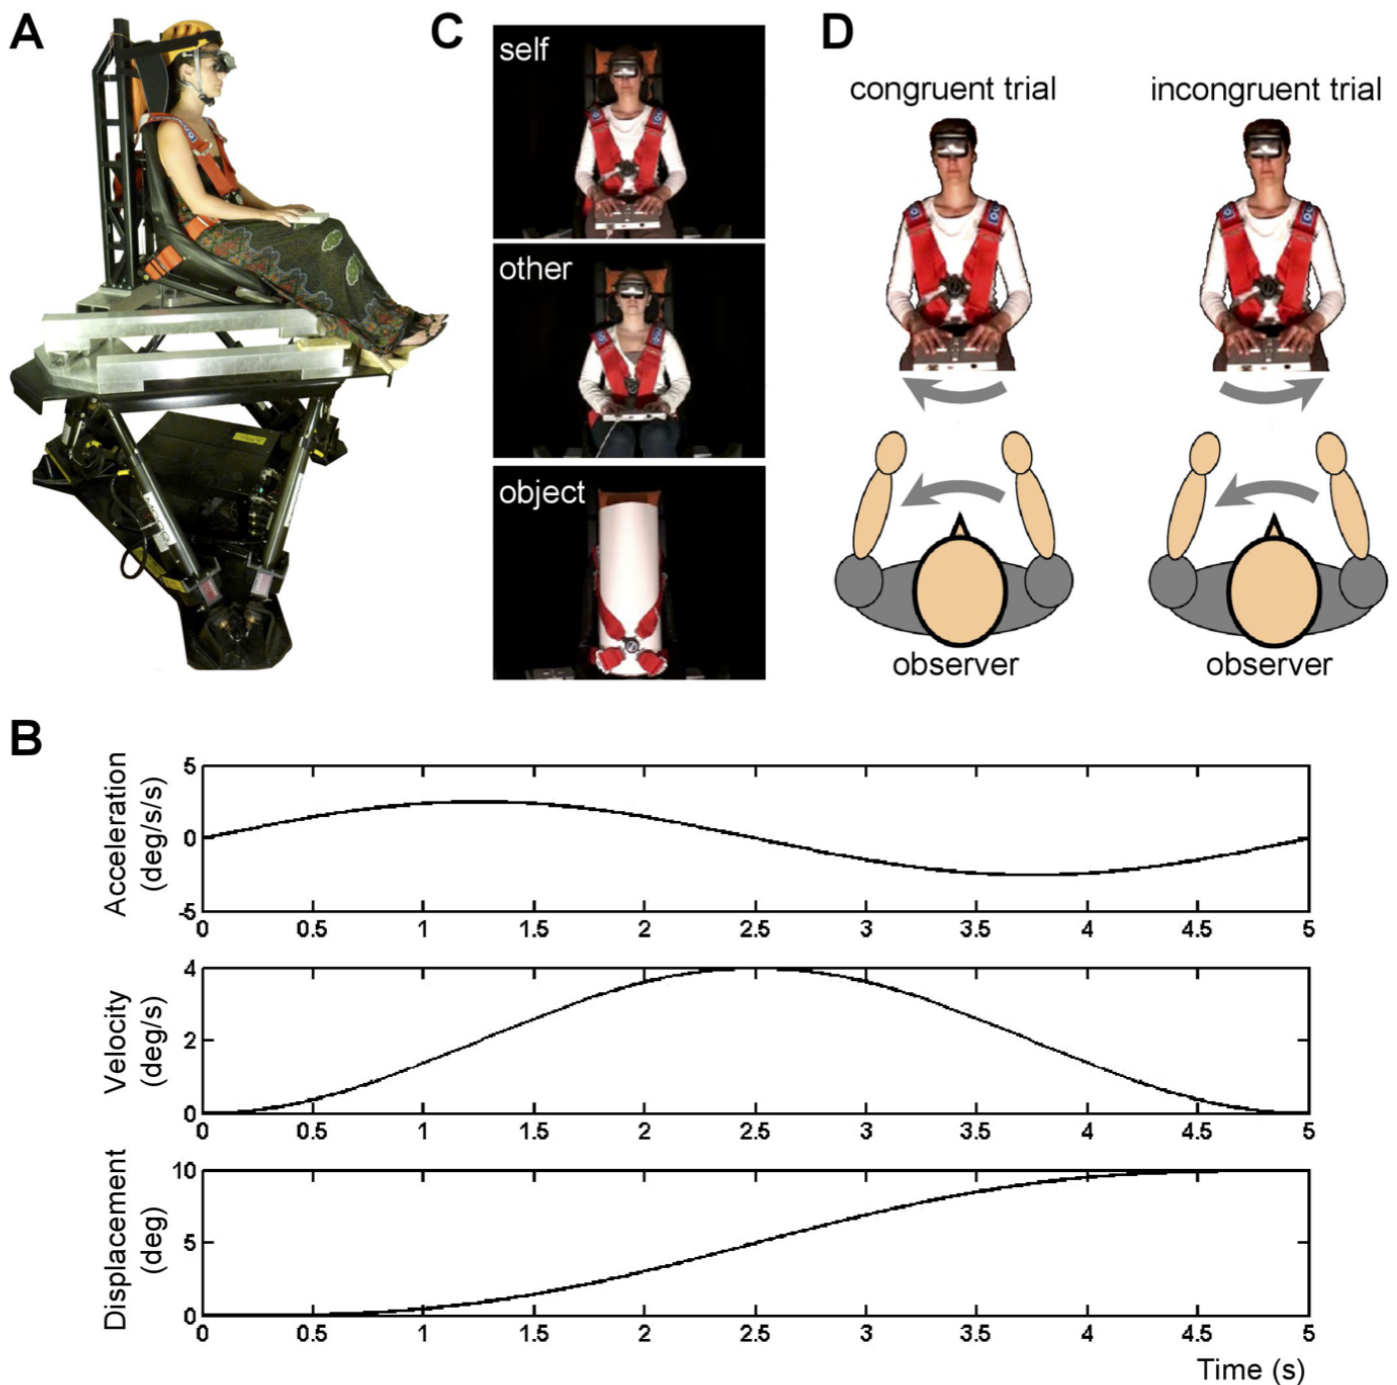

Figure 8: Experimental setup used to measure the influence of body movement observation on whole body self-motion perception. (A) Self-motion perception was tested in twenty-one observers seated on a motion platform. Motion stimuli were yaw rotations lasting for 5s with peak velocity of $0.1^\circ/\text{s}$, $0.6^\circ/\text{s}$, $1.1^\circ/\text{s}$, and $4^\circ/\text{s}$. (B) Example of a motion profile consisting of a single cycle sinusoidal acceleration. Acceleration, velocity, and displacement are illustrated for the highest velocity used at $4^\circ/\text{s}$. (C) Observers wore a head-mounted display through which 5-s videos were presented, depicting their own body, the body of another participant matched for gender and age, or an inanimate object. (D) During congruent trials, the observers and the object depicted in the video were rotated in the same direction (specular congruency). Reproduced from [Lopez et al. \(2013\)](#).

observing pain (Lamm et al. 2011, for a recent meta-analysis), when being touched and observing someone being touched (Keysers et al. 2004), and when inhaling disgusting odorants and observing the face of someone inhaling disgusting odorants (Wicker et al. 2003)

No human neuroimaging study so far has investigated brain mechanisms when experiencing a vestibular sensation and seeing somebody experiencing a vestibular sensation (e.g., being passively moved in space). Yet, recent findings from a behavioural study in humans suggest that the observation of another person's whole-body motion might influence vestibular self-motion perception (Lopez et al. 2013; see figure 8). In this study, participants were seated on a whole-body motion platform and passively rotated around their main vertical body axis. They were asked in a purely vestibular task to indicate in which direction (clockwise vs. counter-clockwise) they were rotated while looking at videos depicting their own body, another body, or an object rotating in the same plane. The spatial congruency between self-motion and the item displayed in the video was manipulated by creating congruent trials (specular congruency) and incongruent trials (non-specular congruency). The results indicated self-motion perception was influenced by the observation of videos showing passive whole-body motion. Participants were faster and more accurate when the motion depicted in the video was congruent with their own body motion. This effect depended on the agent depicted in the video, with significantly stronger congruency effects for the “self” videos than for the “other” videos, which is in line with the effects previously reported for the tactile system (Serino et al. 2009; Serino et al. 2008). Lopez et al. (2013) speculated on the existence of a *vestibular mirror neuron system* in the human brain, that is a set of brain regions activated both by vestibular signals and by observing bodies being displaced. As noted earlier, vestibular regions show important patterns of visuo-vestibular convergence in the parietal cortex, which could underlie such effects (Bremmer et al. 2002; Grüsser et al. 1990b).

On the basis of these findings as well as the data presented above on the importance of vestibular processes in spatial, cognitive, and social perspective-taking, we propose that the vestibular system is not only involved in shaping and building the perception of a bodily self but is also involved in better understanding and predicting another person's (full-body) action through sensorimotor resonance (see also Deroualle & Lopez 2014).

5 General conclusion

During the last years, various theories from psychological, neuroscientific, philosophical, and interdisciplinary perspectives have claimed the importance of multisensory signals and neural body representations for general theories of self-consciousness. Influential theories stated that very basic, and largely implicit and pre-reflective bodily processes crucially underlie the self (Alsmith 2012; e.g., Blanke & Metzinger 2009; Blanke 2012; Gallagher 2005; Legrand 2007). Such theories fueled experimental investigations on multisensory integration and its influence on various aspects of the self. Yet, similarly to Aristotle, who claimed that “there is no sixth sense in addition to the five enumerated—sight, hearing, smell, taste and touch”—this line of research has largely neglected the *vestibular sense of balance*. This is particularly surprising as a recent theory has claimed the importance of more global aspects of the bodily self (Blanke & Metzinger 2009), most importantly probably the sense of immersion or location in a spatiotemporal frame of reference (Windt 2010). This process, as we speculated above, should fundamentally rely on vestibular cues, plausibly among others coded by specific cells in the hippocampus. The vestibular system is activated by gravity, the constant force under which we have evolved, and also during all sorts of passive and active head and whole body movements. Moving in an environment is necessary for the development of a sense of bodily self, and the vestibular system is thus likely to contribute not only to the most basic (or minimal) aspects of the self but also to the different fine-grained implicit and explicit aspects of the experience of

our bodily self in daily life such as body perception, body ownership, agency, and self-other distinction. It is thus not surprising that the vestibular system is intrinsically, highly linked to other sensory systems such as touch, pain, interoception, and proprioception. While some of the links between the vestibular system and the bodily self are rather well-established and the underlying neurophysiological processes known from both non-human animal and human research, several of the relations presented here are still largely speculative. Yet, we believe that the specific and testable hypotheses we have given here—once they are tested and possibly confirmed by experimental studies—might enable us to better describe neural and physiological mechanisms underlying minimal phenomenal selfhood (Blanke & Metzinger 2009) as well as refine current models of the multisensory mechanisms underlying the various aspects of the bodily self.

Perspectival Structure and Vestibular Processing

A Commentary on Bigna Lenggenhager & Christophe Lopez

Adrian Alsmith

I begin by contrasting a taxonomic approach to the vestibular system with the structural approach I take in the bulk of this commentary. I provide an analysis of perspectival structure. Employing that analysis and following the structural approach, I propose three lines of empirical investigation to selectively manipulate and measure vestibular processing and perspectival structure. The hope is that this serves to indicate how interdisciplinary research on vestibular processing might advance our understanding of the structural features of conscious experience.

Keywords

1 Structural vs. taxonomic approaches to vestibular processes

Philosophical work on the senses has largely been concerned with taxonomic issues: What makes an event sensory? Under which sensory kind should that event be classified? Answering these questions requires criteria of individuation. These would enable us to determine

whether an event is the same as (or different to) sensory events in general and whether it is the same as (or different to) sensory events of a specific kind. A criterion of the first sort would allow us to identify vestibular events as sensory events. This would justify the belief that vesti-

bular processes are sensory processes. A criterion of the second sort would allow us to identify vestibular sensory events as being of a specific kind, i.e., distinctively vestibular sensory events. This would justify the belief that there is such a thing as a vestibular sense. Failing to provide a criterion of the first sort would force one to classify vestibular events as non-sensory. But even if one were able to determine that vestibular events are sensory, one would still require a criterion of the second sort to classify vestibular events as sensory events of a kind that is distinct from, e.g., visual or haptic events.

To expand on this last point: as Lenggenhager and Lopez so masterfully describe, central vestibular processes are inherently multisensory, and as a consequence there is scarcely a part of our sensory and cognitive life that vestibular processes leave untouched (see especially §2.2 of the target article). But then, if vestibular processes are implicated in so many sensory and cognitive processes, it may be most accurate to see vestibular processing as simply a common part of many processes, rather than as an independent sensory system. That is, one may begin to seriously consider the possibility that vestibular processing does not constitute a form of sensory processing of its own kind, but rather constitutes a form of processing common to various other processes that are themselves sensory. This is, in effect, an issue that arises from applying a criterion for individuating the senses that includes the physiology (and neurophysiology) of the entire system. One might not be forced to this conclusion if one used an alternative criterion (Macpherson 2011a, 2011b). But it seems that each of the criteria commonly discussed would generate their own problems. For instance, employing a more restrictive criterion that delimited sensory systems according to their peripheral sensory organs would face the issue of whether the sensory organs of the vestibular system ought to include or exclude the so-called “truncal” or “somatic” graviceptors (Mittelstaedt 1992, 1996; Vaitl et al. 2002). Similar issues would be faced when attempting to individuate the senses in terms of a distinctive proximal stimulus. Alternatively, one might

individuate the senses by means of certain distinctive experiences: vision distinctively represents the brightness, hue, and saturation of colours; audition represents the volume, pitch, and tone of sounds. The natural candidates for the vestibular system would be experiences that represent verticality, rotation, and translation. But whilst it is certain that the vestibular system typically contributes to experiences of verticality, rotation, and translation, these are all experiences of a kind that can be had through visual sensation alone, or through a combination of visual, somatic, and proprioceptive sensation. Moreover, although vertiginous experiences are the hallmark of vestibular dysfunction, these are either experiences of rotation, which brings us back to the aforementioned issue, or they are more vaguely classified as pseudo-vertiginous experiences of dizziness that may have any number of non-vestibular aetiologies. Suffice to say that it may be surprisingly difficult to find appropriate criteria to justify the claim that there is such a thing as a *distinctively* vestibular sensory process.

The foregoing characterises what would be the typical philosophical approach to the vestibular system, *qua* sensory system. This *taxonomic approach* captures certain philosophical interests, but it is completely inadequate for the task of bringing out the significance of the scope of the vestibular system’s influence. An alternative, *structural approach* focuses on the role played by vestibular events in processes that exhibit a certain kind of structure, to determine the contribution of those events to that structure. Note that the structural and taxonomic approaches are independent, insofar as they have different epistemic goals. They aim to further our knowledge in different ways. The goal of the taxonomic approach is to determine whether, and if so why, there is a distinctive sensory system of a certain kind. The goal of the structural approach is to determine whether, and if so how, a certain kind of process contributes to a certain kind of structure. By assuming that one can identify processes as objects of study without first employing an exhaustive taxonomy, a structural approach can assume that there are such things as vestibular

processes without any commitment to these processes being wholly distinct from others. And by tracking the varied yet systematic effects of vestibular processes, one can determine whether vestibular processes contribute to a certain kind of structure, irrespective of, whether or not the vestibular system is a distinctive sensory system. As vestibular processes are implicated in so many and various sensory and cognitive processes, the structural approach seems to be the most fruitful in terms of the amount we might learn. It also seems more fruitful in terms of the kind of knowledge we might gain. For we may learn nothing about how vestibular processes affect our experiential life by learning that vestibular processes may not be, in the final analysis, of a distinctive sensory kind. But we will certainly learn something about how vestibular processes affect our experiential life by learning that vestibular processes contribute to a certain experiential structure. Accordingly, I leave aside taxonomic issues in the rest of this commentary and focus on structural issues. Specifically, I focus on issues concerning the role of the vestibular system in providing a particular kind of structure to our experience of the body and the world, namely a perspectival structure.

To begin with, we need a preliminary analysis of experiential phenomena that exhibit perspectival structure. I will call these *perspectival phenomena*. In the next section, I offer a rudimentary analysis of perspectival structure, the aim of which is to show that perspectival phenomena are more differentiated than commonly recognised. In the following three sections, I propose three lines of empirical investigation. Each would attempt to selectively study perspectival phenomena through measurement and manipulation of vestibular processes. If the experiments proposed yielded interesting results, they would further our knowledge of how vestibular processes affect the perspectival structure of our experiential life. Accordingly, the overall aim is to demonstrate how an analysis of perspectival structure might fruitfully interface with empirical research and facilitate understanding of structural features of conscious experience that would otherwise be obscured.

2 The differentiation of perspectival phenomena

The notion of a subjective perspective (sometimes described as a *first-person perspective*) is at the core of contemporary research on bodily self-consciousness (Blanke & Metzinger 2009; Metzinger 2003, 2009). However, its role has often been merely facilitative, serving as a means to study *other* components of bodily self-consciousness, such as the experience of bodily agency, ownership, and self-location (Ehrsson 2007; Lenggenhager et al. 2007; Petkova et al. 2011a, see Serino et al. 2013 for review). Consequently, the fact that the very notion of perspective covers a range of distinct phenomena has tended to be overlooked.¹ Referring to someone's perceptual experience as having a perspectival structure may mean any one of several distinct things. It may mean that there is an *origin* to her sensory field, relative to which certain things (or parts of things) are perceptible and perceived from a particular direction and relative to which certain other things (or parts of things) are not perceptible or noticeably occluded.² Alternatively, it may mean that her experience is organised according to an *egocentric* frame of reference centred upon her body, according to which she experiences locations as situated relative to a particular point at the intersection of three orthogonal axes. Or it may be that, thanks to *egomotion*, the flow of her sensory experience is such that she can see where she is headed as she moves. Taking *another individual's* perspective into account in social interactions can involve either of the first two forms of perspective (Moll & Meltzoff 2011).

¹ My discussion is restricted to spatial perspectival phenomena; I omit discussion of the respects in which temporal experience may be perspectival. This is mostly for the sake of simplicity. However, there is good reason to think that we represent time in a manner that is asymmetrically dependent upon the ways in which we represent space (Boroditsky 2000; Casasanto & Boroditsky 2008). Addressing issues concerning the structure of spatial experience first may thus be prudent.

² This notion is intended to capture the idea that there is a point of "origin" to the so-called line of sight (which is not so much a line as an angle). This corresponds to perhaps the earliest documented notion of perceptual perspective, associated with what Euclid and Ptolemy respectively called the "visual pyramid" and "visual cone", where the apex (origin) of the pyramid or cone is at the eye and the base at the object (Howard 2012).

Figure 1: Three forms of perspectival structure. **A.** An artistic rendition of a human monocular visual field. After Mach 1959, p.18. **B.** An egocentric frame of reference centred upon a human torso. **C.** The directions of deformations in the visual field specifying egomotion. Cf. Gibson 1950, p. 123.

Moreover, the perspective of the subject need not figure explicitly in the experience for it to be perspectival; perspective can structure perceptual experience implicitly, by determining the way in which objects are experienced, without itself being part of the content of the *experience* (Campbell 1994; Merleau-Ponty 2002; Perry 1993; Zahavi 2005).

We can summarise these remarks by saying that perspectival phenomena in spatial experience vary along three dimensions.³ First, perspectival structure can take at least three forms:⁴

- Origin of a sensory field (*origin*)
- Centre of an egocentric frame of reference (*egocentric*)
- Focal point of a sensory flow field in action (*egomotion*)

³ I do not intend the following to be exhaustive. Moreover, although all of the perspectival phenomena that I discuss are visual, I do believe that each of the forms of perspectival structure that I describe also characterises perspectival experience in haptic perception.

⁴ The most I intend to claim here is that these forms of perspectival structure are non-identical. Perhaps the origin of a given sensory field, the centre of a given egocentric frame of reference, and the focal point of a given sensory flow field could occupy the same location under some description. However, this certainly need not always be the case. Moreover, each form of perspectival structure will present the objects of perceptual experience as related to the subject of experience in different ways, e.g., as only partially visible, as straight ahead, or as in one's way. Below I will suggest various ways in which these might be selectively manipulated, but I do not intend to make the case that forms of perspectival structure can be dissociated from one another.

Perspectival phenomena that exhibit any of these forms of perspectival structure can vary along two further dimensions: the perspective of a given perspectival experience may be either *implicit* or *explicit*, and may be attributed to the subject or to another individual. A perspective is *explicit* in a perspectival experience if the subject is consciously aware of the location of the origin, centre, or focal point in question; it is *implicit* if the subject is not.⁵ The perspective in question may belong to the subject, a *first-person perspective*, or it may belong to another individual, a *third-person perspective*.

This simple framework enables one to study perspectival phenomena selectively, rather than studying an undifferentiated cluster of perspectival phenomena simultaneously. In the sections that follow, I shall suggest a number of ways in which one might engage in such a selective study of perspectival phenomena by in-

⁵ When a perspective is explicit, the location of the origin, centre, or focal point is part of the content of the experience. Any beliefs that the subject has about the location in question do not go beyond the content of that experience (cf. Peacocke 1999, p. 265). The experience may represent the location in question in an imprecise or wholly incorrect manner; the subject's beliefs will be correspondingly imprecise or incorrect. Implicit perspectives structure experience without being part of the content of experience. I leave it open whether implicit perspectives are nevertheless experienced *qua* structural feature, or whether, for example, they are merely formal structures that determine the ways in which things are experienced, without themselves being experienced. Issues like this are difficult to evaluate, but for discussion see Alsmith (2012).

tervening upon and registering the activation of vestibular processes.

3 Perspectival variation in multisensory stimulation

One consequence of not distinguishing between perspectival phenomena is that the notion of a *first-person perspective* becomes ambiguous. One can clearly see this ambiguity in descriptions of the role of *first-person perspective* in the multisensory stimulation protocols developed in recent work on the neuroscience of bodily self-consciousness. These protocols all involve participants being touched on their torso whilst visually observing a body-shape (either the body of another person, a mannequin, or a virtual body) being touched on its torso. The protocols differ along two dimensions: the side of the torso stimulated and the location of the origin of the participants' line of sight with respect to the body being observed. In one protocol, the body-swap illusion, participants are stroked on their chest whilst they look at a body being stroked on its chest from a position located where its head would be (cf. Ehrsson 2007; see Petkova et al. 2011b; Petkova & Ehrsson 2008; Petkova et al. 2011a). In another protocol, the full-body illusion, participants are stroked on their back, whilst they observe a body from behind being stroked on its back from a position entirely removed from its location (Ionta et al. 2011; Lenggenhager et al. 2007; Pfeiffer et al. 2013). The body-swap illusion protocol is often distinguished from the full-body illusion protocol as involving first-person perspective as an independent variable (Petkova et al. 2011a). However, recent work on the full-body illusion has demonstrated effects that the authors describe as changes in first-person perspective (Pfeiffer et al. 2014): Participants lain prone whilst feeling and observing strokes on the back report experiences of either looking up or down at the body they observe (Ionta et al. 2011). These variations in report seem to depend upon the individual's relative weighting of vestibular and visual gravitational cues (Pfeiffer et al. 2013).

Admitting the differentiation of perspectival phenomena allows us to make sense of the differences in use of the term *first-person*

perspective. In the terms introduced in the previous section, the *first-person perspective* in the body-swap illusion is an *origin* perspective. It presents the typical view of one's own body with a line of sight originating in the head. The *first-person perspective* in the full-body illusion is an *egocentric* perspective. It forms the centre of an egocentric frame of reference, according to which the observed body occupies a location in a particular egocentric direction (up or down). Distinguishing these forms of first-person perspectival experience reveals that each of these protocols facilitates manipulation of a distinct form of perspectival experience. It also sheds light on the fact that the differences in vestibular and somatosensory processing between these forms of perspectival experience have yet to be compared.

One way of conducting such a comparison would be to use virtual reality display techniques to present an individual with two avatars in series, whilst measuring time-locked vestibular evoked potentials via scalp EEG.

Experiment 1: Participants are stroked on *both* their chest *and* their back whilst supine, whilst wearing a head-mounted display. In the meantime, participants observe either the chest of Avatar 1 being stroked on its chest, presented from a position corresponding to the avatar's head, as in the body-swap illusion, or they observe Avatar 2 being stroked on its back, as in the full-body illusion. Ideally, the two avatars are presented in the same viewing, such that the participant views one avatar and then in a continuous movement shifts their gaze to view the other.⁶

I have claimed that each of the two protocols conjoined in this proposed experiment facilitates manipulation of different forms of perspectival experience. If this is correct, then finding significant differences in vestibularly-evoked potentials between observation of Avatar 1 and Avatar 2 would be a first step in determining differences in vestibular processing between these forms of perspectival experience.

⁶ This would be, I take it, as close as practically possible to viewing the two avatars at the same time, given limitations in the field of view.

As noted earlier, there do seem to be individual differences in the contents of *egocentric* perspectival experience in the full-body illusion. This would suggest that some individuals, those who are more heavily dependent upon vestibular gravitational cues to determine orientation, would experience themselves as looking upwards at Avatar 2. Whereas if the right *visual* gravitational cues were provided, some individuals may experience themselves as looking downwards at Avatar 2 (Ionta et al. 2011; Pfeiffer et al. 2013). This might allow the investigation of the relationship between *egocentric* perspectives and *egomotion* perspectives, by incorporating a second phase into a new experiment:

Experiment 2: Phase 1: experiment 1, described above. Phase 2: Participants continue to be stroked on their back and chest. Participants fixate upon Avatar 2 and observe it rotating about a horizontal axis, whilst being visibly stroked on its back and chest. Both reports of experienced orientation (upward vs. downward) and reports of experienced *egomotion* are gathered.

Participants may experience themselves as rotating around a horizontal axis in just the way they observe Avatar 2 rotating. Alternatively, they might experience themselves as revolving around Avatar 2. In particular, what would be of interest would be the way in which any resultant illusory experiences of *egomotion* might correlate with experienced *egocentric* orientation (upward vs. downward). Moreover, individual differences in experienced *egocentric* orientation might even predict the contents of experienced *egomotion*. This would be a major step in determining both the relative influence of vestibular processing on these forms of perspectival experience and the relationship between these forms of perspectival experience.

4 Perspectival variation in misalignment

In much recent philosophical and neuroscientific research on self-consciousness, the experienced *first-person perspective* is treated as a simple phenomenon identified with the experienced origin of an *egocentric* frame of reference centred upon an individual's own body (Blanke & Metzinger 2009; Vogeley & Fink 2003). But *egocentric* perspective, despite being an *apparently* simple phenomenon, is in fact as potentially complex as the macroscopic structure of the body itself (Smith 2010). Human bodies are composed of a number of parts that are to some degree independently mobile, any of which may serve to centre a distinct *egocentric* frame of reference. As this observation is well known, we may presume that theorists who treat *egocentric* perspective as simple are assuming that locations in these various *egocentric* frames of reference are translated into a single, *ultimate* *egocentric* frame reference which itself determines *egocentric* perspectival phenomena.

However, neurophysiological and neuropsychological research on spatial representation suggests independent motivation for this ultimate frame being centred upon the head (e.g., Avillac et al. 2005) or the torso (e.g., Karnath et al. 1991). By rotating head and torso in opposite directions, an *egocentric* frame of reference centred upon the head can be misaligned with another frame centred upon the torso. In such a “misalignment” situation, a single object may be “to the right” with respect to the head and “to the left” with respect to the torso (Longo & Alsmith 2013). Following Christopher Peacocke's (1992) description of the phenomenology of experienced direction, one would hypothesise that differences in experienced posture would determine differences in *egocentric* perspectival experience.⁷ One could thus use mis-

alignment to investigate the relationship between experienced orientation and experienced *egomotion*. This would be a major step in determining both the relative influence of vestibular processing on these forms of perspectival experience and the relationship between these forms of perspectival experience.

⁷ Peacocke writes: “The use of a particular set of labeled axes in giving part of the content of an experience is not a purely notational or conventional matter. The appropriate set of labeled axes captures distinctions in the phenomenology of experience itself. Looking straight ahead at Buckingham Palace is one experience. It is another to look at the palace with one's face still toward it but with one's body turned toward a point on the right. In this second case the palace is experienced as being off to one side from the direction of straight ahead, even if the view remains exactly the same as in the first case” (1992, p. 62). Assuming that Peacocke's prediction is correct, then in this example changes in the *egocentric* perspectival structure of visual experience follow changes in the orientation of the torso. By misaligning the torso from the direction of the gaze, one discerns that (in the case as described) the appropriate set of labeled axes centre upon the torso. In the paradigm described in experiment 3, both head and torso may be misaligned with the individual's gaze. This makes it possible to determine the contribution of both head- and torso-centred frames of reference to the individual's *egocentric* perspectival experience of a given location. It would then be possible to discern whether, for the *egocentric* perspectival experience of a given location: (i) the appropriate set of axes centre on the torso; (ii) the axes centre on the head; (iii) both sets of axes make relative contributions to the structure of the experience.

alignment situations to determine the respective contributions of the head and the torso to the organisation of *egocentric* perspectival experience at a given point in time in the following experiment:

Experiment 3: Standing with their head and torso aligned or misaligned $\pm 15^\circ$, participants perform a task that involves either an *explicit* or only an *implicit egocentric* perspective (see below). The angular deviation of the stimulus in relation to the head and/or torso is recorded, such that one would be able to assess the respective contributions of each body-part's orientation to the participants' *egocentric* perspectival judgments. Participants would receive either galvanic vestibular stimulation (GVS) or tendon vibration stimulation to precisely assess the relative contribution of vestibular processes to *egocentric* perspective.

In more detail, the suggestions are these. For an explicit task, stimuli could be presented across the entire visual field in regular intervals, varying in distance and elevation, and participants would judge whether a stimulus presented looks "to their left or to their right". A potential limitation of the explicit task is that in using overt left/right judgements, participants' responses may reflect a stipulated meaning of these terms that is independent of the *egocentric* perspectival structure of their experience. However, a recent study using a covert attentional cuing paradigm found that rotation of the torso primes participants to respond more quickly to visual stimuli appearing on the side of a computer screen congruent to the direction of rotation (Grubb & Reed 2002).⁸ One could adapt this paradigm to directly compare the respective influences of head and torso by rotating the head and/or the torso $\pm 15^\circ$ relative to the screen where stimuli would be presented. Target and cuing visual stimuli would appear on either congruent or incongruent sides of the screen and participants would make speed responses to indicate whether the target appears to the left or the right on each trial. Again, as

the angular deviation of the stimulus in relation to the head and/or torso would be known, one would be able to assess the respective contributions of each body-part's orientation to the participant's *egocentric* perspectival judgments.

Based on previous work, I would expect participants' judgements to implicate *both* their head *and* torso as determining their *egocentric* perspectival experience (Alsmith & Longo 2014). More specifically, I would expect that both head- and torso-centred reference frames would influence *explicit* and *implicit egocentric* perspectival phenomena (Longo & Alsmith 2013), though the exact weighting will be unequal at lateral extremes of each body part and will differ between individuals (Alsmith et al. in preparation). The further prediction would be that manipulating vestibular and proprioceptive processing will modulate felt postural misalignment and thereby systematically influence performance on *explicit* and *implicit egocentric* perspectival tasks.

5 Perspectival variation in sensorimotor control

Arguably, one of the core structural features of the experience of intentionally-directed bodily movement is the presentation of the agent as the "perspectival source" of the motion experienced (Horgan et al. 2003; Marcel 2006). However, a strikingly robust experimental finding is that individuals will correct for a deviation introduced into a movement they perform via a bias in visual input, thereby ensuring the action they intend achieves its goal, whilst nevertheless *not* reporting such corrections in their movement (Fournier & Jeannerod 1998; Knoblich & Kircher 2004; Slachevsky et al. 2001). Recent developments of this paradigm have adapted it to test *explicit egomotion* perspectival experience in walking movements, by using a motion-tracked avatar, observed from the rear. Kannape and colleagues found that by introducing a slight bias into the subject's visual experience of the trajectory of the avatar, they could induce subjects to perform appropriate corrective movements in walking to a target, whilst not noting the discrepancy between their actual movements and the avatar (Kannape

⁸ It is perhaps worth noting that by "congruent" I intend the more general sense of the term, as often used in describing the design of behavioural studies, the meaning of which is equivalent to "in agreement". I do not intend the more specific geometrical sense of the term, which expresses identity of a certain kind, typically of form.

et al. 2010). Again, the corrections went largely unnoticed within a certain range of angular deviation between observed and actual movements.⁹ Thus, a natural explanation of the pattern of data is that the mechanisms enabling the experience of agency present bodily movements in a manner that is far more coarse-grained than the level of detail required to make corrective changes in movement trajectory. In short, *egomotion* perspectives structure experiences of intentionally-directed bodily movement. They do so by specifying what we might call coarse-grained phenomenal grooves, within which a movement must unfold if it is to seem like the movement that the subject intended or is trying to perform.

Strangely, as yet the potential contributions of the vestibular system to the structuring of agentive experience by *egomotion perspective* have not been manipulated. Moreover, as noted, the work that has been done in this area has been restricted to *explicit egomotion* perspectival phenomena. A natural further step would be to investigate the nature of vestibular processing in implicit *egomotion* perspective, by controlling a participant's optic flow in a manner corresponding to the control of the avatar's motion in Kannape and colleagues' original study.

Experiment 4: Study 1: Participants view a textured environment via HMD in which optical flow fields are regulated by their motion-tracked movements. Study 2: Participants control a motion-tracked, real-time avatar seen from behind. In both studies, participants are tasked with walking directly towards a virtual target. All the while, they either receive GVS or sham stimulation and visual feedback (optic flow or avatar position) that is either faithful to motion-tracking or systematically deviated left/right of the participant's mid-line, as a function of distance from a point of displacement onset.

Participant trajectory could thus be compared to the dynamics of the flow field or avatar trajectory and participants could be

asked to rate the degree to which their movements in the virtual environment or the movements of the avatar corresponded to their actual movements, as respective measures of *implicit* and explicit *egomotion* perspectival experience. The question would be whether, in trials in which GVS is applied, the range of angular deviation in which participants would judge that movements in the virtual environment correspond to their own would be equal to or larger than trials in which participants receive only biased visual feedback. If the latter occurs, then in the evocative terms used above, it would suggest that vestibular processes are one of the determinants of the coarseness of the phenomenal groove specified by an *egomotion* perspective.

6 Conclusion

I began by contrasting a taxonomic approach to the vestibular system with the structural approach I have taken in the bulk of this commentary. I then provided an analysis of perspectival structure. Employing that analysis and following the structural approach, I proposed three lines of empirical investigation that would selectively manipulate and measure vestibular processing and perspectival structure.

Day & Fitzpatrick (2005) quip that vestibular processes provide a "silent sense" (see also §2.2.1 of the target article). I suggested at the outset that (following the taxonomic approach) it might be surprisingly difficult to say with any precision why vestibular processing provides a sense of its very own. But even if it is true, that is, if the experiments described yield the expected results, they would show that vestibular processing is hardly silent. Indeed, each of the proposed lines of investigation would be a step towards a better understanding of how vestibular processes affect myriad forms of perspectival structure, all of which would further demonstrate the centrality of vestibular processing to our experiential life. In any case, my hope is that these remarks display the extent to which I have found Lenggenhager and Lopez's work to be not only inspirational, but also a rich and fruitful avenue for interdisciplinary research into the structural features of conscious experience.

⁹ The authors write that "deviations of 5°, 10°, and 15° lead to many erroneous self-attributions", found to be "decreasing in magnitude with increasing angular deviation" (Kannape et al. 2010, p. 1631). As broached above, one explanation of this pattern would be that deviations below 15° all fall (to a greater or lesser degree) within the phenomenal groove of the action specified by the task.

Vestibular Sense and Perspectival Experience

A Reply to Adrian Alsmith

Bigna Lenggenhager & Christophe Lopez

To answer Alsmith's questions about the existence of a vestibular sense, we outline in the first part of our reply why we believe the vestibular sense is a true "sixth sense". We argue that vestibular information constitutes distinct sensory events and that absolute coding of body orientation and motion in the gravity-centered space is the important unique feature of the vestibular system. In the last part of our reply, we extend Alsmith's experimental suggestions to investigate the vestibular contribution to various perspectival experiences.

1 Is there a vestibular sense?

The first section of Alsmith's commentary ("Structural vs. taxonomic approaches to vestibular processes") raises an important question: *is there a vestibular sense?* The enduring lack of a clear answer to this seemingly simple question might stem from the old assumption that there are five and only five senses, all of

which giving rise to a distinct conscious sensation. The relatively late identification of the anatomical structures that code self-motion ([Wade 2003](#); [Lopez & Blanke 2014](#)) has probably further contributed to the neglect of the "vestibular sense" in philosophy and science. We comment below on two questions raised by

Alsmith concerning this debate: (1) *Are vestibular events sensory events?* and (2) *Are vestibular events of a specific kind, i.e., distinct from other sensations?*

(1) Are vestibular events sensory events? Several criteria have been proposed to determine whether an event is sensory or not (Macpherson 2011).¹ Following this type of approach, vestibular events can be described as sensory events because a sensory organ is dedicated to coding gravito-inertial forces and because there is a phenomenal experience associated with vestibular stimulation. Indeed, there are many situations during which passive own-body motions are characterized by distinct self-motion sensations. Imagine, for example, a situation in which we are sitting with eyes closed in the train and feel the departure, or when we are standing with eyes opened in a lift and experience vertical movement of the body. In such situations visual and somatosensory signals do not (or only weakly) contribute, but changes in vestibular signaling result in the conscious perception of self-motion, i.e., of “being translated forward” or “being elevated”.

Self-motion perception due to vestibular stimulation is also testable in the laboratory using motorized motion platforms (rotating chairs or translational platforms, see Palla & Lenggenhager 2014): participants are usually tested sitting on a chair, while non-vestibular sensory signals are largely excluded by having the participant’s body strapped to the chair and stabilized with cushions, by testing participants with eyes closed, by reducing auditory cues via white noise presented in headphones, and by testing participants with gloves and long sleeves (e.g., Grabherr et al. 2008; Hartmann et al. 2013; Lopez et al. 2013; Macaudo et al. 2014; Valko et al. 2012). Participants are able to accurately detect and report self-motion and its direction, which forms the basis for the measurement of *vestibular thresholds*, which are comparable to auditory or tactile thresholds. When accelerations are

applied above the threshold of the mechanoreceptors in the inner ear (e.g., above $0.6^\circ/\text{s}^2$ for rotations around the vertical axis), a motion sensation emerges in healthy participants, which in our opinion is the sensory event corresponding to the vestibular sensation “I was moved”. Such sensory events therefore constitute the basis of what has often been referred to as the “sixth sense” (Goldberg et al. 2012; Wade 2003; Berthoz 2000). Further compelling support comes from patients with dysfunctions of the peripheral vestibular apparatus like benign paroxysmal positional vertigo, vestibular neuritis, or Menière’s disease, who experience strong vestibular sensations in the form of vertigo (Brandt 1999).

We acknowledge, however, that in situations where we actively move the head with eyes opened in space, vestibular signals from self-motion do not give rise to such distinct “vestibular” sensation of self-motion. As explained in our target article, in conditions of active, self-generated head movements, vestibular signals are cancelled or strongly attenuated in the vestibular nuclei (Cullen 2011; Roy & Cullen 2004). This is probably why the vestibular sense has been termed a “silent sense” by some authors (Day & Fitzpatrick 2005).

(2) Are vestibular sensory events of a specific kind, i.e., distinct from other sensations? Vestibular sensations are sensations of own-body rotations, translations, and orientation (sensation of whole-body orientation with respect to the vertical) in space. Such sensations may in principle also emerge from the stimulation of other sensory systems, such as the visual, somatosensory and auditory systems. Impressively, illusory self-motion might be evoked by large optic flows, tactile stimulation under the feet, or displacement of auditory stimuli (Berthoz et al. 1975; Dichgans et al. 1972; Lackner & DiZio 2001, 2005; Våljamäe 2009). These findings resulted in Alsmith’s claim that “one may begin to seriously consider the possibility that vestibular processing does not constitute a form of sensory processing of its own kind” (this collection, p. 2). Yet if vestibular processing does

¹ For example, according to Macpherson, four main approaches to describe the senses can be distinguished: “the representational criterion,” “the phenomenal character criterion,” “the proximal stimulus criterion,” and “the sense-organ criterion” (2011).

Figure 1: A) *Crise de désinvolture* (2003) an artwork by Philippe Ramette. Copyrights: © 2015, ProLitteris, Zurich. All rights are reserved. Reproduction and any other use without permission - except for the individual and private use - is prohibited. B) Drawing of the “haunting sway”, a “gravity-defying” device that was originally developed in the US in the 1890s for amusement parks. The visitors had the impression that they were turning with the sway, while actually the room was turning around them.

not constitute a distinct form of sensory perception, to which type of sensory processing does it belong? Some authors have proposed that vestibular processing might relate to *proprioception* (since the vestibular system detects own body motions) or to *exteroception* (since it detects gravitational acceleration), but these propositions link vestibular processing to a function rather than a sensory modality. As recently pointed out by Macpherson (2011), “it is not even clear which sensory modality equilibration should be assimilated to, if indeed it should be assimilated to any” (p. 18).

Although vestibular, visual, and somesthetic signals may all support self-motion perception, this does not mean that the phenomenal experience of self-motion based on vestibular signals is similar to the experience based on visual signals. Actually, they may strongly differ in their content since, for example, the vestibular system is specialized in coding

high-frequency movements whereas the visual system is tuned to low-frequency movements (see also next paragraph).² And even at the neurophysiological level, vestibular signals interact very early with visual and somatosensory signals; yet this does not mean that these signals provide the exact same sensation of body motion and orientation. An analogy might be when we observe a person speaking: both auditory and visual signals from the speaker’s lip movements contribute to the experience of listening to a voice; nevertheless both signals provide clearly distinct sensations and experiences. We believe the same holds for vestibular processing. Vestibular sensations might be clearly distinct sensations, but in daily life they are often integrated with other senses, confounding a pure conscious sensation (Angelaki & Cullen 2008; Angelaki et al.

² We add that while visual, auditory, and somatosensory signals about self-motion can be suppressed, vestibular signals about body accelerations are *necessarily present*.

2009). Vestibular-only neurons are found in the vestibular nuclei, which are not influenced by visual signals or eye movements, suggesting that vestibular signals are not entirely fused with other sensory signals (Goldberg et al. 2012). Similarly, intracranial stimulations in epileptic patients have showed that pure vestibular sensations could be evoked during electrical stimulations of the superior temporal cortex and insula (Penfield 1957; Kahane et al. 2003; Mazzola et al. 2014).

2 A unique feature of the vestibular system: The representation of absolute self-motion and orientation

As mentioned by Alsmith, the vestibular system, unlike other sensory systems, does not code unique properties of sensory inputs such as loudness or hue. Yet, as already argued in the target article, the coding of *absolute* self-motion in space and self-orientation within gravity-related space is unique to the vestibular system. While relative (self-) motion and orientation can be detected by other sensory systems (e.g., vision and proprioception), gravity itself is not directly visible to these senses.³ Because vestibular organs contain gravito-inertial sensors, they provide a coding of body translations and rotations that is independent from external references (unlike visual, auditory, and somatosensory coding of whole-body motions). For this reason, vestibular organs code self-motion even when the eyes are closed, while we are jumping on a trampoline, or swimming in the sea.

With these properties the vestibular system, especially otolith signaling, also gives us the sensation of an “up” and a “down” by encoding gravitational acceleration. This process might be less accessible to consciousness in normal circumstances, as gravitational pull is constantly acting on vestibular mechanoreceptors. However, there is a large body of data showing that an “internal model of gravity” (predicting how objects move in the physical world according to Newton’s laws; McIntyre et al. 2001) which is strongly

based on otolith processing, shapes at a pre-conscious level several aspects of the visual perception of objects, body movements, and structure (e.g., Indovina et al. 2005; Lacquaniti et al. 2013; Lopez et al. 2009; Maffei et al. 2015; Yamamoto & Yamamoto 2006). A further illustration of the importance of the coding of body orientation in a gravity-centered space can be provided by the “tilted room illusion,” in which the furniture is aligned in a way that is incongruent with gravitational vertical (see figure 1A for an example by the French artist Philippe Ramette⁴), which has been used in a moving version as well in theme parks (the haunting swing, a “gravity-defying” ride, see figure 1B). Experiments conducted in this type of tilted environment have shown that the participant’s perception and posture are biased by tilted visual references, but not totally (Jenkin et al. 2003; Oman 2003). Merleau-Ponty has nicely noted the ambiguity of space-coding regarding the experience of *up* and *down*: “A direction can only exist for a subject who traces it out, and although a constituting mind eminently has the power to trace out all directions in space, in the present moment this mind has no direction and, consequently, it has no space, for it is lacking an actual starting point or an absolute here that could gradually give a direction to all determinations of space” (2012). It is interesting to note Merleau-Ponty’s claim that what is missing for the experience of up and down is an “absolute”. Merleau-Ponty also explains that “[w]e cannot, then, understand the experience of space through the consideration of the contents, nor through that of a pure activity of connecting, and we are confronted by that ‘*third spatiality*’ that we foreshadowed above, which is neither the spatiality of things in space, nor that of spatializing space [...] We need an ‘*absolute within the relative*’, a space that does not skate over appearances, that is anchored in them and depends upon them” (2012, p. 296–297; our italics). Although Merleau-Ponty did not mention the vestibular system when he described the necessity of a “third spatiality,” we now know that the otolithic sys-

³ Of course we can infer about (the direction of) gravity by the relative motion and specific properties of certain objects; however this process is much slower, less intuitive, and not always applicable.

⁴ To be precise, Ramette does not glue the furniture to the roof or wall, but rather “glues” himself to the wall. His position is thus tilted compared to gravity, not the furniture.

tem provides the “absolute within the relative” he mentions and allows the coding of absolute self-orientation in space (see also [Berthoz 2011](#) for a detailed account).

3 Vestibular system and perspectival experience—Experimental suggestions

In this last part we elaborate on the experimental suggestions provided by by Alsmith, proposed in order to investigate more fine-grained forms of perspectival perceptions and their interaction with vestibular processes. In the target article we used the term first-person perspective (mainly in the context of mental perspective taking and out-of-body experiences) to refer to an egocentric visuo-spatial perspective. Alsmith proposes a subdivision of this perspective into three forms of perspectival structures: “origin,” “egocentric frame of reference,” and “focal point of sensory flow (egomotion),” which might be differentially influenced by vestibular signals. While we do not necessarily agree on the importance and justification of these (and *exactly these*) components, we appreciate the experimental suggestions, on which we will briefly comment below.

3.1 Experiments I and II: Changing vestibular processes through change in perspective

A common approach to testing the influence of the vestibular system on high-level cognition is to alter vestibular information during a specific task—for example a perspective-taking task. This can be done either by applying galvanic ([Lenggenhager et al. 2008](#)) or caloric ([Falconer & Mast 2012](#)) vestibular stimulation, by natural vestibular stimulation ([Van Elk & Blanke 2014](#)), by exposing participants to microgravity ([Grabherr et al. 2007](#)), by changing the body orientation relative to gravity ([Arzy et al. 2006](#)), or by testing patients with vestibular dysfunction ([Grabherr et al. 2011](#)). What Alsmith describes⁵ in the first two experiments

mentioned in the commentary is the opposite approach, namely assessing vestibular processing during specific tasks, or bodily states, respectively.⁶ We believe that this is a potentially powerful way to better understand vestibular implication in fine-grained aspects of the bodily self and their interrelation—both in experimental work and research in patients with bodily-self disturbances (see e.g., [Brugger & Lenggenhager 2014](#) for a recent review). We would like, however, to point out a few important issues that should be considered.

Alsmith suggests that we measure time-locked vestibular-evoked potentials without stating more precisely what vestibular stimulation to use. However, this is crucial, since there are various ways to test vestibular processing, mostly by stimulating a specific part of the vestibular system (see e.g., [Palla & Lenggenhager 2014](#) for a recent review). One possibility (in the suggested experiment) could be to use sound-induced vestibular-evoked potentials. The advantage of these is that they can be recorded in a static condition, unlike other forms of vestibular stimulation (e.g., rotatory evoked cortical potentials; [Keck 1990](#)), which is important for the suggested full-body illusion paradigms. When designing experiments along these lines, it is indispensable to know what part of the vestibular system is stimulated by the used technique. Sound-induced cortical vestibular potentials, for example, represent cortical processing of otolith signals, mainly from the saccule, thus coding preferentially linear movements in the vertical plane (i.e., up and down movements in a standing position). If we rather expect a difference in coding the front-back movement, as proposed in Experiments 1 and 2, a vestibular stimulation of the utricle might be more appropriate (e.g., [Todd et al. 2014](#), using evoked-potentials by impulsive accelerations). Since testing all different aspects in all the proposed conditions is technically impossible, the specific vestibular stimulation should be carefully chosen based on the hypothesis. Alternatively,

⁵ This idea of measuring vestibular processes during situations of altered sense bodily self evolved in the framework of a grant entitled “Finding Perspective” awarded to Adrian Alsmith, Christophe Lopez and colleagues by the Volkswagen Foundation.

⁶ A similar approach has been used for other sensory processes such as the measure of body temperature during the rubber hand illusion ([Lenggenhager et al. 2014](#); [Moseley et al. 2008](#)) or the full-body illusion ([Macauda et al. 2014](#); [Salomon et al. 2013](#)).

more indirect measures could be used to test a vestibular implication, such as changes in posture or stability during various experimentally-induced alterations in the bodily self, e.g., via dynamic posturography using a moving platform, as it is commonly used in clinical settings (e.g., Ghulyan et al. 2005).

3.2 Experiment III: Egocentric perspective

In the third proposed experiment, Alsmith considers which (bodily) reference (e.g., eye, head or body centered) is taken as the egocentric reference frame. The fact that there are multiple bodily frames of reference has been nicely shown in a classical task where ambiguous letters (e.g., d/p) are written on the skin. They are typically perceived differently depending on the bodily location on which they are written (Sekiyama 1991); and interestingly the perspective can be modified by vestibular stimulation (Ferrè et al. 2014). Alsmith here suggests that there is a need to investigate the egocentric perspective both with implicit and explicit measures in a situation where body and head⁷ are misaligned, as previously done to test spatial cognition (Schindler 1997) and heading direction during passive motion (Ni et al. 2013). This is a very interesting suggestion; however from the experimental description it is not entirely clear how Alsmith thinks that the vestibular contribution should be investigated. Furthermore, his hypothesis only concerns the respective contribution of head and torso position, but not its vestibular contribution. He suggests that participants might receive galvanic vestibular stimulation or tendon vibration stimulation to investigate “the relative contribution of vestibular processes to egocentric perspective.” One way to test this could be to align the participant’s head and torso, but use tendon vibration or galvanic vestibular stimulation in order to induce an illusory tilt or turn the participant’s head, thus inducing an illusory misalignment of the head and body. By doing the suggested task in such a condition, vestibular or proprioceptive contribution could be isolated.

While this is theoretically very interesting, there might be practical difficulties: vestibular and proprioceptive illusions are usually susceptible to huge individual differences, and inducing illusory shift of $\pm 15\%$ could be difficult. Furthermore, in the proposed experiment that misaligns body and head around the yaw axis, gravitational cues do not differ between the position of the torso and the head in the misaligned condition. Adapting the experiment to a lying-down position,⁸ where body and head would be at different angles with respect to gravity, could help investigating the otolithic influence on perspective.

4 Conclusion

In response to Alsmith’s inspiring theoretical suggestions, we have argued that there is a true vestibular sense, with distinct and important properties. We believe and agree with Alsmith that better understanding its contribution to various aspects of experiential life is crucial and that this might also facilitate taxonomic and structural approaches. Alsmith’s response exemplifies, in our view, the mutual benefit of an interdisciplinary dialogue, as his thorough analysis of current experimental data, paired with new theoretical considerations, leads to concrete experimental suggestions, which might reshape theoretical considerations depending on the potential results. In our reply we have pointed out some possible methodological difficulties, some possible ways to overcome these, and some new directions such experimental work could take. In particular, we are optimistic that analyzing vestibular processing in the brain using electrophysiological approaches will provide in the near future important new data about the vestibular contribution to the sense of self. We hope that our reply will help foster interdisciplinary collaborations that further investigate the role of the vestibular system in shaping our mind.

⁷ Additionally, eye-position could be manipulated.

⁸ Or generally test various body orientations (e.g., as in Lopez et al. 2009).

Self-as-Subject and Experiential Ownership

Caleb Liang

In what follows, I investigate the distinction between the sense of self-as-object and the sense of self-as-subject, and propose an account that is different from Shoemaker's immunity principle. I suggest that this distinction can be elucidated by examining two types of self-experience: the sense of *body ownership* and the sense of *experiential ownership*. The former concerns self-as-object: whether a body part or a full body belongs to me. The latter concerns self-as-subject: whether I represent myself as the unique subject of experience. A key point is that misrepresentation can occur not only in the sense of body ownership but also in the sense of experiential ownership. Then I examine the most relevant neuroscientific accounts of the sense of self-as-subject, including Damasio's account of the core-self, Panksepp's affective neuroscience, neural synchrony, and the sub-cortical-cortical midline structures. I argue that none of these successfully explains the neural basis of the sense of self-as-subject. In order to make progress, I suggest, the first step is to look for and then to study the various conditions in which one can pursue the "Wittgenstein Question".

1 Introduction

This paper investigates a central form of self-consciousness from an interdisciplinary perspective: *the sense of self-as-subject*.¹ How philosophers understand this form of consciousness has been influenced by two ideas. One is Wittgenstein's distinction between "I"-as-object and

"I"-as-subject. In the *Blue Book* (1958), he says that: "there is no question of recognizing a person when I say I have toothache. To ask 'are you sure it is *you* who have pains?' would be nonsensical". The other is Shoemaker's immunity principle. Developing Wittgenstein's distinction, Shoemaker (1968) argues that we are "immune to error through misidentification relative to the first-person pronouns (IEM)". Many consider IEM to be solely addressing semantic

¹ Here I will focus on the minimal sense of self-as-subject, which means that the sense of self-as-subject does not require exercising conceptual capacities and can be transient. It is contrasted with the "narrative self" or "autobiographical self", which involves episodic memory and persists through time (Gallagher 2000).

or conceptual issues. But for philosophers of mind, it decisively sets apart two types of self-consciousness. When one is conscious of oneself-as-object, error is always possible; however, when one is conscious of oneself-as-subject, a particular sort of mistake about *who* the subject is becomes impossible.

The first goal of this paper is to propose an alternative explication of the sense of self-as-object and the sense of self-as-subject. I aim to provide an account that is both phenomenologically precise and empirically useful. The distinction, I will suggest, can be better understood as two types of self-experience: a sense of body ownership and a sense of experiential ownership. I will argue that sometimes it makes perfect sense to ask a subject “are you sure it is *you* who feels pain?” For brevity, I will call this type of question the “Wittgenstein Question”. I will also argue that IEM, or at least some versions of it, faces counterexamples from empirical research. The second goal of this paper is to examine empirical accounts related to the sense of self-as-subject. There are currently many neuroscience programs devoted to self-consciousness, and recently some researchers claim to have explained the neural mechanisms of the sense of self-as-subject. Investigating these programs will reveal how philosophy can contribute to neuroscience in understanding this target phenomenon.

I discuss the sense of body ownership in section 2, and explain how it helps to clarify the sense of self-as-object. Section 3 introduces the notion of experiential ownership. I use this notion to specify what it is like to experience the self-as-subject. A crucial claim is that *being* the subject of an experience does not imply experiencing oneself *as* the subject of experience. If this is correct, at least some forms of IEM fail. Consequently, if we want to talk about a sense of self-as-subject we need more empirical studies. Section 4 examines Damasio’s account of the core-self and Panksepp’s affective neuroscience. Both claim to explain the neural basis of the sense of self-as-subject, but I argue that they only address the sense of self-as-object. In section 5, I criticize two proposals that some neuroscientists use for explaining the sense of

self-as-subject: neural synchrony and subcortical-cortical midline structures (SCMS). The overall positive lesson we can take from these accounts will be presented in the final section.

2 Body ownership and self-as-object

The sense of body ownership concerns whether a body part or a whole body is experienced as belonging to me. For example, I am now typing this paper with two hands, and I have a sense that the two hands are mine. To clarify this concept of self-experience, three distinctions will be very useful. One is between the *fact* of body ownership and the *sense* of body ownership (Dokic 2003; de Vignemont 2011). The former is a biological fact about the anatomical structures of one’s body. The latter is a conscious experience of the fact of body ownership. As the syndrome of somatoparaphrenia indicates, these two aspects are dissociable. A prominent feature of somatoparaphrenia is that patients deny that parts of their body, e.g., a hand, belongs to them (Vallar & Ronchi 2009). Their sense of body ownership fails to match up with the facts—namely, that that the hand is theirs.

In healthy subjects, the sense of body ownership can also be mistaken. In the rubber hand illusion (RHI), participants experience a fake hand as belonging to them. The set-up is simple: The subject’s own hand is blocked from view. The subject sees a rubber hand in front of her, clearly distinct from her own real hand. The experimenter uses paint brushes to touch the real hand and the rubber hand either synchronously or asynchronously (Botvinick & Cohen 1998; Tsakiris & Haggard 2005). In the synchronous condition, many subjects report that they feel as though they are being touched on the rubber hand rather than on their real hand. More interestingly, many subjects feel as if the rubber hand were their own hand.²

Another form of misrepresentation involves the full body—an illusion that induces some interesting aspects of out-of-body experience

² Proprioceptive drift is another aspect frequently associated with RHI: many subjects judge (by proprioception) their real hand as being located closer to the rubber hand, rather than as where it really is. But Rohde et al. (2011) have recently shown that this aspect can be dissociated from the feeling of the rubber hand as one’s own.

(OBE) (Lenggenhager et al. 2007).³ In experiments of this type, the subject wears a three-dimensional head-mounted display (HMD), and a stereo camera stands two meters behind her. The scenes registered by the camera are transmitted to the HMD such that the subject sees the back of his virtual body in front of her. Then the subject's back is stroked either synchronously or asynchronously with the virtual body. In the synchronous condition, many subjects feel as if the virtual body were their own.⁴

The second distinction is between the first-personal sense and third-personal sense of body ownership. In daily experience, the sense of body ownership is often first-personal as well as pre-reflective (Legrand 2007, 2010). That is, by proprioception and somatosensation, I can experience the body as mine *from the inside* without watching it or reflecting upon it (de Vignemont 2012). Consider simple activities such as walking. When I talk to someone while walking, my attention can be fully absorbed in the conversation. In this case, I don't pay any attention to my leg movements. Still, due to the firing patterns of muscle spindles in my legs, I implicitly experience that my legs take turns entering into the stance phase (touching the ground) and the swing phase (leaving the ground) to move my body forward. In contrast, the sense of body ownership can sometimes be third-personal and reflective. When looking at a

monitor in an airport showing the image of my body, I may wonder whether the body that I see is mine. In this case, instead of experiencing it *from the inside*, I consider my body from the third-person point of view. That is, the body is treated as the object of visual experience, attention, or reflection.⁵ In the rest of this paper, I will use "the sense of body ownership" to indicate the first-personal sense of the term.⁶

These two distinctions have been suggested before. But now I want to propose a third distinction to help elucidate what we mean when we talk about the sense of self-as-object. This third distinction refers to the difference between a sense of body ownership and a sense of self *as a physical body*.⁷ The former relates to questions like "Is this my hand?" and "Is that body mine?", whereas the latter concerns issues such as "What am I?" and "Am I a physical object?" This distinction marks two notions of bodily self-consciousness: experiencing a body part or a full body as one's *own*, on the one hand, and being conscious of oneself *as a physical body* on the other. Conceptually, the sense of *having* a body and the sense of *being* a body are different notions.⁸ However, they are closely related *experientially*. I suggest that experien-

³ Cf. Ehrsson (2007) for a different OBE experiment.

⁴ The relationship between body-part and whole-body representations for body ownership is a controversial issue. Clearly they are not the same. The issue is: are they fundamentally different? Or is the difference only a matter of degree? As an anonymous reviewer points out, during the rubber-hand illusion, one's self-location and global body ownership are unaffected. However, during full-body illusions these aspects are affected and misrepresented because they concern the whole-body. Some researchers might therefore think that there exist some fundamental differences between body-part and whole-body representations for body ownership. One can also reasonably hypothesize that the neural mechanisms that are responsible for hand ownership do not need to involve brain regions that process leg or trunk representations. However, in my opinion more interdisciplinary studies would be required to really solve this issue. My current position is that, regarding the sense of body ownership, the difference between body-part and whole-body representations is a matter of degree. First, conceptually speaking, there doesn't seem to be a sharp distinction between body-part and whole-body representations. Second, if we consider the experimental set-ups of the rubber hand illusion and of the full-body illusions (either Lenggenhager's version or Ehrsson's), the differences between them seem to be a matter of degree as well. Of course, these are not arguments yet. I have recently designed a set of experiments precisely to deal with this issue, and I hope to be able to say something about it soon.

⁵ Are there borderline cases between the first-personal and the third-personal experiences of one's own body? I think so. For example, to use the above example again, if one of my legs suddenly hurts a little bit, I may be able to continue my conversation without disruption, but I have to pay attention to proprioception in order to walk normally. In this case, I submit, the distinction between the first-personal and the third-personal senses of body ownership is not sharp. However, this will not affect my proposal below regarding the relationship between the sense of full-body ownership and the sense of self-as-object.

⁶ Both the first-personal and the third-personal senses of body ownership are involved in RHI and OBE. On the one hand, the fake hand or the virtual body that the subject sees is the object of visual awareness, which is experienced as standing apart from their visual perspective. In addition, by filling in the questionnaires after the experiment, the subject makes explicit judgments about body ownership. This is the third-personal sense of body ownership. On the other hand, during the experiment, the synchronous touch and proprioception causes the subject to feel as if "it is my body that is being touched". This is the first-personal sense of body ownership, which can be indirectly measured by skin conductance response (SCR). In RHI and OBE, both the third-personal and the first-personal senses of body ownership are prone to misrepresentation.

⁷ Here, "physical body" is broadly construed such that it can refer not only to a physical object but also to a biological organism or a flesh-and-blood person.

⁸ A Cartesian dualist might say that, although I experience a particular body as mine, I fundamentally conceive of myself *as* a thinking being rather than as a physical body. For the purpose of this paper, we can set Cartesianism aside.

cing ownership of a full body provides a sense of self as a physical body. When I engage in daily activities, there is not only a sense that this body is mine but also a sense that I *am* a physical body. Consider ordinary experiences like eating, running, bleeding, standing behind a desk, etc. These experiences involve a sense of body ownership, i.e. what it is like to *have* a body. But I also experience what it is like to *be* something that is eating, running, bleeding, etc. That is, I have a sense about *what* I am, or a sense of myself as a physical body that is doing these things.

I suggest that the sense of full-body ownership helps us to understand the sense of self-as-physical-body.⁹ The sense of self-as-physical-body, in turn, helps us to specify what it means to be conscious of the self-as-object.¹⁰ When I experience these hands as mine, there is a sense in which I am implicitly aware of myself *as* a physical body such that these two hands *are parts of me*. The proposal here is that I am conscious of myself-*as-object* when I am conscious of myself as a physical body. This holds not only in cases where I take myself as an object of vision or attention, such as seeing myself in a mirror. It holds even when I experience myself as a body from the first person perspective.¹¹

⁹ The idea is that we know how to conduct empirical research in order to study the sense of full-body ownership which, as Blanke and Metzinger suggest, is connected with the following features: (i) the global sense of identification with a physical body as a whole (self-identification); (ii) the sense of being situated in a specific place (self-location); and (iii) the sense of possessing “a point of projection functioning as its origin in sensory and mental processing (weak 1PP)” (2009, pp. 7–8). Together, these features characterize what Blanke and Metzinger call minimal phenomenal selfhood (MPS), defined as “the conscious experience of being a what” (2009, p. 7). It is my view that these three features articulate what it is like to be a self *as a physical body*. In this regard, the sense of full-body ownership helps us to understand the sense of self-as-physical-body. Also, thanks to the recent findings of the RHI and the OBE experiments, we have now better ideas regarding how misrepresentation may occur in the sense of body ownership. This, in turn, suggests that the sense of self-as-physical-body can involve misrepresentation as well.

¹⁰ In my account, “the sense of self-as-physical-body” serves as a conceptual bridge between “the sense of full-body ownership” and the “sense of self-as-object”. Experientially, the sense of full-body ownership and the sense of self-as-physical-body are closely related. I deliberately leave open whether these two notions denote the same or different experiences. I think more interdisciplinary work will be required to fix this issue.

¹¹ My proposal here is very different from what might be called the Pre-reflective Account of self-consciousness (Legrand 2006, 2007, 2010, 2011; Gallagher 2005; Zahavi 2005). According to this account, self and body are constitutively tied together, and body can provide a sense of self-as-subject, i.e., one can experience one’s body-*as-sub-*

ject. Let me draw some remarks made by Wittgenstein to support this proposal. Consider his examples of “I”-as-object: “My arm is broken”, “I have grown six inches”, “I have a bump on my forehead” (1958, p. 67). These examples clearly refer to the speaker’s body. This fits my suggestion that consciousness of self-as-object can be understood as consciousness of self-as-physical-body—I have the sense that I am a body that has a broken arm or that has grown six inches. Now consider his examples of “I”-as-subject: “I see so-and-so”, “I try to lift my arm”, “I have toothache” (1958, pp. 66–67). As indicated by his own italicization, the use of “I”-as-subject is about *who* the perceiver, agent, or the subject is. But notice that these examples refer to the speaker’s body *as well*. What does this tell us? My interpretation is that it implies that the idea of *who the subject is* should not be regarded as the same as the idea of *what* does the perceiving, lifting, or undergoes toothache. The sense of self-as-subject is not equivalent to the sense of self-as-physical-body.

Towards the end of *The Blue Book*, Wittgenstein makes two important remarks. First, “we can perfectly well adopt the expression “this body feels pain”, and we shall then, just as usual, tell it to go to the doctor, to lie down, and even to remember that when the last time it had pains they were over in a day” (1958, p. 73).¹² His point is that we should not construe the thing that suffers pain as a Cartesian immaterial ego. The notion of body in the expression

ject. Pre-reflectively experiencing the self as a physical body would correspond to the sense of body-as-subject rather than as-object. The difference between my view and this account centers on whether the notion of object in “self-as-object” is construed as a physical body or as an “intentional object of consciousness”. I contend that the sense of self-as-subject is different from the sense of body-as-subject. Experiencing the self as the subject of experiences is not the same as experiencing the self as a perceiving or acting body. I address these issues in another paper.

¹² Just before this, Wittgenstein says: “Let us now ask: ‘Can a human body have pain?’ One is inclined to say: ‘How can the body have pain? The body in itself is something dead; a body isn’t conscious!’ And here again it is as though we looked into the nature of pain and saw that it lies in its nature that a material object can’t have it. And it is as though we saw that what has pain must be an entity of a different nature from that of a material object; that, in fact, it must be of a mental nature. But to say that the ego is mental is like saying that the number 3 is of a mental or an immaterial nature, when we recognize that the numeral ‘3’ isn’t used as a sign for a physical object” (1958, p.73).

‘this body feels pain’ can perfectly well refer to a physical object, i.e. to a person or to a biological organism that can consciously feel pain. Wittgenstein states this point from the third-person perspective. But there is no reason why this point cannot be formulated from the first-person perspective. That is, by “this body” I can refer to myself. As I suggested above, I can experience my body *from the inside*. Someone else can tell me to go to the doctor or to lie down, etc. In this case, I can be aware of myself as *having* a body that is in pain (a sense of body ownership), and I can have a sense of myself *as* a body that is in pain (the sense of self-as-physical-body).

This brings us to Wittgenstein’s second remark: “The kernel of our proposition that that which has pains or sees or thinks is of a mental nature is only that the word ‘I’ in ‘I have pains’ does not denote a particular body, for we can’t substitute for ‘I’ a description of a body” (1958, pp. 73–74). My interpretation of this remark is that, even when it is my body that is in pain, there remains a difference between saying “I have pains” and saying “this particular body feels pain”. When Wittgenstein says that “the word ‘I’ in ‘I have pains’ does not denote a particular body”, this remark can apply to the speaker’s body considered *from the first-person perspective*. The reason why we can’t substitute for “I” a description of a body is *not* because my body has to be described from the third-person point of view or that it has to be treated as an intentional object of consciousness. Rather, the reason we can’t substitute for “I” a description of a body is that the “I” in “I have pains” captures the sense of *who* feels pains, while “a particular body” captures the sense of *what* feels pains. This difference, then, marks two different types of self-consciousness. In the former case, I am conscious of myself as the subject of pain experience. In the latter case, I am conscious of myself *as the body* that feels pain. I do not mean that this is the only possible interpretation of Wittgenstein’s remarks. My claim is that it is a plausible interpretation, according to which the sense of self as subject of experience is

distinct from the sense of self as a physical body, even when the body is characterized from the first-person perspective.

So far I have suggested an empirical approach to understanding the sense of self-as-object. The sense of full-body ownership provides theoretical and experiential grounds for understanding the sense of self-as-physical-body, which, in turn, helps to explicate the sense of self-as-object. This means that we can understand consciousness of self-as-object by studying the sense of full-body ownership. This fits Wittgenstein’s and Shoemaker’s assertions that the “I”-as object allows misrepresentation. The main advantage of my approach, however, lies in the fact that we know how to conduct empirical research on the sense of self-as-object. Now, in cognitive neuroscience there are plenty of exciting studies on full-body illusions and their neural mechanisms (Lenggenhager et al. 2007; Petkova & Ehrsson 2008; Ehrsson 2007; Ehrsson 2012; Ionta et al. 2011; Blanke 2012; Serino et al. 2013). A philosophical account will certainly benefit from looking at these. But what about the sense of self-as-subject? In the next section, I will appeal to the notion of experiential ownership in order to capture this basic form of self-consciousness.

3 Experiential ownership and self-as-subject

The sense of experiential ownership is not about ownership of body parts or a whole body, but about whether I represent myself as the unique *subject* of experience. As I am typing, for example, I do not only experience tactile sensations in my fingers. I also have a sense that I am the one who is having these tactile sensations. This corresponds to Wittgenstein’s assertion: “To ask ‘are you sure it is you who have pains?’ would be nonsensical.” In this section, I will (1) illustrate that the sense of experiential ownership is different from the sense of body ownership; and (2) draw two distinctions to explicate the sense of experiential ownership. I will then (3) describe some varieties of the immunity principle (IEM); and (4) provide two counterexamples against two major forms of

IEM. We will see that, *pace* Wittgenstein and Shoemaker, we need another way of articulating the distinction between the sense of self-as-object and the sense of self-as-subject.

Moro et al. (2004) describe two patients with somatoparaphrenia. These patients suffered not only from somatoparaphrenia but also from hemispatial neglect and tactile extinction. They denied ownership of their left hand, in which they had no sensation, and their left visual field was lost. So far, we might think that these cases involve only misrepresentation of body ownership. But there is more. When the researcher moved the patients' left hand to the right-hand side so that they could see it, their tactile sensation was restored. But despite representing themselves as the subjects who felt the sensations, the two patients still denied the ownership of their left hands (2004, p. 440–441). This shows that it is possible to have the sense of experiential ownership without the sense of body ownership. The two types of self-experience are conceptually and empirically dissociable.

To clarify the notion of experiential ownership, let me begin with the point that every phenomenal state has a *what*-component and a *who*-component. The *what*-component includes the representational content and the phenomenal character of that state. The *who*-component ties the *what*-component to a unique subject. The basic assumption here is that every phenomenal state has one and only one subject. The sense of experiential ownership is exclusively about the *who*-component—it concerns whether one experiences oneself as the subject of a phenomenal state. I will now draw two distinctions to further clarify this point.

The first distinction is between the *fact* of experiential ownership and the *sense* of experiential ownership. When a subject experiences a phenomenal state, there exists a *fact* that he is the subject of that state. This fact of experiential ownership is constitutive of every conscious experience—i.e. every experience has a unique subject. For every conscious experience, we can ask “Who is the subject of that experience?” and there exists a fact of the matter. For example, right now it is me, not you, who is ex-

periencing lower-back pain. The fact of experiential ownership is objective in that it refers to a biological fact about whether a subject undergoes a phenomenal state.

When a subject experiences herself *as* the unique subject of a phenomenal state, she has the *sense* of experiential ownership, i.e. she experiences herself as the subject of that state. This aspect is captured by the Wittgenstein Question: “Are you sure it is you *who* has pains?” When a subject answers this question, she relies on her sense of experiential ownership. When I have a tactile sensation, I experience *what it is like for me* to undergo that sensation. The *what-it-is-like* aspect, i.e., the phenomenal character, belongs to the *what*-component. The *for-me* aspect refers to the subjective sense that I am the one who is having the sensation.¹³

The fact of experiential ownership and the sense of experiential ownership are two different aspects of experiential ownership: the *factual* aspect and the *subjective* aspect. These are not numerically different states or events that can be detached from a phenomenal state. Rather, they are two ways of characterizing the *who*-component of that state. The factual aspect addresses whether a subject experiences a phenomenal state; the subjective aspect concerns whether the subject is conscious of the factual aspect. But many philosophers do not see that these two aspects are not the same. To sustain this distinction, I will later argue that the factual aspect of experiential ownership can be misrepresented, which means that sometimes the Wittgenstein Question can be perfectly intelligible. Misrepresentation, as I shall explain, happens when the subjective aspect fails to match the factual aspect of experiential ownership.

The second distinction is between the first-personal sense and third-personal sense of experiential ownership. Suppose I experience a phenomenal state—say, lower-back pain. Not only do I experience the phenomenal character of the pain but also, *in the very same experience*, I have the sense that it is *me* who is experiencing that particular pain. This sense of

¹³ For other views about the *for-me* aspect, cf. Kriegel (2009) and LeGrand (2007).

experiential ownership is first-personal, since it is part of the pain experience rather than resulting from a separate act of reflection. I experience a sense of experiential ownership by experiencing the pain without requiring any further attention or introspection.

Now suppose I participate in an experiment where several subjects receive tactile stimulations in a random order and everyone is simultaneously scanned with fMRI equipment.¹⁴ Later, using the fMRI data on my somatosensory cortex, I can judge whether it was me who experienced a particular stimulation a few minutes ago. In this case, the sense of experiential ownership is considered from the third-person point of view, where the sense of experiential ownership is the content of a further judgment or reflection rather than an integral part of the respective phenomenal states.

I suggest that the sense of self-as-subject is captured by the first-personal sense of experiential ownership. Being conscious of oneself-as-subject just *is* to experience oneself as the subject of a phenomenal state. This implies that the sense of self-as-subject is exclusively about the *who*-component of a phenomenal state—no parts of the *what*-component belong to it. The sense of self-as-subject concerns whether I experience myself as the subject of a phenomenal state and nothing else. For the rest of this paper, I will use the term “the sense of experiential ownership” strictly in the first-personal sense.

Can one’s sense of self-as-subject go wrong? Following Wittgenstein and Shoemaker, most philosophers believe that the answer to this question is negative. According to Shoemaker, “in being aware that one feels pain one is, tautologically, aware, not simply that the attribute *feel(s) pain* is instantiated, but that it is instantiated *in oneself*” (1968, pp. 563–564; emphases in original). Hence, when I consciously feel a sensation, I *cannot be wrong* about whether it is me who feels it. This immunity (IEM) is widely considered to be a conceptual truth.¹⁵

I want to argue, however, that both Shoemaker and Wittgenstein are wrong. IEM is not a conceptual truth, and sometimes it makes perfect sense to ask the Wittgenstein Question—namely, “Are you sure it is you who is having a so-and-so experience?” Using my own terms, I will argue that the *sense* of experiential ownership can misrepresent the *fact* of experiential ownership. First, let me briefly mention some varieties of IEM. (1) Pryor (1999) distinguishes between *de re* misidentification and *which-object* misidentification.¹⁶ *De re* misidentification is false identification of two particular objects. It occurs when a mental state that *a* is F involves an assumption that *a* = *b*, but in fact *a* ≠ *b*. For example, when looking in the mirror, I misidentify someone else as myself (Pryor 1999, p. 276). A mental state enjoys *de re* immunity just in case it is not possible for the state to be in error through *de re* misidentification. In the case of *which-object* misidentification, one makes an existential generalization that there is something that is F based on suitable grounds, but misidentifies *which thing* is F (Pryor 1999, p. 281). For example, when listening to a symphony orchestra, I can tell that one of the trumpet players is slightly out of tune, but I misidentify which one it is. A mental state enjoys *which-object* immunity just in case it is not possible for the state to be in error through *which-object* misidentification. (2) De Vignemont (2012) recently distinguished bodily immunity from mental immunity. Mental immunity concerns whether certain self-ascriptions of mental states, including thoughts, judgments, or sensations, etc., enjoy IEM. By contrast, bodily immunity is not about mental states but about bodily properties. It concerns whether certain self-ascriptions of bodily states enjoy IEM, e.g. “my legs are crossed”.¹⁷

the self requires that when ascribing a mental state to oneself, e.g. “*a* is F”, one needs to demonstrate both “*b* is F” and “*a* = *b*.” But “*b* is F” would in turn require both “*c* is F” and “*b* = *c*”, and hence generates an infinite regress. This, Shoemaker argues, shows that the sense of self-as-subject must be identification-free.

¹⁶ Although disputed (Coliva 2006), many still consider this distinction useful.

¹⁷ Other varieties of IEM have been proposed in the literature. For example, Shoemaker (1968) distinguishes between circumstantial and absolute immunity, and between *de facto* and logical immunity (Shoemaker 1970; cf. also Coliva 2006). Pryor (1999) distinguishes between relative and absolute immunity. The former refers to im-

¹⁴ The method used here is called hyperscanning; cf. Montague et al. (2002).

¹⁵ Also, when specifying the “I”-as-subject, Shoemaker remarks that “not every self-ascription could be grounded on an identification of a presented object as oneself” (1968, p. 561). Because identification of

My target is a form of mental immunity that I call *experiential* immunity. *Experiential* immunity concerns phenomenal experiences. It is a form of *relative* immunity—that is, it is relative to first-personal access to phenomenal states, such as introspection, somatosensation, proprioception, etc. Experiential immunity is then the phenomenon that, when I am aware of a phenomenal state through first-personal access, I cannot be wrong about whether it is me who feels it. Experiential immunity can be construed as *de re* or *which-object* immunity. In the following section, I present counterexamples against both versions of experiential immunity. This will show that the sense of self-as-subject can be erroneous.

Bottini et al. (2002) describe a somatopraphrenia patient (“FB”) who has lost tactile sensation in her left hand and insists that her left hand belongs to her niece. They conducted the following tests on the patient, each involving several trials: (i) FB was blindfolded and told by the researcher that her left hand would be touched. Then the researcher actually touched the dorsal surface of her left hand. The result was that FB always reported feeling no sensation. (ii) FB was again blindfolded and was told that her *niece’s* hand would be touched. The result in this case was that, when the researcher touched the dorsal surface of her left hand, surprisingly, FB reported feeling the touch.¹⁸ The relevance of this case to IEM lies in the fact that, since FB was blindfolded during these tests, she relied on internal and first-personal access (e.g., introspection, somatosensation, proprioception) to determine whether or not she felt the touch. The perplexity lies in the difference between tests (i) and (ii). For the researcher, the only difference between the two

was the verbal cues given to FB before touching her hand. The remaining conditions were the same. But for FB, the difference was dramatic. Why is it that FB felt nothing when she expected that she herself would be touched, but felt the sensations when she expected that her niece would be touched? What is the best description of this strange phenomenology?

My view is that, during test (ii), FB misrepresented her tactile sensations as belonging to someone else, namely her niece. For the sake of argument, Shoemaker and I can agree on the following claims: (1) for every phenomenal state there must be a subject who experiences it; (2) every phenomenal state is in principle available to first-personal access (Shoemaker 1996); (3) every phenomenal state is experienced by the one who has first-personal access to that state. The crucial point is that (1)–(3) do not imply that (4) every phenomenal state is, from the first-person point of view, *represented as* experienced by the one who has first-personal access to that state. In FB’s case, (4) fails. FB fails to represent from her first-person perspective that she is the owner of the sensations. During test (ii), the factual aspect of her experiential ownership of the tactile sensations was intact when she was told that her niece would be touched, i.e., she was indeed the one who felt the tactile sensations. What went wrong was her sense of experiential ownership. Although FB felt the sensations, she misrepresented this fact as it being her niece who felt them.¹⁹ This shows that it is empirically possible for a subject, while being aware of a phenomenal state via a first-personal

munity relative to certain rational grounds G, and the latter immunity by every possible ground. Regarding judgments and beliefs, Coliva (2006) suggests a distinction between immunity relative to the subject’s own rational grounds and immunity relative to background presuppositions.

¹⁸ Test (ii) was conducted for four sessions, and FB reported feeling touches in 70%, 70%, 100%, and 80% of the trials respectively. As Bottini et al. observe: “her tactile imperceptions dramatically recovered” (2002, p. 251). To test if FB was just guessing, she was again blindfolded and told that her right hand (which is normal) would be touched. But actually the researcher did not touch her right hand. The result was that FB never reported feeling sensations—i.e., she passed the catch trials.

¹⁹ Shoemaker describes IEM as follows: ‘The statement ‘I feel pain’ is not subject to error through misidentification relative to ‘I’: it cannot happen that I am mistaken in saying ‘I feel pain’ because, although I do know of someone that feels pain, I am mistaken in thinking that person to be myself’ (1968, p. 557). Based on this description, some might insist that the self-ascriptions involved in IEM must be propositional in form, i.e. judgments, beliefs or statements. However, I contend that this restriction is unnecessary. What is crucial for IEM is that the self-ascriptions are based on first-personal grounds such as introspection, somatosensation, and proprioception, etc. As Bottini et al. have stated: “The patient was blindfolded and instructed to say ‘yes’ when she felt a touch and ‘no’ when she did not feel any touch” (2002, p. 251). So when FB said “yes” during test (ii), there is no reason why this wouldn’t count as a self-ascription. Applying Shoemaker’s description to FB’s case: I am mistaken in reporting ‘yes’ during test (ii) because, although I do know of someone that feels the sensations (via first-personal access), I am mistaken in my thinking about who that person is. Shoemaker’s IEM can be violated.

method, to commit a *de re* error regarding who the subject of that state is. Hence, *de re* immunity fails. Using my own terms, the sense of experiential ownership can misrepresent the fact of experiential ownership.²⁰

The second case against Shoemaker's IEM is the "body swap illusion" (Petkova & Ehrsson 2008, figure 6). This involves agentive experience—I experience myself as someone who is doing something. In an experiment, subjects wore a head-mounted display (HMD), and stood face-to-face with the experimenter, who wore two closed-circuit television (CCTV) cameras. The images registered by the CCTV cameras were transmitted concurrently to the subjects' HMD, such that through the HMD the subjects saw their own body facing themselves. Both the subjects and the experimenter extended their right hands, took hold, and then squeezed synchronously for two minutes. Twenty college students participated in this experiment. The authors describe their phenomenology: "after the experiment, several of the participants spontaneously remarked: 'I was shaking hands with myself!'" (2008, p. 5)

This strange phenomenology indicates that the subjects' agentive experience was mistaken. It was the experimenter who was shaking their hands, not the subjects themselves. Again, Shoemaker and I can agree that: (1) for every agentive experience there must be a subject who experiences it; (2) every agentive experience is in principle available to first-personal access; and (3) every agentive experience is experienced by the subject who has first-personal access to it. However, (1)–(3) together do not imply that: (4) every agentive experience is, from the first-person perspective, *represented as* experienced by the subject who in fact has first-personal access to it. In this case, *which-object* immunity fails because (4) was violated by

those who experienced the strange phenomenology in the body swap illusion. They were aware that there was someone having the agentive experience of squeezing their hands, but they misrepresented themselves as the subject of that experience.²¹

As such, it is possible for the subject of a given conscious experience, while being aware of that experience via a first-personal standpoint, to be mistaken about who the subject is.²² Thus Wittgenstein is wrong: it would make perfect sense to ask FB and the body-swap subjects: 'Are you sure that it is *you* who is having a so-and-so experience?' And Shoemaker is wrong, too: experiential immunity is violated both in FB's case and in the body-swap illusion. One's sense self-as-subject can be mistaken—that is, the sense of experiential ownership can misrepresent the fact of experiential ownership. Therefore, since both the sense of self-as-object and the sense of self-as-subject can involve misrepresentation, Shoemaker's IEM fails to distinguish between them.²³

21 Again, one might wonder whether the misrepresentation in this case was about the judgment rather than about the sense of experiential ownership. My reply is that since the subjects were normal college students, their reportability was not in question. So it is plausible to assume that their reports that "I was shaking hands with myself" were based on their subjective phenomenology, and more specifically on their sense of experiential ownership. Hence it was their sense of experiential ownership that committed misrepresentation.

22 There are at least two other (possible) cases of misrepresentation of the sense of experiential ownership. One is *voice ownership*: an illusion in which a stranger's voice, when presented as the auditory concomitant of a participant's own speech, is perceived as a modified version of one's own voice. "It felt as if the voice I heard was my voice" (Zeng et al. 2011). The other is *perception ownership*: A twenty-three-year-old male (DP) suffered from right inferior temporal hypometabolism (Zahn et al. 2008). The authors of a study on this male described his sensations as follows: "It appeared to him that he was able to see everything normally, but that he did not immediately recognize that he was the one who perceives and that he needed a second step to become aware that he himself was the one who perceives the object."

23 Let me briefly compare my position with other views. First, following Shoemaker, Coliva (2000) states that "If a subject is introspectively aware of pain, this just means that she is feeling pain [...] it is a matter of *conceptual truth* that if a subject is introspectively aware of a certain mental state, then she herself is having it and, therefore, that *mental state is her own*" (my emphasis). In contrast to Coliva, my account rejects IEM as a conceptual truth. From the fact that a subject experiences a mental state it does not necessarily follow that the subject represents herself as the one who experiences that state. I take the possibility of misrepresentation to be an important feature of the sense of experiential ownership. Second, Legrand (2007) emphasizes that consciousness of self-as-subject is pre-reflective, meaning that it is not an object of intentional consciousness. She says that the self-as-subject "is neither an external object (for example, it is not my body that I can observe in

20 One might object that the mistake that FB made was about the judgment of experiential ownership, not the sense of experiential ownership. My reply is that since FB was blindfolded, her report was based on first-personal grounds, i.e. on introspection. In addition, FB passed the catch trials mentioned in. As Bottini et al. have stated, FB "did not show any other sign of mental deterioration on the Mini Mental State Examination" (2002, p. 251). Therefore, no evidence suggests that her reports were unreliable. These considerations support the idea that the mistake was FB's sense of experiential ownership rather than her judgment. For other objections and responses, cf. Lane & Liang (2011).

I propose that this distinction can be made clearer by looking again at the sense of body ownership and the sense of experiential ownership. As I suggested in the last section, the sense of self-as-object can be understood in terms of a sense of self-as-physical-body which, in turn, can be understood via a sense of full-body ownership. Hence, when one experiences full-body ownership, one is conscious of oneself-as-object. In this section, I have suggested that we take an empirical approach to understanding the sense of self-as-subject. We can understand the consciousness of self-as-subject by studying the sense of experiential ownership.²⁴ In the

the mirror) nor an internal object [...] I am simply looking outside at the external world, and within this single act of consciousness I pre-reflectively experience myself-as-subject" (2007). I agree that the sense of self-as-subject is often implicit rather than explicit. But Le-grand's view neglects the distinction that I draw between the fact and the sense of experiential ownership. This is indicated by the fact of her embracing IEM. The fact of experiential ownership can be secured simply by looking outside at the external world, but whether one's sense of experiential ownership is correct is another issue.

²⁴ What is the relationship between the sense of body ownership and the sense of experiential ownership? The short answer is that the former presupposes the latter, but a full treatment would require another paper. Here, let me draw on Metzinger's Self-model Theory of Subjectivity (2003, 2008) to briefly address this issue. According to this theory, PMIR (phenomenal model of the intentionality relation) is a phenomenal experience that represents the relation between a subject and an object component. For example, I take a bite of an apple. The PMIR contains a subject component (I), a relation component (tasting), and an object component (the apple). But I want to propose a revised version of PMIR. Since the PMIR is a complex phenomenal property experienced by a subject, it would sometimes be legitimate to ask who is experiencing this particular PMIR. Does the subject attribute the sense of experiential ownership of this PMIR to him or herself? My proposal is that PMIR consists of three components: (1) the sense of experiential ownership; (2) intentional relations; and (3) an object component. On this view, PMIR already involves the sense of experiential ownership as the subject component, which is distinct from intentional relations and the object component. This revised version of PMIR helps to unpack the phenomenological structures of the sense of body ownership as follows. The subject component is served by the sense of experiential ownership. The object component can be one of the following: my hand, a rubber hand, someone else's leg, my whole-body, or a virtual body, etc. The intentional relations include vision, touch, proprioception, location, motion, introspective awareness, affective feelings, and so on. Four quick remarks are relevant here. First, the sense of body ownership is itself a phenomenal state, about which (2) and (3) specify the *what*-component. The *who*-component of the sense of body ownership is characterized by (1) the sense of experiential ownership. Hence, the sense of body ownership presupposes the sense of experiential ownership. Second, it is (1) and (2) that generate the sense that (3) is part of my body. Third, the difference between the sense of body-part ownership and the sense of full-body ownership lies in (3), while (1) and (2) may remain the same. Finally, based on my proposal in section 1, the sense of self-as-physical-body can be understood in terms of the following structure of PMIR: (1) the sense of experiential ownership; (2) intentional relations; and (3) a whole body. And the sense of self-as-object can be understood in terms of the same structure of PMIR as well.

next two sections, I examine some of the most relevant empirical accounts about the sense of self-as-subject. I argue that none of them are satisfactory. The reasons for this will be valuable when we consider where to go from here.

4 Core-self and affective-self

For animals, many biological values, such as finding food and shelter, avoiding predators, etc., have to do *homeostasis*—namely maintaining overall physiological states within the range required for survival (Damasio 1999, 2010; Panksepp 1998, 2005). To explain this, both Damasio and Panksepp propose that the brain has distinctive emotion systems and self-systems (the “proto-self” and the “core-self”). These inter-connected systems regulate homeostasis by integrating external information from perception with internal information from the body.²⁵ Despite their differences, Damasio and Panksepp share the following views: (1) emotions and homeostasis play essential roles in explaining how the sense of self is generated in the brain; (2) the key brain areas related to the self involve not only cortical but also sub-cortical regions, especially the brain stem possessed by both humans and many animals; (3) those brain areas are crucial, because multifarious types of neural information are integrated in those regions and provide representations of the whole body; (4) both Damasio and Panksepp believe that their accounts explain not only the sense of self-as-object but also the sense of self-as-subject. In the following I elucidate these points and then examine whether their goals are achieved.

According to Damasio, animal brains have what he calls the proto-self system, which is “a dynamic collection of integrated neural processes, centered on the representation of the living body” (2010, p. 9). The neural processes of

²⁵ Both Damasio and Panksepp distinguish between emotions and their neural substrates, on the one hand, and feelings (Damasio) or affective feelings (Panksepp), on the other. Emotions refer to innate patterns of neural and physiological responses to environmental events. Feelings (or affective feelings) refer to phenomenal consciousness of emotions (Damasio 1999, p. 42, p. 55; Damasio 2010, pp. 108–110; Panksepp 1998, pp. 48–49; Panksepp 2005, p. 32). The emotion-systems closely interact with the self-systems to regulate and manage homeostasis.

this system represent “moment by moment, the most stable aspects of the organism’s physical structure”, on the one hand, and “the externally directed sensory portals”, on the other (2010, p. 190). This generates *primordial feelings* that “reflect the current state of the body” and “provide a direct experience of one’s own living body, wordless, unadorned, and connected to nothing but sheer existence” (2010, p. 21, p. 185). The proto-self system and primordial feelings account only for the sense of self-as-object (2010, p. 9, p. 202). The sense of self-as-subject is generated when an animal interacts with the environment such that a neural representation of the interaction is generated in the brain (2010, pp. 9–10, p. 91, p. 202). By interacting with external objects, the current state of the body and the proto-self system are modified. This modification activates the core-self system, which enhances attention to external objects and “engenders a sense of ownership” (2010, pp. 202–203). This is closely related to the sense of experiential ownership discussed above. It is part of what Damasio calls *core consciousness*, which “displays [...] moment by moment, that you rather than anyone else are doing the reading and the understanding of the text” (1999, p. 10).

Damasio’s key idea is that the brain produces not only first-order representations of external objects and of the body (2010, p. 76, p. 84, pp. 91–97), but also *second-order representations* of the relationship between objects and the organism (1999, pp. 169–170; 2010, pp. 71–72, p. 181). These are “the source of the sense of the self in the act of knowing” (1999, p. 169). When the core-self is *felt* (1999, p. 172), i.e. when the second-order representations become conscious states (2010, p. 248), core consciousness emerges. This includes a minimal sense of self-as-subject, a transient sense that “it is you [...] doing the seeing” (1999, p. 169; cf. 2010, p. 168), or the sense that I am the subject of current experiences (cf. 2010, p. 185, p. 203, p. 209). As we can see, this account is highly relevant to our current investigation.

Damasio emphasizes that the most crucial neural structures related to the proto-self and the core-self systems are found in the subcor-

tical regions, especially the brain stem (2010, p. 195, p. 205).²⁶ They include, among others, the nucleus tractus solitarius (NTS), the parabrachial nucleus (PBN), the periaqueductal gray (PAG), the hypothalamus, and the superior colliculus (2010, pp. 98–99, pp. 191–192; 1999, pp. 180–183). Why are these neural structures so critical for the core-self and core consciousness? According to Damasio, core consciousness results from *integration* of interoceptive, proprioceptive, and exteroceptive information, which produces second-order representations (2010, p. 76, p. 97, pp. 190–196, p. 199, p. 203, pp. 206–209). The brain areas just mentioned receive input from many other regions, which process information about external objects and internal bodily conditions (2010, p. 78, p. 80, pp. 84–85, p. 94, pp. 99–100, pp. 207–209). Thus it is in these areas that integration is thought to take place. Integration in those areas constitutes core consciousness because they provide neural representations of the organism’s *whole body* (2010, p. 68, pp. 94–97, p. 209, pp. 244–245), and the integration is implemented by neural synchrony in the gamma range (2010, p. 20, pp. 86–87).

Panksepp points out seven basic innate emotion-systems in mammals: seeking, rage, fear, lust, care, panic, and play.²⁷ These emotion-systems generate affective feelings, which characterize how animals respond to environmental challenges. Panksepp & Northoff (2009) also postulate that the proto- and core-self systems monitor and regulate homeostasis. The proto-self is ‘the most ancient form of coherent body representation’, and the core-self gives rise to “affective consciousness”.²⁸ Both systems are

²⁶ For Damasio, the cortical areas that are important for the core self include insular and somatosensory cortices (2010, pp. 205–209).

²⁷ According to Panksepp, emotions and affective feelings are internally generated by neuronal mechanisms to respond to life-challenging events. The neural systems of emotions compute and monitor homeostasis by evaluating an organism’s adaptation to the environment. Each emotion system refers to a specific neural network, mainly in the subcortical areas.

²⁸ Panksepp and Northoff prefer to use the expressions “proto-SELF” and “core-SELF” to emphasize neural mechanisms rather than mental phenomena, but this emphasis need not concern us here. They describe the relation between core-SELF and affective consciousness as follows: “What is subjectively experienced here is the relation of one’s body to the incentives in the environment as well as internally generated emotional arousals—the core-SELF thus enables the organism to access this relation in terms of subjective experience, e.g., a primitive form of phenomenal consciousness, which at this level is essentially affective” (2009, p. 196).

causally mediated by what they call affective *self-related processing*, which integrates interoceptive information from the body and exteroceptive stimuli from the environment. The main mechanism that underlies this processing is a subcortical-cortical midline system (SCMS) (2009, p. 197). The subcortical parts of this network include “the Periaqueductal gray (PAG), the superior colliculi (SC), and the adjacent mesencephalic locomotor region (MLR), as well as preoptic areas, the hypothalamus, and dorso-medial thalamus (DMT)” (2009, p. 201). On the superior colliculi (SC) and the periaqueductal gray (PAG), they tell us that:

The colliculi and the PAG are among the most richly connected areas of the brain; both receive afferents from several exteroceptive sensory regions (occipital, auditory, somatosensory, gustatory, and olfactory cortex) and, at the same time, afferents from other interoceptive subcortical regions. In addition, the PAG and the colliculi are connected with the cortical midline structures (CMS). (2009, p. 201)

Like Damasio, Panksepp and Northoff believe that the SC and the PAG play important roles in instigating the core-self system because they are the central areas where exteroceptive sensory information and interoceptive bodily information are integrated. They suggest that, due to anatomical convergence and neural synchronizations within the SCMS, “an archaic scheme of the *entire body* may be constituted in brain regions as low as the medial brainstem” (2009, p. 202; my emphasis).

Panksepp and Northoff claim that their theory explains what philosophers call the ‘experiential self’ and the ‘primitive form of selfhood’ (2009, p. 209). Self-related processing “intrinsically integrates affectivity, appropriateness and belongingness, and the phenomenal dimension of mineness into the *ownership of experience*” (2009, p. 199; my emphasis). This comes very close to the sense of experiential ownership that I discussed above. They consider self-related processing by the SCMS to be the mech-

anism not only of affective consciousness but also of the sense of self-as-subject.

In sum, Damasio, Panksepp and Northoff suggest that the sense of self-as-subject can be explained by full-body representations implemented by neural synchrony or by the SCMS. Now the key issue is: Do their accounts really specify the neural mechanisms that produce the sense of self-as-subject? Or do they specify only the mechanisms of the sense of self-as-object, i.e., of consciousness of oneself as a physical body interacting with the world? I argue that they address only the sense of self-as-object; they do not really provide a genuine account of the sense of self-as-subject.²⁹ Below I raise this theoretical issue; empirical arguments will follow in the next section.

Damasio claims that core consciousness is constituted by a second-order neural representation of the relation between animal and the environment. But this seems to require more explanation. Yet an explanation is not really provided by Damasio. I can agree that, for the sense of self-as-object, one must not only represent the external world, but also the body. But we cannot assume that the same account will automatically apply to the sense of self-as-subject. The problem with Damasio’s account is that the theoretical link between full-body representation and the sense of self-as-subject is lacking. And Panksepp and Northoff’s account is afflicted with the same defect. It might be that full-body representations are part of the biological conditions *necessary* for generating the sense of self-as-subject. But since they are also necessary for the sense of body ownership and the sense of self-as-object, it is far from obvious whether they are *sufficient* for the sense of self-as-subject. Let me elaborate.

Consider the full-body illusion mentioned in section 1. According to Blanke & Metzinger (2009), this illusion contains three central features related to self-consciousness. The first is *self-identification*. When the subjects experienced OBE during the experiment, “they felt as if the virtual body was their own” (2009, p. 12). We can see that this feature turns on the ques-

²⁹ Cf. Legrand (2007) for a slightly different criticism of Damasio.

tion “Is that body mine?” rather than “Am I the one who is having this experience?” So self-identification is about the sense of full-body ownership rather than the sense of experiential ownership. The second feature is *self-location*, which concerns “where my body is located in space and time”. Again, this is about the spatiotemporal position of the body rather than the sense of experiential ownership. Blanke and Metzinger call the third feature a *weak first-person perspective*, defined as a geometrical point of projection and nothing more (2009, p. 8). So construed, even a camera could possess such a perspective. Hence, this feature does not specify the sense of self-as-subject, either.

The point is that, in the OBE experiment, the sense of experiential ownership is not in question and hence not measured. This means that explanations of the mechanisms of full-body representation or the sense of body ownership do not necessarily apply to the sense of experiential ownership. As such, self-related processing can help explain full-body representation *without* explaining the sense of self-as-subject. Damasio, Panksepp and Northoff neglect the theoretical gap between full-body representation and the sense of self-as-subject, hence their accounts do not really explain the sense of self-as-subject. They suggest that the sense of self-as-subject results from integration by neural synchrony in the brain stem or the SCMS. But it remains unexplained why and how this could be so. To investigate these worries, I examine in the next section the two major proposals by neuroscientists regarding the mechanisms of the sense of self-as-subject: neural synchrony and processing in the SCMS.

5 Neural synchrony and subcortical-cortical midline structures

Neurons in different brain regions may exhibit rhythmic firing patterns. This is called neural oscillation, the frequency of which can be recorded by an electroencephalogram (EEG). When a group of neurons fire together with the same oscillation pattern, they are in *synchrony*. Neural synchrony is considered to be a central mechanism of many cognitive functions. In the

case of conscious perception, multifarious types of visual information are processed in different brain regions, which need to be combined in order to produce coherent percepts. Many researchers suggest that transient synchronization in the visual system provides such a binding mechanism (Engel & Singer 2001; Singer 2004; Singer 2007; Koch 2004). In addition to vision, synchronization in the beta and gamma ranges is also found in the olfactory, auditory, and somatosensory systems, as well as in other brain areas that influence (or are influenced by) perception, such as the pre-frontal cortex, the motor cortex, and the hippocampus (Singer 2007).

However, if this is all there is to neural synchrony, it would not explain the sense of self-as-subject at all. What we are looking for is not the mechanism that explains what I consciously perceive, but the mechanism that produces the sense that I, rather than someone else, am the subject of these perceptions.³⁰ Thus, information integration by neural synchrony may explain the content of consciousness without explaining the sense of experiential ownership, i.e., it explains *what* one experiences rather than *who* the subject of that experience is. In the following I consider three recent developments that connect neural synchrony more closely with self-consciousness.

(1) Uhlhaas et al. (2009) recently suggested that there are high correlations between disorders of self-consciousness and abnormalities in neural synchrony. Symptoms of schizophrenia, epilepsy, autism, Alzheimer’s disease, and Parkinson’s disease are related to dysfunctions of synchronization. For example, correlations have been suggested between reduced or abnormal alpha- or gamma-band oscillations, on the one hand, and impaired visual binding, auditory hallucination in schizophrenia, and impaired linguistic and auditory performance in autism, on the other. The problem is that the sense of experiential ownership is not itself targeted in these studies. Researchers measured how abnormal neural synchrony relates to impaired cognitive performance, rather than to who the subject of the experience is.

³⁰ The sense of experiential ownership is not studied in Singer’s work on neural synchrony at all.

(2) [Lou et al. \(2010\)](#) used transcranial magnetic stimulation (TMS) to show that a medial paralimbic network is crucial for minimal self-consciousness.³¹ This network may “bind conscious experiences with different degrees of self-reference through synchrony of high frequency oscillations” (2010, p. 185). They tested three conditions that represent different degrees of self-reference: maximal (“Self”), intermediate (“Franz”), and minimal (“Syl”). In each condition a set of adjectives were sequentially presented on a screen.³² In the “Self” condition, the subject’s task was to make personal judgments concerning how well each adjective fitted him or herself. However, none of these conditions are about the sense of experiential ownership. Whether it was “I” who looked at the screen and made the judgments was not in question. Hence, the sense of self-as-subject was not measured by the reported patterns of synchronization.

(3) [Kanayama et al. \(2009\)](#) used EEG to investigate the rubber hand illusion (RHI), and found high correlation between the visual-tactile integration process and gamma-band synchrony in the parietal cortex. The stronger the subjects experienced the illusion, the higher the synchrony was. The authors suggested that RHI is caused by gamma band synchrony. In addition, a study of the full-body illusion by [Lenggenhager et al. \(2011\)](#) found high correlation between alpha-band oscillations in the sensorimotor cortex and the medial prefrontal cortex, on the one hand, and subjects feeling themselves to be located in space, on the other. Unfortunately, these studies do not really tell us about the sense of self-as-subject. In these experiments, what was misrepresented was the sense of ownership of a body part or a whole body. Whether “I” was the one who was experiencing the illusions was not in question. The synchronization reported by these studies can help explain the sense of body ownership, but not the sense of self-as-subject.

³¹ [Lou et al. \(2010\)](#) suggest that this network includes the anterior cingulate, medial prefrontal and posterior cingulate, and the medial parietal cortices, connected via the thalamus.

³² In the ‘Franz’ condition, the subject judged how well each adjective fitted a well-known German football star Franz Beckenbauer. In the “Syl” condition, the subject’s task was to decide whether each of the different sets of adjectives had an even or odd number of syllables.

As far as I know, no empirical study on neural synchrony really targets the sense of self-as-subject. We cannot explain the sense of experiential ownership simply by describing the mechanisms of content of conscious perception, cognitive deficits, or body ownership. The lesson here is that we need first to ascertain that the neural information being integrated by synchrony is *about* the sense of self-as-subject, and not just about representation of the organism’s bodily condition. Unless we know exactly how the integrating processes bring about that one represents oneself as the subject of phenomenal or conscious states, we cannot say that the mechanisms of the sense of self-as-subject have been found. As I will suggest below, the key here is to identify the right research question. And this is where philosophy can make contributions to neuroscience.

The second proposal regarding the mechanisms of the sense of self-as-subject, suggested by [Panksepp & Northoff \(2009\)](#), is self-related processing implemented in the subcortical-cortical midline system (SCMS). This mechanism is notably related to the so-called resting state and the default mode network. Researchers have found that some brain areas are highly activated in the resting state, i.e. when the subject is not actively engaging with its environment (e.g. lying quietly in a scanner with eyes closed but awake) ([Raichle et al. 2001](#)). Interestingly, the activations decrease significantly when the subject performs tasks that involve focusing on the external world. These brain areas constitute what is now called the default mode network.

How one should interpret the neural activities in the resting state and the default mode network, and how they relate to self-consciousness, are controversial issues. For example, [Gillihan & Farah \(2005\)](#) point out that different research programs on the self employ divergent methodologies and implicate a wide range of brain areas. Putting all the data together, we do not obtain a specific or unitary picture, because pretty much the entire brain is involved in processing the sense of self. This and other criticisms suggest that we should be

cautious when interpreting the alleged empirical evidence about the sense of self-as-subject.³³

Still, many researchers maintain that resting state activities and the default mode network are closely related to the self (cf. Gusnard 2005; D'Argembeau et al. 2007). Northhoff et al. (2006) reviewed a vast number of imaging studies, and compared the processing of what they call self-related tasks and non-self-related tasks.³⁴ They found that the data indicate the same group of brain areas, including “the medial orbital prefrontal cortex (MOFC), the ventromedial prefrontal cortex (VMPFC), the sub/pre- and supragenual anterior cingulate cortex (PACC, SACC), the dorsomedial prefrontal cortex (DMPFC), the medial parietal cortex (MPC), the posterior cingulate cortex (PCC), and the retrosplenial cortex (RSC)” (2006, pp. 441–442). These areas constitute the cortical midline structures (CMS), i.e. the cortical parts of the SCMS. Compared with non-self-related tasks, when subjects perform self-related tasks their CMS reveal high activation across all domains (2006, p. 450). The authors suggest that the CMS correspond to the default mode network,³⁵ and that neural activity in the CMS constitutes “an experiential self that mediates ownership of experience” (2006, p. 441). “Ownership”, they claim, “describes the sense that I am the one who is undergoing an experience” (2006, p. 448), which makes this account directly relevant to our investigation.

Legrand & Ruby (2009) argue against Northhoff et al. that the CMS are at most self-related, i.e. related to the self only to some extent, but not *self-specific*, i.e., not specific

enough to capture the sense of self-as-subject.³⁶ Partly because of this criticism, but more because of new findings by his own group, Northhoff's view has changed significantly in recent times. First, Qin et al. (2010) recently studied the CMS in patients who are in a vegetative state. Surprisingly, by showing the patients their own names, various regions in their CMS were activated. Assuming that vegetative patients have lost the capacity to experience themselves as subjects, this finding undermines Northhoff's previous claim that the CMS constitutes an “experiential self that mediates ownership of experience.” In fact, Northhoff now agrees that the neural processing in the CMS is at most a necessary condition for the experiential self.³⁷

Second, after conducting a meta-analysis on eighty-seven imaging studies covering 1433 participants, Qin & Northhoff (2011) suggest that self-related processing involves far fewer areas in the CMS. It is the perigenual anterior cingulate cortex (PACC), rather than the medial prefrontal cortex (MPFC) or posterior cingulate cortex (PCC), that is specifically involved in self-processing. This indicates that they have become more cautious about interpreting data. However, they still maintain that there exists a strong connection between the PACC and the sense of self. They argue that “our sense of self may result from a specific kind of interaction between resting state activity and stimulus-induced activity, i.e., rest-stimulus interaction, within the midline regions” (2011, p. 1221). That is, a narrower network *within* the CMS is not just necessary but indeed sufficient for “generating our sense of the self” (2011, p. 1222). I will comment on this last claim below.

Whether or not Qin and Northhoff take their notion of “sense of self” to include the sense of

³³ Another criticism is that, when the subject is interacting with the world, the neural activity in the default mode network is not totally extinguished. Some studies show that it is “reorganized in response to the working memory task” (Fransson 2006). Others have suggested that it could “function to support exploratory monitoring of the external environment when focused attention is relaxed” (Buckner et al. 2008).

³⁴ Many of these studies used a “judgment paradigm”. Subjects made explicit evaluative judgments about first- vs. third-person perspectives, own vs. others' judgments, self vs. others' decisions, own vs. others' personality traits, etc. The domains that Northhoff et al. (2006) reviewed include verbal, spatial, memory, emotional, facial, agency, ownership of movements, and social tasks.

³⁵ CMS show a high level of neural activity during the resting state. Non-self-referential tasks elicit large signal decreases in the CMS (Northhoff et al. 2006, p. 450).

³⁶ Legrand and Ruby indicated that the CMS are involved not only in self-related tasks, but also in several cognitive tasks that are not related to self-consciousness at all. For example, their review showed that some areas in the CMS are activated in others' mind reading, inductive and deductive reasoning, resting state, and memory recall. Moreover, these areas are “sometimes more activated for the self than for others and sometimes more activated for others than for self” (Legrand & Ruby 2009, p. 258).

³⁷ Northhoff et al. tell us that “the neural mechanisms underlying SRP [self-related processing] may only be considered a necessary condition which is not sufficient by itself to constitute a self with its self-specific contents” (2011, p. 55).

self-as-subject, I argue that their meta-analysis does not capture the sense of self-as-subject. They describe the operational criteria as follows: “the specificity of the self (e.g. hearing one’s own name, seeing one’s own face) was tested and compared across familiar (using stimuli from personally known people) and other (non-self–non-familiar, i.e. strangers and widely-known figures) conditions” (2011, p. 1211). The tasks in the “self condition” include “trait adjective judgment, retrieval of personality traits, face recognition, body recognition, personal thinking, name perception, autobiographical memory, own feeling, self-administered pain, person perspective tasks and agency tasks” (2011, p. 1224). All these tasks are about participants making judgments about whether a certain property may be suitably attributed to themselves. From the first-person point of view, the participants are judging whether the contents of the stimuli accurately characterize themselves. But again, whether “I” am the one who is experiencing the stimuli and making the judgments is really not in question, and hence not reflected in the data. Once again, the sense of self-as-subject is not measured by Qin and Northoff’s most recent study.

I conclude that Damasio, Panksepp, and Northoff have all failed to explain the mechanisms of the sense of self-as-subject. A theoretical gap exists between neural synchrony and the SCMS, on the one hand, and the sense of self-as-subject, on the other. But it is important to see exactly where the shortcoming is. It is not that neural synchrony and the SCMS are completely irrelevant to the sense of self-as-subject. Rather, the failure is that why and how they are relevant have not really been explained. This is because the neuroscientists have not clarified and captured the sense of self-as-subject well enough, such that they over-interpret data and make unjustified claims about this target phenomenon. In this regard, my proposals in sections 2 and 3 have provided the required clarification.

6 Conclusion

I have suggested that the sense of self-as-subject can be explicated by examining the sense of experiential ownership, which is distinct from the

sense of body ownership. Having a conscious experience secures only the fact of experiential ownership, not the sense of experiential ownership. This provides a reinterpretation of the distinction between the sense of self-as-object and the sense of self-as-subject. I elucidated the sense of self-as-object by looking at the sense of body ownership, and the sense of self-as-subject by examining the sense of experiential ownership. It became clear that both can misrepresent. The possibility of misrepresentation makes the sense of self-as-subject open to empirical as well as philosophical investigations. It is important to investigate how misrepresentation of the sense of experiential ownership is generated. This requires us to identify the right research question—which, I suggest, is precisely the Wittgenstein Question. When examining pathological cases or conducting experiments, researchers should ask their subjects questions like: “Are you sure it is you who is feeling your niece’s sensations?” or “Are you sure it is you who is shaking your own hand?” Then psychophysical and fMRI experiments can be developed to study the subjects’ responses. As such, to move forward, the first step is to look for and then to study the various conditions about which one can pursue the Wittgenstein Question.

Are there Counterexamples to the Immunity Principle? Some Restrictions and Clarifications

A Commentary on Caleb Liang

Oliver Haug & Marius F. Jung

Our commentary focuses on the sense of experiential ownership and its implications for the Immunity Principle. In general we think that Liang elaborates the self-as-object and the self-as-subject in an interesting and refreshing way. Nevertheless, there are some problems that we want to address. (1) First, we argue that the sense of experiential ownership cannot misrepresent the fact of experiential ownership. (2) Second, we argue that neither the sense of experiential ownership in particular nor phenomenal states in general are eligible for identity judgments. (3) Then we claim that the two alleged counterexamples actually do not provide any valid argument against IEM. (4) We close by evaluating whether it makes sense to talk about the Immunity Principle as a non-trivial property, or whether the relevant properties are just mispredication or misguided reference.

1 Introduction: Preliminaries and conceptual clarification

Liang investigates some interesting issues concerning self-consciousness and its relation to conscious phenomenology and bodily self-con-

sciousness. His argumentation, which has the aim of being interdisciplinary fruitful, is closely tied to some conceptual distinctions that are

also very important for our commentary. First, he refines the initial point of the Wittgensteinian distinction between self-as-object and self-as-subject (Wittgenstein 1958). An important distinction concerning the former is the sense of body ownership and the sense of self as physical body, which describes the self-as-object in a more fine-grained manner. The self as subject is also sub-classified in terms of the fact of experiential ownership and the sense of experiential ownership. The sense of experiential ownership describes mental states that refine proprietarily aspects of *who* is having the experience in question. Liang claims that the sense of experiential ownership is not privileged in the sense that it gives rise to the well-known property *immunity to error through misidentification* (IEM). In the second part of his investigation he is concerned with theoretical and empirical investigations made by Damasio, Panksepp and Northoff, which do not provide substantial evidence in their measurements for the sense of self as experiential subject. They rather concern the self-as-object and therefore disregard substantial aspects of self-consciousness. Our commentary will focus on the sense of experiential ownership with regard to IEM. According to Liang, there are several counterexamples to IEM, mainly to be found in misrepresentations (like in the body-swap illusion) due to a sense of experiential ownership. In this commentary, we ask ourselves the following questions: is the sense of experiential ownership a plausible candidate for exemplifying the property of IEM, and could there be serious counterexamples to that principle? We defend the following four theses:

- (1) The sense of experiential ownership cannot misrepresent the fact of experiential ownership (cf. section 3).
- (2) Phenomenal states like the sense of self as experiential subject are ineligible to serve as *bearers* of IEM as a property (cf. section 3).
- (3) Liang's counterexamples do not provide real counterexamples to IEM, be-

cause they do not aim at the target phenomenon (cf. section 4).

- (4) IEM is either a very trivial property of judgments or beliefs or could be explained in terms of immunity to misguided reference (cf. section 5).

In order to defend these four theses we introduce two conceptual distinctions by which we hope to describe the target phenomenon in greater detail. Some philosophers, such as Evans (1982) and Shoemaker (1968) consider IEM to be a property of *judgments*, whereas others, such as Coliva (2002) and Bermúdez (1998), talk about some phenomenal aspects. Let us summarise these two accounts of IEM as follows:

First-person pronoun immunity (IEM-FP): A speaker who uses the singular indexical expression “I” knows a thing to be φ and conducts a predication “a is φ ”. This judgment is based on the rule of *identification-freedom*, so that it is clear that “I am φ ” is a judgment that does not depend on any further identification component.¹

Phenomenological immunity (IEM-P): Immunity to error through misidentification is a property of phenomenal states that characterises the constituents of first-person judgments. These identification-free constituents manifest themselves in phenomenological experiences about oneself.²

1 In other words, a judgment is identification-free if to judge that “a is φ ” *eo ipso* is to judge that “I am φ ”. Shoemaker's argument for identification-freedom (subject-use) can be summarized as follows. (1) The utterance “a is φ ” gives rise to an error through misidentification, if a speaker knows a thing to be φ and mistakenly thinks that ‘a’ refers to φ (cf. Shoemaker 1968). (2) Not every subject-use, which can give rise to knowledge about oneself, depends on identification, because this would lead to an infinite regress (cf. *ibid.*). (3) Since there is no identification of an object with a thinker in subjective first-person judgments, they are clearly incorrigible (relative to the first-person pronoun (e.g., some proprioceptive judgments or “I feel pain”; Shoemaker 1968). (4) Since the use-as-subject does not depend on identification, an error through misidentification is impossible.

2 This is a highly controversial metaphysical generalization of IEM, because it assumes that *there are* phenomenal constituents of IEM that serve for IEM as a property of judgments. Lane (2012), for instance, denies that there are any unique constituents that could explain *mineness* or mental ownership. Nonetheless, we suspect that the authors who defend theories of phenomenological immunity, like Liang, have to accept this generalization in one or another way. François Recanati (2012) seems to defend a similar position. A sub-

There is a strong inclination that the above philosophers who describe IEM as a property of judgments claim IEM to be something like a conceptual truth. But this would be overhasty, because of the fact that it is not yet clearly elaborated what a judgment with regard to the property in question actually is. We turn to this problem later. Liang seems to be a proponent of IEM-P, which holds that IEM is a property of phenomenal states:

My target is a form of mental immunity that I call experiential immunity. Experiential immunity concerns phenomenal experiences. It is a form of relative immunity—that is, it is relative to first-personal access to phenomenal states, such as introspection, somatosensation, proprioception, etc. (Liang [this collection](#), p. 8)

What distinguishes Liang’s account from others is that he emphasises that IEM does not hold necessarily. In an older paper he and Lane state that the philosophical orthodoxy of IEM has never been empirically challenged. That is because the majority of philosophers hold IEM as a conceptual truth, which has nothing to do with the empirically-tractable structure of reality (cf. [Lane & Liang 2011](#)). Our commentary is structured as follows. First, we summarize Liang’s most interesting claims and distinctions (cf. section 2). In section 3 we claim that it is impossible that the sense of experiential ownership can misrepresent the fact of experiential ownership, and that phenomenal states are not eligible bearers of IEM as a property. In section 4 our main claim is that Liang’s interpretation

subject experiences a state, for instance, through a proprioceptive mode, whereas the subject is not explicitly represented. He calls this *implicit de se* immunity to error through misidentification (IEM). This mode of experience is immune to error through misidentification because it is identification-free. Then the subject reflects upon this mode of experience, which means that she represents explicitly *who* the subject is. This is the *explicit de se*. The explicit involvement of a subject is constituted by the implicit involvement of the subject, which is identification-free. Since the former, the constituent, is IEM, it is also the latter. Recanati’s argumentation was the inspiration for summarizing proponents of phenomenal (or perceptual) immunity, as we did with IEM-P. The question arises whether some systems without any instantiated phenomenal properties could have beliefs that have the property of IEM. Since we are skeptical about IEM-P as a constituent of IEM-FP, as will be argued, nothing excludes this possibility according to our account.

of some empirical studies does not provide counterexamples to IEM. Section 5 develops the consequences of this claim and concludes with some aspects concerning the way in which we could talk about IEM in a more deflationary and less mysterious manner, such as in terms of immunity to misguided reference (IMR) or mispredication. In section 6 we conclude with some proposals for future research.

2 The sense of body ownership vs. the sense of experiential ownership

Before we discuss the self-as-subject in a more detailed manner, we focus on Liang’s conceptual refinements of the self-as-object. Liang proposes three important distinctions that are very helpful for the debate on bodily self-consciousness. The first marks out the fact of body ownership and the sense of body ownership. The fact of body ownership has nothing to do with phenomenal experiences of one’s own body. It just describes “[...] a biological fact about the anatomical structures of one’s body” (Liang [this collection](#), p. 2). In contrast, the sense of body ownership describes the experiences of the factual aspect of body ownership. Hence, to experience something as belonging to one’s own body is to experience a biological fact. Then Liang distinguishes between *the first-personal sense* and *the third-personal sense of body ownership*. We think that this is a very explanatorily fruitful distinction. The first-personal sense of body ownership describes some pre-reflective states such as walking or proprioceptive states. But these states could be third-personal or reflective as well if there are experienced from the outside, for instance through mirror recognition of one’s own body parts.

The last distinction concerning the self-as-object is between *the sense of body ownership* and *the sense of self as physical body*. The sense of body ownership is the experience of various body parts belonging to one’s own body, while the sense of self as a physical body concerns more ontological questions of the self. Here Liang introduces the sense of self as physical body as the sense of being a person of flesh and blood.

Let us concentrate on the distinction between *the first-personal sense* and the *third-personal sense of body ownership*. For us it is a rich conceptual tool that can help us refine the classic Wittgensteinian distinction between self-as-object and self-as-subject. We suggest that the notions of the first-personal sense of body ownership and the sense of experiential ownership are often used interchangeably. There are closely related but of course distinct from each other. Imagine a person who recognises that her legs are crossed through the first-personal sense of body ownership. She experiences her legs to be her own crossed legs. But here the Wittgenstein question makes perfect sense. Is it really she who is experiencing that very state? This open question marks out the sense of experiential ownership. We share Liang's criticism that the lack of a distinction between a sense of bodily ownership and a sense of experiential ownership could result in overinterpretation of some empirical data. If this distinction makes sense—as we think it does—then Liang's claim that Damasio, Panksepp, and Northoff's conceptions of the core self do not target the sense of self as experiential ownership sufficiently is plausible. The claims fit rather with *the first-personal sense of body ownership*.

In order to target the sense of experiential ownership, the Wittgenstein question could be asked to the participants of some experiments. Then we could, according to Liang, measure and elaborate on not only *what* is experienced but also on *who* is experiencing. Liang convinces us that there is more to explain than just senses of body ownership. If the sense of experiential ownership marks out a specific phenomenal target property, then much has to be done in philosophical and interdisciplinary empirical research. If Liang is right—which we think he is—and the target phenomenon of the sense of experiential ownership is empirically tractable, some further research would be very interesting and illuminating.

3 IEM-P—A conceptual matter?

In order to discuss this appropriately we first have to recall some of Liang's conceptual refine-

ments. One important distinction we want to discuss is the distinction between the fact of experiential ownership and the sense of experiential ownership, which mark out the factual and the subjective aspect of experiential ownership. The third-personal sense of experiential ownership describes the factual aspect, which can be observed from the outside via fMRI. Liang calls it a biological fact that, when a subject undergoes an experience, there is an objective fact of experiential ownership that is constitutive of the sense of experiential ownership. The first-personal sense is a phenomenal property of mental states, which means that it does not require further informational states to ensure that the one *who* is experiencing it *from the inside* sense herself experiencing it, which would be the “for-me” aspect. This is the property which concerns the aspect in which we and Liang are interested in: the self-as-subject. In order to evaluate the arguments of IEM, Liang uses the conceptual refinement offered by Pryor (1999), namely the *de re* and *which-object misidentification*. The former has been challenged through cases of somatoparaphrenia, the latter by the so-called body-swap illusion, both of which provide cases of misrepresentation. What happens in cases of misrepresentation? For Liang the sense of experiential ownership misrepresents the fact of experiential ownership. We argue that there are some aspects of the fact of experiential ownership and the sense of experiential ownership that are not that clear. Our thesis is that the fact of experiential ownership has nothing to do with IEM-P in the first place, but is rather what some philosophers describe as the conceptual truth of a subject having an experience. If you are describing the specific phenomenological richness of an instantiated experience, it is obviously true that it is an experience of a subject.³ Since subjects are the bearers of experiences (as opposed to objects) it is quite obvious that there is a *fact* that somebody

³ It is important to mention that a subject can experience a state “from the inside”, which she does not experience as her own. Experienced “from the inside”, it could belong to someone else or to nobody (Lane 2012). But this fact, which we take to be an analytic truth, is something ascribed “from the outside”. To say that somebody has an experience, is just to say that the experience is instantiated in a subject, regardless of which experience the subject undergoes exactly.

has this experience. This can be illustrated in Liang's own words: "[w]hen a subject experiences a phenomenal state, there exists a fact that he is the subject of that state" (Liang [this collection](#), p. 6). But this is just analytically true, since experiences are not free-floating occurrences—because they, as a matter of principle, have a subject of experience. This is about using the words "somebody's experience" correctly and is rather a description from the outside. It tells us nothing substantial about IEM-P. Perry (1998, pp. 96–97) talks about a similar phenomenon while recapitulating Locke's idea of personal identity. He claims that "[a]n instance of being aware of an experience, and the experience of which one is aware is known, necessarily belong to the same person [...]". To say something substantial it would be important for the content of the phenomenal experience of a specific state to *concern* the subject itself. But the content, experienced "from the inside", is of course different from an analytical truth, because phenomenal states have nothing to do with the right usage of words. The content of the phenomenal experience is what Liang calls the sense of experiential ownership, experienced *from the inside*. Granted that these two conceptualizations are correct, it is impossible that a phenomenal state like the experiential ownership represented from the inside can misrepresent something that is rather a conceptual ascription or description from the outside. They are completely different categories. To understand this we can think of a patient suffering from dissociative identity disorder (DID), who has many different personalities. What would be the fact of experiential ownership here? To answer this question a very specific and rigorous conception of personal identity is needed, which cannot be discussed here.

Let us summarise the argument:

Sense of experiential ownership cannot misrepresent fact of experiential ownership

(1) The fact of experiential ownership is to describe (as we see it), as a matter of logical necessity, that an experience is instantiated in a subject, that is (according to Liang), if a sub-

ject undergoes an experience in the actual world, a matter of fact.

(2) The sense of experiential ownership concerns the content of a phenomenal experience, which can either be experienced as owned by a subject or by nobody.

(3) Phenomenal experiences do not represent facts or states of affairs and even less analytic truths.

(4) The sense of experiential ownership cannot represent the fact of experiential ownership.

(5) A representation necessarily goes together with the possibility of a misrepresentation.

(C) The sense of experiential ownership cannot *misrepresent* the fact of experiential ownership.

Does it generally make sense to talk about IEM-P as a property of phenomenal states? The remaining story about IEM-P could be that it serves as the basis for judgments that usher in beliefs (see section 4). The immunity would then hold just through the structure of experience itself. But does it?

We claim that there no error through misidentification is possible, because of the lack of judgments and cognitive elaboration at the phenomenal level. An identity judgment requires identifying two conceptually-represented ingredients. Phenomenal states can be accompanied by conceptual ingredients, but they are not basic properties of phenomenal states themselves.⁴ Thus, they are distinct from one another. Hence we could say that phenomenal states are neither *eligible* for such a kind of error in general nor for a *de re* or which-object misidentification in particular. The intelligibility of IEM-P is very doubtful. Let us again summarise the argument:

Ineligibility of IEM-P

(1) To talk about identification is to talk about judgments and inferences that can be identified with one another, which means that they are *judged* to be identical.

⁴ Proponents of *Cognitive Phenomenology* would probably deny this claim. We stick with Carruthers & Veillet (2011), who says that cognitive thoughts could causally initiate some phenomenal experiences. The stronger claim, that thoughts constitute phenomenal experiences, lacks substantial argument. Hence we stick to the position that phenomenal states and thought contents could occur in isolation from each other.

(2) To talk about misidentification is to talk about some defective judgments.

(3) Phenomenal states have nothing to do with judgments and inferences in the first place.

(C) Phenomenal states lack the basic properties to be defective.

The ineligibility of phenomenal states of course satisfies the rule of identification-freedom. But since phenomenal states are always identification-free, the claim that they are immune to error through misidentification is misleading. Why is that? Remember that the content of phenomenal experience could occur without being owned by somebody (Lane 2012). Nevertheless, an experience is instantiated in a subject, which is just a matter of principle or the factual aspect. If the content of a phenomenal experience just occurs, without an experience of *mineness*, then the rule of identification-freedom tells us nothing substantial, because of the lack of any committed judgment. An interesting question, of course, is whether there are any judgments that are identification-free.

We would recommend talking about IEM as a property of judgments or beliefs (IEM-FP) instead of talking about phenomenal states. Nevertheless, there are also some problems with IEM-FP that we will present and discuss in section 4. Let us now have a closer look at the two alleged counterexamples that Liang proposes.

4 Two counterexamples to IEM-FP?

IEM is generally considered to be a property of judgments concerning the first-person perspective and respectively involving the first-person pronoun. A major problem in the current discussion about IEM is that no solid account of what judgments are is given. In contrast to philosophers that are concerned with beliefs, who usually give a brief declaration of what they take beliefs to be (e.g., relations, sentence operations etc.), philosophers involved in the IEM discussion seem to take judgments to be already widely understood. Since the initial paper written by Shoemaker (1968) focuses on the identification-freedom of judgments, we think that what philosophers

usually talk about using the term “judgment” is inference or reasoning.⁵

So we take judgments to consist of propositional reasoning. Let us have a look at some examples:

Judgment A:

- (1) John is a fish. (Fa)
- (2) Fish can swim. $(\forall x)(Fx \rightarrow Gx)$
- (C) John can swim. (Ga)

Judgment B:

- (1) John is a fish. (Fa)
- (2) John is Jim’s best friend. (a=b)
- (C) Jim’s best friend is a fish. (Fb)

Though usually the conclusion of these inferences is what is referred to using the term “judgment”, we do not think that philosophers generally tend to take judgments as being adequately analysed as propositional attitudes (as relations between persons and propositions like

⁵ The reason for this is the following: if you talk about “identification-components”, there must be something that is composed of at least one identification-component, and probably of something else as well. The identification component (as described by current philosophers— $a=b$) is either a sentence or a proposition, either expressing an identification or representing it. (This distinction is just made to satisfy Platonists and nominalists.) What is it that is composed of identification- and other components? We think, according to the usual use of language of philosophers debating IEM (She sees a bleeding hand in the mirror and thus judges “I am bleeding”), that the most probable answer is that they are part of an inference. Whenever you say that one “judges” p , you want to express not only that she believes p , but also that she has come to this belief through inference. We take this to be an adequate interpretation of the term “judgment” as used in Shoemaker, Pryor, Barz, and probably Liang as well. It is probably inadequate for every instance of “judgment” in philosophy, because our interpretation suggests that there are (hidden or opaque) processes that are important for calling something a judgment. Even though proponents of accounts that are Rylean (Ryle 2009), for example, would strongly disagree (because they wouldn’t accept that there are hidden processes that we want to talk about using the term “judgment”), we think that there is in fact an ontological or categorical difference between judgment and beliefs: either judgments *are* processes and beliefs *are* states, or judgments are a subclass of beliefs, but a subclass of beliefs that one has come to through a process of inference (which is not necessarily the case with beliefs—just imagine someone manipulating your brain such that you gain new beliefs). So, unlike Ryle, we would say that as long as we are talking about human beings, judgments are certainly something that happen in the hidden depths of the human brain. And we can represent them—for our purposes—as structured like logical inferences. Please note that this is just an additional remark concerning our positive account of judgments that a lot of papers seem to lack. Our central argumentation does not rely on this specific ontological reading of “judgment” and “belief”.

“Jim believes that it is raining”). We take the whole inference to be what is referred to with the term “judgment”, and the conclusion to be what is referred to using the term “belief”.⁶ Judgments A and B are analogous in the following sense: they are both judgments involving two premises and their logically necessary conclusions. But they differ in a particular aspect that is of the highest importance concerning IEM: only judgment B involves an identification, whereas judgment A is identification-free. So the first thing we can say is that IEM following from identification-freedom is not an exclusive property of judgments involving the first-person pronoun—there are numerous judgments that do not contain any identification-components. This is our first reason for thinking that IEM may hold, but is not a remarkable or significant property exclusively reserved for judgments involving the first-person pronoun.

What Shoemaker wants to make clear is that there are certain judgments that cannot take the logical form of judgment B and that these judgments involve the first-person pronoun, in the sense of Wittgenstein’s “subject-use”. Let us take a look at what Shoemaker means by giving examples for the object-use and the subject-use:

Object-use:

- (1) The person in the mirror is looking tired. (Fa)
- (2) I am the person in the mirror. (a=b)

- (C) I am looking tired. (Fb)

As you can see, there are judgments involving the first-person pronoun that also involve an identification-component—at least that is what Shoemaker (1968) thinks. But when he claims that there are judgments that are immune to error through misidentification, he does not claim that they are immune to *any* error, and nor does he claim that the identity relation holds with metaphysical necessity—he just

claims that whenever one judges and this judgment involves certain kind of predicates (or properties) it is automatically identification-free. One of those predicates (or properties) is being in pain. Let’s have a look at how the judgment would work with this special predicate that we may call P*.

Subject-use:

- (1) There is something that is in pain. ($\exists x$) (P*x)
- (2) P* is always a property of the person recognizing it. (P*gen)

- (C) I am in pain (P*a)

In fact this formal representation of such a judgment is even weaker than what Shoemaker may have had in mind, thus the strong reading of his idea of judgments that are IEM because of their identification freedom would be:

- (1) There is something that is in pain. ($\exists x$) (P*x)

- (C) I am in pain. (P*a)

This reading gets closer to Shoemaker’s idea, because he would not agree that judgments explicitly involve a generalization such as (2). We undertook this brief exercise first of all to put pressure on the following point: although philosophers of different generations have been talking about IEM for decades, they usually fail to give an *explicit account* of what judgments are and how they work.⁷ This exercise was meant to fill this theoretical gap for the purpose of the current discussion. So whenever someone utters “John is a fisherman”, we take this sentence to express a propositional attitude—a belief. But when we believe that he *judges* “John is a fisherman”, we also take that person to have made an inference, simply because that is what we want to say when we ascribe a judgment to him. Shoemaker’s claim that judgments like “I am in pain” are immune to error through misidentification does not mean that there are hidden structures, neither of the sentence ex-

⁶ Note that we in fact think that beliefs are brain states and judgments (if they are inferences) are cognitive processes—but they do not need to be brain states and cognitive processes. Depending on which understanding of propositions you prefer (e.g., the meaning of sentences or informational packs), any machine that is capable of some kind of reasoning can judge and have beliefs.

⁷ This means that there are no papers about IEM that give a positive account of judgments, e.g., Shoemaker (1968), Evans (1982), Barz (2010).

pressing the judgment nor of the propositional attitude expressed by the sentence “I am in pain”; it means that no identification-component was involved in the inference that has been made.

The second reason for undertaking this exercise is that we want to have a look at whether Liang’s counterexamples (especially the somatoparaphrenia example) are real counterexamples. We do not think that the two examples Liang gives are in any way counterexamples to IEM—though they are philosophically very interesting, especially concerning theories of self-consciousness. Liang claims that the two counterexamples falsify the Immunity Principle, but we claim that they do not meet the conditions that have to be met to falsify this theory. So we must first see what Liang takes to falsify the IEM theory and then settle on a criterion for how the IEM theory could be falsified.

Liang thinks that the following would suffice for IEM to hold:

- (1) for every phenomenal state there must be a subject who experiences it; (2) every phenomenal state is in principle available to first-personal access (Shoemaker 1996); (3) every phenomenal state is experienced by the one who has first-personal access to that state. The crucial point is that (1)–(3) do not imply that (4) every phenomenal state is, from the first-person point of view, represented as experienced by the one who has first-personal access to that state. (Liang this collection, p. 8)

Liang also considers his two counterexamples (the somatoparaphrenia patient and the body-swap illusion) to be counterexamples to (4), so the IEM-principle does not hold. In fact we agree with Liang that at least one of these examples is a counterexample to (4) but we do not agree that (4) is necessary for IEM to hold. So let us first have a look at how a falsification of the IEM-theory would have to look. The IEM-theory comes in the form of a material conditional: *if* a person judges “I am φ ”, *then* she cannot be wrong because of a misidentification. The truth conditions for a material condi-

tional are clear: the conditional is wrong if and only if the antecedent is true and the consequent is wrong. This brings us to the definition of a theoretical falsification of IEM:

Falsification of IEM =_{Df} : **1.** The IEM-theory would be falsified if and only if a person judges “I am φ ” and is wrong in her judgment because of a misidentification. Or, more precisely: **2.** The IEM-theory would be falsified if and only if there is an example of a person that believes “I am φ ” and comes to this belief through inference (the judgment) that involves an identification component and this identification is wrong.

Thus, speaking more formally, a judgment of the following two forms must be present (cf. Pryor 1999):

wh-judgment⁸

- (1) $(\exists x)(Fx)$ (predication to a variable)
 - (2) I am x (identification, $x=a$)
-
- (C) I am F (predication to a constant, depending on the identification), (Fa)

or

de re judgment⁹

- (1) A particular thing (*de re*) is F (Fa)
 - (2) I am that particular thing ($a=b$)
-
- (C) I am F (Fb)

We pick these two different structures to emphasise that Shoemaker did not exclusively talk about *de re* “attitudes” but also about “existential quantification”, though he did not do so explicitly. Note that besides the presence of belief states such as (c) it is necessary for the falsification of IEM-theory that this conclusion is only wrong because (2) is wrong.

⁸ A *wh*-judgment involving an identification starts with existential quantification over a variable. You know that there is *something* that has a particular property and then you identify that something with, e.g., yourself.

⁹ A *de re* judgment involving an identification starts with a predication to a particular thing—a constant. So you know a *particular* thing to have a particular property and then you find that thing to be identical with, e.g., yourself.

The crucial question concerning Liang's counterexamples is: do they meet this condition? Consider the first example. It is—as Liang sees it according to Pryor—an example of a *de re* misidentification. *De re* misidentifications occur, for example, when there are two objects equally eligible for exemplifying the property in question. To show that Liang's first example is a counterexample to IEM one would have to prove, first, that the structure of a *de re* judgment as stated above holds, and second that the judgment is only wrong because the second premise is not true. Recall the first experiment: a patient suffering from somatoparaphrenia, FB, is touched on her hand and asked whether she feels her hand being touched. She answers “No”. When she is asked whether she feels her niece's hand being touched, she gives a positive answer (FB believes that her hand is in fact her niece's hand, and has been placed on her body). But since she does not judge “I am being touched on my hand”, the necessary conditions for falsifying the IEM-theory are not met. The material conditional could only be proved wrong if the antecedent (a person judging that she has a certain property) is true, but in this case it is not true. The conditions would have been met if she had answered “I feel being touched on my hand”, even though she was not, and even though the only reason why she was wrong was because she misidentified her own sensations with someone else's. But she does not commit the error of judging “I am being touched” in the first place, so the IEM-theory is not falsified. It is crucial here to understand that falsification of IEM does not depend on what exactly she said, but whether she judged that she had a certain property. Unfortunately wrongly judging that one is not touched, though one is touched, does not get close to a falsification of IEM, by definition of the truth conditions of material conditionals.

Now let us have a look at Liang's second counterexample: the body-swap illusion. This, according to Liang and Pryor, is an example of a *wh*-misidentification that happens when someone simply knows a property to be there (e.g., a smell) and falsely ascribes this property to a particular object. In this setup, the participants

judge that they are shaking hands with themselves. This example gets much closer to the claim of IEM, because they in fact judge, and judge falsely, that they experience something, and there *is* another person who really seems to have that experience. So it seems that one of the following inferences is made:

- | |
|--|
| (1) A particular person is shaking hands with myself. (Fa) |
| (2) I am that person. (a=b) |
| (C) I am shaking hands with myself. (Fb) |

or

- | |
|---|
| (1) There is something that is shaking hands with myself. ($\exists x$)(Fx) |
| (2) I am that something. (x=a) |
| (C) I am shaking hands with myself. (Fa) |

If these judgments occurred it is obvious that they are false because the second premise is false—thus an error through misidentification was made. But did the participants really commit such an error? Recall that the IEM thesis would be falsified if a person believed a certain proposition but was mistaken because and only because she misidentified herself with someone else. Did the participants really believe that they were shaking hands with themselves? We assume that they most certainly did not. Of course they remarked that they were shaking hands with themselves, but we take them to speak merely metaphorically and not literally. If one wanted to be sure, the same experiment would have to be made, asking the participants whether they believed that they were shaking hand with themselves (not if it felt as if they were). Even if they believed that they were shaking hands with themselves, the judgment would probably not have the form stated above, because they did not have the experience of the other participant—only if they had an experience that that very (exactly the same) experience depended upon another person, and only if they accidentally identified themselves with that person—only in that case would the IEM-theory be falsified. But the participants did not have the experience of the other person wearing the

camera. They were having their very own experience—caused by the informational flow starting with the display (monitoring not the perspective of the person wearing the camera, but the camera’s perspective) and their own lenses, their own retina, and so on. The experience they ascribed to themselves was not the experience of another person or agent, it was their own experience. They were only wrong in judging that they were shaking hands with themselves because they in fact did not shake hands with themselves. This is not a misidentification but simply a mispredication. This problem will be elaborated in section 5.

So why does Liang think that these examples are counterexamples to IEM? Because he takes (4) to be crucial for IEM to hold. The differences between what Shoemaker and Evans take to be the theory of IEM and what Liang takes it to be are the following:

Shoemaker/Evans: If a person believes that she has certain properties, she cannot be mistaken in having them by misidentifying herself (or her phenomenal states) with someone else or someone else’s states. In this conditional, the antecedent implies a person to believe something about herself or, speaking in Liang’s terms, a person to represent herself as having a so-and-so experience. But Liang’s conditional looks quite different:

Liang: “(4) every phenomenal state is, from the first-person point of view, *represented as* experienced by the one who has first-personal access to that state.” (Liang [this collection](#), p. 8)

So what used to be the antecedent in the original theory becomes the consequent in Liang’s theory—thus Liang is right that (4) does not hold and that the somatoparaphrenia patient and her reports are counterexamples to (4), but he is not right in taking this fact to falsify the IEM-theory.

5 Why does IEM-FP hold?

There seems to be an immunity relative to the first-person pronoun, which at least guarantees that you cannot have a belief like “I believe that I am in pain” and accidentally take

someone else to have that belief. It probably also guarantees that in this case you cannot be wrong about who is in pain. We think that there are a few good theoretical candidates for explaining this kind of immunity. These candidates are:

1. Irrelevance of misidentification
2. Immunity to misguided reference
3. Reference magnetism

Since reference magnetism¹⁰ is a highly controversial, metaphysical notion and it would take too much time to elaborate this view correctly (which would certainly include a refreshment of Lewis’ philosophy of reference), we will focus on the first two for the sake of this commentary.

1. Irrelevance of misidentification:

If you take judgments about yourself to be a) always starting with *de re* beliefs and b) single-predicative in form, it seems impossible to construe misidentification as being relevant to the truth-value of a sentence or proposition. This point has been made by Barz (2010). Barz takes the current discussion to assume that there are two fundamentally different kinds of errors that can occur: an error through misidentification and an error through mispredication. It should be clear what an error through mispredication is supposed to be: an error through mispredication occurs when a person’s judgment is wrong and is only wrong because the predicate she thinks applies to a particular object in fact does not apply to that object. Barz’ definition of an error through misidentification (in general) is the following:

General error through misidentification (EM-G): A person S (i) believes (*de re*) of a certain thing that it is *F*, (ii) believes that

¹⁰ A short explanation: reference magnetism is a theory that claims that there are metaphysically distinguished objects of reference in the world (no matter whether they are abstract or concrete) that function as magnets for certain expressions. This could, for example, hold for natural kinds and existential quantification. In the case of existential quantification, some philosophers, like Theodore Sider (2009), claim that there is no possibility of talking about *existence* without talking about the very same thing that everybody talks about—as long as there is no explicit or implicit quantifier restriction. Reference Magnetism plays an important role in the debate about quantifier variance and verbal debates.

thing to be identical with a , and (iii) thus judges that a is F . But (iv) a is not identical with the thing S believes to be F .

According to Barz this kind of error cannot happen at all, so the proponents of the IEM-theory are right—but in fact IEM is not an exclusive property of judgments concerning the first-person or involving the first-person pronoun, and is instead a property of any judgment. His argumentation can be summarised in one sentence: since there are examples of judgments involving misidentification that are nevertheless true, and since there cannot be judgments involving mispredication that are true, there are no errors through misidentification. A judgment is right or wrong solely depending on whether the predicate applies to the object.

Imagine the following situation that is usually used to distinguish between notional and referential use of singular terms: Peter is a detective, investigating the case of Smith's murder. Participating in the judicial proceedings, a man, accused of having murdered Smith, behaves so strangely that Peter, the detective, judges: Smith's murderer is a maniac. He is using the term "Smith's murderer" to refer to the person that is accused of having murdered Smith, and according to most theories of reference he does in fact refer to that person with that term. But what if that person is not the one who murdered Smith, but is nevertheless still a maniac? Thus a misidentification has occurred, but no error. On the other hand, if the person were Smith's murderer but not a maniac (maybe his weird behaviour was the result of pharmaceutical treatment)—Peter's judgment would be wrong.

The same goes for the traditional wrestler example. Imagine that wrestler A and wrestler B are in a close wrestling fight and wrestler A does not misidentify her arm with the arm of wrestler B but still, for some strange reason—maybe there are blood smears caused by a bleeding bird that flew over the two wrestlers—comes to judge "My arm is bleeding" (although wrestler B's arm is actually bleeding). She would be wrong, but her error would not be one of misidentification but of mispredication. Thus, as Barz believes, there are no errors through misidentification, because the

only thing that necessarily suffices for the falsity of a judgment is mispredication.

As one can guess, Barz' theory does not completely fit with our theory of judgments. While we take judgments to be processes of inference, thus involving several propositions, Barz seems to take judgments to be relations to single, structured propositions. We can agree with Barz if he can explain how the identification component in the judgment—which would, in our terms, be one of the premises used during the inference—is in fact a kind of predication.

2. Immunity to misguided reference:

Howell (2007) wants to distinguish between two kinds of immunity: immunity to error through misidentification and immunity to misguided reference:

IEM is often confused with what I call Immunity to Misguided Reference (IMR). A judgment that x is F has IMR if it is impossible for someone to make that judgment while being mistaken about the reference of x . All I-judgments have IMR, while not all I-judgments are IEM. (Howell 2007, p. 584)

To say that there is something like immunity to misguided reference (IMR) does not mean that one can never be wrong about the reference of any term one uses. It just means that whenever you want to refer to yourself using the term "I" you cannot fail to do so.

We think that a majority of the proponents of IEM are in fact proponents of IMR. And because IEM is thought to be an immunity relative to the first-person pronoun (what we have termed IEM-FP), it makes sense to say that this immunity is in fact an immunity of referring acts in general and not of judgments exclusively. Talking about IMR can be helpful in two ways: first, it can be helpful in stressing the fact that IEM is not a theory about the self or about subjectivity but simply a theory about linguistic rules and reference. Thus IEM-FP is a trivial property that can be explained by the semantic rules of usage of the word "I".

Second, it can be helpful for explaining our intuitions in complicated cases of self-refer-

ence and by determining the objects of beliefs. Think of the two wrestlers again. When one of the wrestlers states “I am bleeding” or “My arm is bleeding”, she is wrong, but it seems as if she is not necessarily wrong because of a misidentification. Let’s have a look:

- (1) Wrestler A correctly describes her belief, intending to refer to herself using the first-person pronoun.
- (2) One cannot fail to refer to oneself when using the first-person pronoun. (IMR-rule)
- (3) Wrestler A has a belief about herself (granted by accepting 1 and 2).

So far the argument is trivial—stating that Wrestler A has a belief about herself just means that she has *any* kind of belief. It does not show that Wrestler A has a *de re* belief about herself. This comes from the second part of the argument:

- (4) A *de re* belief is a belief that holds if the believer is in a non-conceptual, contextual relation to the object the belief is about.¹¹
- (5) One is always in a non-conceptual, contextual relation to oneself.¹²
- (C) Wrestler A has a *de re* belief about herself (granted by accepting 3, 4 and 5).

Opponents of the IEM-theory would have to state that wrestler A has no *de re* belief about herself, because the object her belief is really about is not herself, but wrestler B, misidentified with herself (thus creating a *de dicto* belief about herself and a *de re* belief about wrestler B). But by accepting IMR and certain accounts of *de re* attitudes we can see that wrestler A’s attitude is a possible candidate for a *de re* belief about herself. Thus the only reason why she would be wrong is—as we have seen above—mispredication.

6 Concluding remarks

The question with which we began was how the sense of experiential ownership is related to the well-known property of IEM, and whether, if it

is, the proposed counterexamples are cogent. First of all we argued that it is impossible to talk about the sense of experiential ownership misrepresenting the fact of experiential ownership, since the latter is a conceptual ascription from the outside that has nothing to do with phenomenal states that are experienced from the inside (cf. thesis 1). Second, IEM-P is an incoherent notion, because phenomenal states lack the basic properties that are possessed by judgments and inferences, namely to be defective—which suffices for a misidentification. Since they lack these properties, the claim that phenomenal states are immune to error through misidentification is misleading (cf. thesis 2). Third, we argued that the alleged counterexamples to IEM are just counterexamples of Liang’s fourth premise. But premise four is not necessary for IEM to hold. In any case, the counterexamples do not seriously challenge IEM, because the necessary conditions for a falsification are not met (cf. thesis 3). The last section addressed some aspects concerning how to talk about IEM convincingly in future philosophical research. Our suggestion is somehow deflationary, since it is not necessary, but very likely that the more interesting properties for talking about are mispredication and IMR (cf. thesis 4).

We are looking forward to the time when philosophical as well as empirical interdisciplinary research concerning the mind focuses on Liang’s commitments on self-consciousness, most interestingly the sense of experiential ownership. We think that this *explanandum* has not yet been enriched with empirical data. Here Liang perhaps provides a good starting point for future research. In order to provide fruitful data, we think that to ask the Wittgenstein question, as Liang proposes, is a promising idea. But nonetheless the question has to be subdivided in order to provide a fruitful questionnaire. Here are some proposals that are, of course, provisory, which could be more fine-grained, depending on the experiment:

On a scale from 1 to 10, how much do you feel the experience as being owned by you? Have you felt parts of your body as detached from yourself? If yes, how much were you able to control the belongingness of this body-experi-

¹¹ This is to accept a *de re/de dicto* distinction that is compatible with non-propositional attitudes.

¹² This does not mean that one is always only and exclusively in a non-conceptual relation to oneself. Of course one can have *de dicto* beliefs about oneself.

ence? Have you felt some experiences belonging to another subject, not being owned by yourself?

Here are some further theoretical questions: How is the sense of experiential ownership connected to beliefs? Could it serve to justify some beliefs? How is the sense of experiential ownership generally related to self-knowledge? We are looking forward to a fruitful discussion in philosophy of mind and in cognitive sciences with regard to the elaborated topics.

Acknowledgements

First of all, we are appreciative for the illuminating target paper. In addition to that, we would like to thank the two anonymous reviewers and Thomas Metzinger and Jennifer M. Windt for their editorial reviews. We are grateful to Thomas Metzinger and Jennifer M. Windt for the opportunity to contribute to this project. Furthermore, we want to thank Ralf Busse for the insightful suggestions with regard to some issues within IEM-accounts.

Can Experiential Ownership Violate the Immunity Principle?

A Reply to Oliver Haug & Marius F. Jung

Caleb Liang

In what follows, I respond to Haug and Jung's criticisms of my target paper and defend the following claims: (1) the sense of experiential ownership can misrepresent the fact of experiential ownership; (2) the sense of experiential ownership is eligible to serve as a bearer of IEM; (3) at least some versions of IEM face genuine counterexamples; and (4) as far as the sense of self-as-subject is concerned, IEM is not a trivial property. Finally, I describe a new set of experiments that induced what I call "the self-touching illusion." The data, I suggest, strengthen the view that both the sense of self-as-subject and IEM are open to empirical as well as philosophical investigation.

1 Introduction

Does the sense of self-as-subject conform to the immunity principle (IEM)? When I experience a phenomenal state, does it guarantee that based on first-personal access I cannot be wrong about whether it is me who experiences it? In "Self-as-Subject and Experiential Ownership", I elucidated the sense of self-as-subject in terms of the sense of experiential ownership, and argued that the sense of experiential ownership does not enjoy IEM. Haug and Jung raise very

substantial issues against my overall position.¹ Here, I respond to Haug and Jung's criticisms and intend to show how an interdisciplinary approach may enhance our understanding of the sense of self-as-subject.

Let me begin by suggesting that the following two issues regarding IEM are different:

¹ I am very thankful for Haug and Jung's criticisms, from which I have learnt a great deal. Below I will use "the sense of self-as-subject" and "the sense of experiential ownership" interchangeably.

(1) Does IEM correctly specify how we use the first-person pronoun “I”? (2) Does IEM really mark the line between the sense of self-as-object and the sense of self-as-subject? While (1) concerns a linguistic rule, (2) is about the nature of self-consciousness. The issue addressed in my paper was (2). I investigated the best way to understand the distinction between the sense of self-as-object and the sense of self-as-subject. I argued that IEM, or at least some versions of it, fails to draw the distinction between the two types of self-consciousness. I proposed an alternative account, according to which the distinction can be better articulated in terms of the sense of body ownership and the sense of experiential ownership.

2 Experiential ownership and the immunity principle

The first issue raised by Haug and Jung concerns whether the sense of experiential ownership could misrepresent the fact of experiential ownership at all. For ease of discussion, I will present my argument against IEM again, and then reply to Haug and Jung’s objection. Here is the argument:

- (1) For every phenomenal state there must be a subject who experiences it.
- (2) Every phenomenal state is in principle available to first-personal access.
- (3) Every phenomenal state is experienced by the one who has first-personal access to that state.

However, (1)~(3) do not imply:

- (4) Every phenomenal state is, from the first-person point of view, *represented as* experienced by the one who has first-personal access to that state (Liang [this collection](#), p. 8).

Three remarks are in order: first, when Haug and Jung characterize the fact of experiential ownership as a conceptual truth or a matter of logical necessity, what they say can be accommodated by (1) above. I agree with (1), but that is not my notion of the fact of experiential ownership. For me, the fact of experiential ownership is an *empirical* fact: it is not just that every phenomenal state has a subject; rather, it concerns exactly who is the subject of a specific

experience in a given situation. For example, right now, it is me, not you, who is experiencing back pains. So, the fact of experiential ownership is captured and fixed not by (1) but by (3) in my argument above; i.e., the question “who is the subject of that particular phenomenal state?” can be answered by ascertaining which particular subject has first-personal access to that state. Second, I would not characterize the sense of experiential ownership as concerning “the content of a phenomenal state” (Haug & Jung [this collection](#), p. 5). As I stated in the target paper (Liang [this collection](#), pp. 6–7), the representational content and the phenomenal character of a phenomenal state belong to the *what*-component of that state. The sense of experiential ownership is exclusively about the *who*-component, which is captured by (4) in my argument. Third, central to my argument is that (3) and (4) are not equivalent: as in FB’s case of somatoparaphrenia, feeling sensations is one thing, but whether she experiences herself *as* the subject of those sensations could be another. Misrepresentation may occur in one’s sense of self-as-subject when there is a mismatch between (3) and (4), i.e., when the sense of experiential ownership fails to pick out the same subject as the one settled by (3). As I suggested, the best way to describe FB’s case is that, while the fact of her experiential ownership is intact, her sense of experiential ownership fails to represent that fact. Given these remarks, the first four premises of Haug & Jung’s argument (on p. 5 of their commentary) seem to be problematic.

The second issue is about whether the sense of experiential ownership, as a phenomenal state, is eligible to serve as a bearer of IEM.² Haug and Jung insist that self-ascriptions relevant to IEM must be an explicit judgment (or belief) in an inference. However, it is not obvious that this restriction is mandatory. Given that my focus is on how to understand the sense of self-as-subject, I think that what is crucial for IEM is that the self-

² Note that, as I suggested in the target paper (Liang [this collection](#), p. 6), the fact of experiential ownership and the sense of experiential ownership are not numerically different states or events that can be detached from a phenomenal state. Rather, they are two ways of characterizing the *who*-component of that state.

ascriptions are justified on first-personal grounds, e.g., introspection, somatosensation, proprioception, etc. (cf. footnote 19 of the target paper). As the examiners of FB said: “The patient was blindfolded and instructed to say ‘yes’ when she felt a touch and ‘no’ when she did not feel any touch” (Bottini et al. 2002, p. 251). When FB said “yes” based on her sense of experiential ownership, there is no reason why this response shouldn’t count as a self-ascription. If we wish, we can reconstruct FB’s response in propositional form: I am mistaken in reporting “yes” during the test (ii) because, although I do know of someone that feels the sensations (via first-personal access), I am mistaken in thinking about who that person is. This seems to be a clear threat to IEM.

Also, it is worth pointing out that not all defenders of IEM think that self-ascriptions must explicitly be in propositional form. According to what may be called the Pre-reflective Account (Legrand 2006, 2007, 2010; Gallagher 2012; Zahavi 2005), at the pre-reflective level, the sense of self-as-subject is a constitutive component of the conscious state rather than an intentional object of consciousness. This phenomenological structure makes the sense of self-as-subject identification-free and hence enjoys IEM: when I am pre-reflectively conscious of myself-as-subject, I *cannot* be wrong about whether I am the subject of experiences. For the proponent of this account, making judgments about one’s sense of self-as-subject would count as *reflective* rather than pre-reflective self-consciousness, and hence ceases to be identification-free (Gallagher 2012, pp. 207–209). Given these considerations, I believe that the premises of Haug and Jung’s argument for the ineligibility of IEM-P are not as firm as they might think.³

The third issue is whether the specific case of somatoparaphrenia and the body swap illusion that I discussed are genuine counterexamples to IEM. The way that Haug and Jung oppose my counterexamples is related to our dispute above concerning whether IEM

has to be in the form of judgment. Haug and Jung define “judgment” as referring to a whole inference and “belief” as the conclusion of an inference. They then use their definitions to articulate a version of IEM and the necessary conditions for falsifying it. I concede that I don’t see why their account is obligatory for investigating the connection between IEM and the sense of self-as-subject. IEM has many varieties (cf. Liang this collection, pp. 7–8 and footnote 17). In my paper (Liang this collection, pp. 2 and 6), I did not claim that the two counterexamples would undermine all versions of IEM. It was “experiential immunity” in its *de re* and *which-object* forms that came under my attack. According to experiential immunity, when I am aware of a phenomenal state through first-personal access, I cannot be wrong about whether it is me who feels it. This variety of IEM focuses on phenomenal states rather than judgments, and a key feature is that it is *relative to first-personal access*, such as introspection, somatosensation, and proprioception. This feature accommodates a widely accepted view that whether a self-ascription enjoys IEM *depends on its grounds* (Pryor 1999; Coliva 2006). The feature, however, is omitted from Haug and Jung’s account, which indicates that their version of IEM is different from my target.

Haug and Jung argue that FB’s case is not a genuine counterexample because she did not judge “I am being touched on my hand”, and hence the necessary conditions for falsifying their version of IEM are not met. However, the perplexity of this case is not why FB felt nothing when she expected that she would be touched, but why she felt the sensations when she expected that her niece would be touched. So, when FB reported feeling the sensation in test (ii), a more appropriate reconstruction of FB’s self-ascription would be: “I am being touched on my niece’s hand.” She was wrong because in fact it was her own hand being touched by the researcher, not her niece’s hand. Then, my interpretation in the paper suggested that, using Haug & Jung’s formulation, “the only reason why she was wrong was because she misidentified her own

³ I discuss the Pre-reflective Account in “Body ownership and experiential ownership in the self-touching illusion” (Liang et al. 2015).

sensations with someone else's" ([this collection](#), p. 9). This provides a falsification of experiential immunity.

Regarding the case of the body swap illusion, Haug and Jung argue that this is simply a case of mispredication. Instead of adding in more conceptual analyses to compete for the best interpretation of the study by [Petkova & Ehrsson \(2008\)](#), I will briefly describe a set of new experiments that combine the RHI and the body swap illusion. They explicitly address the Wittgenstein Question and measure the sense of experiential ownership. Before doing so, let me reply to the last issue raised by Haug and Jung.

The last issue concerns whether IEM is merely a trivial property. Here, I will limit myself to one remark. Haug and Jung consider IEM as purely a linguistic rule regarding how to use the first-person pronoun. Although many philosophers share this view, the goal of my paper was not to attack a linguistic rule. The opponents that I have in mind are those who try to use IEM to distinguish between the sense of self-as-object and the sense of self-as-subject. For these philosophers, IEM is not trivial at all. It matters to them and it matters to me if it turns out that the sense of self-as-subject really is fundamentally different from the sense of self-as-object. Because if the answer is yes, it would be very significant to consider whether the necessary and sufficient conditions for these two types of self-consciousness are distinct, and whether they are generated by different (though partially overlapping) neural mechanisms.

3 The self-touching illusion

At the end of my target paper I suggested that the next step for the investigation of the sense of self-as-subject would be to study the various conditions where one can pursue the Wittgenstein Question. I recently designed a set of experiments that allow us make exactly this step. The subject wore a head-mounted display (HMD) connected to a stereo camera positioned on the experimenter's head. Sitting face to face, they used their right hand to

hold a paintbrush, and brushed each other's left hand (figure 1).⁴ Through the HMD, the subject adopted the experimenter's 1PP as if it was his/her own 1PP. In Experiment 1, the participant watched from the adopted 3PP (180°) the front side of his/her own virtual body, including not only the torso, legs, and face, but also his/her own right hand holding a paintbrush (figure 2). In Experiment 2, the participant watched from the adopted 3PP (180°) the front side of his/her own virtual body, including the torso and legs, but not the face. The participant also saw his/her own left hand being touched by a paintbrush held by the experimenter's hand (figure 3). Compared with the asynchronous condition, the synchronous full-body condition generated a "self-touching illusion": the subject felt "I was brushing my own hand!"⁵

Two "Wittgenstein Questions" in the questionnaires were designed specifically to measure the participants' sense of experiential ownership: "It was me who felt being brushed, not someone else" (WQ1), and "The one who felt being brushed was not me" (WQ2). Notice that these two statements are directly opposed to each other. In addition, they are not about the sense of body ownership, but about *who* felt the tactile sensations caused by brushing. In Experiments 1 and 2, the participants were touched by a paintbrush, so they were indeed the subjects of those tactile sensations. This fixed the *fact* of their experiential ownership. The task was to examine whether this fact was correctly represented by their *sense* of experiential ownership. Focusing on the syn-

4 The experiments and data presented here are part of a bigger project; cf. "Body ownership and experiential ownership in the self-touching illusion" ([Liang et al. 2015](#)). Four students conducted the experiments under my supervision: Si-Yan Chang, Wen-Yeo Chen, Hsu-Chia Huang, Yen-Tung Lee.

5 The self-touching illusion was measured by two questionnaire statements: "It felt as if I was brushing my own hand" (S1), and "The one whom I brushed was me, not someone else" (S2). A Likert scale from "strongly disagree" (-3) to "strongly agree" (+3) was used for the questionnaires. In both Experiment 1 (sync. n=38, async. n=35) and Experiment 2 (sync. n=28, async. n=14), the statistics showed significant differences between the synchronous and asynchronous conditions (Exp. 1, S1: $p < 0.0010$, S2: $p < 0.0010$; Exp. 2, S1: $p < 0.0010$, S2: $p = 0.0003$; one-tailed t-test). The measurements of skin conductance responses (Exp. 1, sync. n=15, async. n=15; Exp. 2, sync. n=13; async. n=13) showed the same differences (Exp. 1, $p = 0.0080$; Exp. 2, $p = 0.0473$; one-tailed t-test). This provided objective support for the questionnaire data.

chronous conditions, the average scores on WQ1 were 1.58 and 1.04 in Experiments 1 and 2 respectively, and the average scores on WQ2 were -1.03 and -0.50 in Experiments 1 and 2 respectively.

Figure 1: Experimental set-up.

Figure 2: Subjects' view via the HMD in Experiment 1.

Figure 3: Subjects' view via the HMD in Experiment 2.

Suppose that the participants understood WQ1 as addressing themselves. That is, from their subjective point of view: it was *me* who felt the brushing. Then, according to IEM, no participants would commit mistakes regarding their sense of experiential ownership. One would expect that most participants would answer “strongly agree” (+3) or at least “agree” (+2) on WQ1. But that is not the case. In fact, 13.2% of participants in the synchronous conditions of Experiments 1 and 2 disagreed with WQ1 (i.e., they answered either -1, -2, or -3), and the average scores of WQ1 reported above were much lower than this interpretation requires. I discuss other possible interpretations elsewhere and argue that neither of them can support IEM.⁶ Based on the data, it is more plausible that at least some participants in these experiments were uncertain and hence prone to error about whether they were the subjects of the tactile sensations that they actually felt. That is, the fact of having tactile sensations does not guarantee that the participants will necessarily have the *sense* that “I am the one who felt them.”⁷ Overall, the data provide empirical evidence for the possibility that one’s sense of experiential ownership can misrepresent the relevant fact of experiential ownership. Hence, IEM could potentially be falsified.

⁶ Cf. “Body ownership and experiential ownership in the self-touching illusion” (Liang et al. 2015). Briefly, (i) suppose for some reason that the participants understood WQ1 to be addressing someone else. That is, in their subjective experiences, it was *not me* who felt the brushing. Then, according to IEM, one would expect that most participants would answer “strongly disagree” (-3) or at least “disagree” (-2) on WQ1. But this is not the case either. This time, the average scores of WQ1 were too high to fit this interpretation. (ii) Suppose that the participants did not all understand WQ1 in the same way: some took it as addressing themselves, but others as addressing someone else. Then, assuming IEM holds, one would expect the participants to answer either +3 (or at least +2) or -3 (or at least -2). But, again, that is not the case. Many participants answered “slightly disagree” (-1), “not sure” (0), or “slightly agree” (+1). In fact, the standard deviation in each experiment is large (Exp. 1, SD=1.5001; Exp. 2, SD=1.5512), suggesting that the participants’ responses to WQ1 varied widely.

⁷ In addition to WQ1, we also presented WQ2 (“The one who felt being brushed was not me”) in the questionnaires. The direct contrast between WQ2 and WQ1 was so obvious that, even if the participants felt uncertain about WQ1, the contrast can still be easily recognized. So, if IEM holds, one could reasonably expect that participants’ responses would manifest a *strong* “negative correlation” between WQ1 and WQ2. For example, if a subject answers +3 to WQ1, then he/she would likely answer -3 (or at least -2) to WQ2, etc. However, we only observed a weak negative correlation between these two sets of results (coefficient $R=-0.3278$).

4 Conclusion

The defenders of IEM will try to find ways to interpret these data differently. It would not surprise me if what these data mean continues to be controversial. However, I hope that experiments like these and the discussions in the target paper will at least convince many researchers that sometimes it does make sense to ask Wittgenstein Questions (like WQ1 and WQ2 above). Both the sense of self-as-subject and IEM are open to empirical as well as philosophical investigation.

Mathematical Cognition

A Case of Enculturation

Richard Menary

Most thinking about cognition proceeds on the assumption that we are born with our primary cognitive faculties intact and they simply need to mature, or be fine-tuned by learning mechanisms. Alternatively, a growing number of thinkers are aligning themselves to the view that a process of enculturation transforms our basic biological faculties. What evidence is there for this process of enculturation? A long period of development, learning-driven plasticity, and a cultural environment suffused with practices, symbols, and complex social interactions all speak in its favour. In this paper I will sketch in outline the commitments of the enculturated approach and then look at the case of mathematical cognition as a central example of enculturation. I will then defend the account against several objections.

1 Introduction

Since cognitive science took an ecological turn it has been casting around for new frameworks in which to conduct its main business: experimental research. Those who have taken the ecological turn are convinced that classical and brain-bound frameworks don't provide the necessary conceptual and experimental tools required to make sense of cognition in the wild ([Hutchins 1995](#)). A number of alternative frameworks have been proposed, with embodied cognition the most frequently adopted. The theoretical framework one uses to understand cognition has profound empirical consequences for scientific practice. For example, it influences

what we consider to be the relevant phenomena of interest, what questions we ask about them, how we design and perform experiments, and how we interpret results ([Beer 2000](#)). The theoretical framework of classical computation, for example, approaches cognitive processing as a matter of input represented symbolically, which is then syntactically processed according to stored knowledge that the system has. It proposes a single "sandwich style" layer of cognitive processing, involving input, computation, and output ([Hurley 2010](#)).

The theoretical framework of CI (cognitive integration; [Menary 2007](#)) proposes something

altogether different: multiple cognitive layers where neural, bodily, and environmental processes all conspire to complete cognitive tasks. Although the framework is unified by a dynamical systems description of the evolution of processing in the hybrid and multi-layered system, it recognises the novel contributions of the distinct processing profiles of the brain, body, and environment. Furthermore, the CI framework explains our cognitive capabilities for abstract symbolic thought by giving an evolutionary and developmental case for the plasticity of the brain in redeploying older neural circuits to new, culturally specific functions—such as reading, writing, and mathematics (Menary 2014). I call this a process of enculturation.

This paper seeks to outline the phylogenetic and ontogenetic conditions for the process of enculturation. It will take mathematical cognition, particularly the evolutionary basis for mathematical cognition, as a core example of enculturation. In so doing, I hope to have given an account of why enculturation exists, how it happens, and in what ways it can be defended against objections. In the [first](#) section I will explore the relationship of CI to cognition embodied, embedded, enacted, extended (4E) cognition and then explain why social and cultural practices are important to the process of enculturation. In the [second](#) section I will outline the core concepts required to make sense of enculturation: continuity, transformation, novelty, and uniqueness. The [third](#) section will introduce the example of mathematical cognition, moving from the evolutionary basis for numerosity and numerical cognition to the precise operations of mathematics. The [fourth](#) section will give an account of mathematical cognition as a case of enculturation. In the [final](#) section I outline two possible objections and respond to them.

2 Where does CI sit in the 4E landscape?

Traversing the 4E landscape one rises from the lowlands of weakly embodied and embedded cognitive science to the giddy heights of strong embodiment and embedding. Embodied cognition is the thesis that at least some of our cognitive states and processes are constituted by

bodily processes that are not brain-bound. Embodied cognition is the thesis that our cognitive systems are located in and interact with the surrounding physical and social environment. Enactive and extended approaches to cognition inhabit the rarefied atmosphere of the strongly embodied and embedded peaks. However, there are important differences between enaction and extension and between those variants and CI. To determine where CI and enculturation sit in the 4E landscape, I will use a dimensional analysis I first introduced in [Menary \(2010\)](#).

Embodied mind

Embodied mind weak: the mind/brain is embodied (compatible with internalism/individualism [Smart 1959](#); [Stich 1983](#))

Embodied mind moderate: some of our mental and cognitive processes and states depend¹ upon our non-neural body ([Gallagher 2005](#); [Gallese 2008](#))

Embodied mind strong: some of our mental and cognitive processes and states are constituted by processes of the body acting in and on the environment (compatible with enactivism [Varela et al. 1991](#), and CI [Menary 2007](#))

Embedded mind

Embedded mind weak: All the perceptual inputs to and behavioural outputs from cognitive systems are found in the environment (compatible with internalism/individualism [Adams & Aizawa 2008](#); [Rupert 2009](#))

Embedded mind moderate: Mental and cognitive states and processes are scaffolded or causally depend upon the environment ([Sterelny 2003](#); [Wheeler 2005](#))

Embedded mind strong: Some mental and cognitive processes and states are integrated with environmental states and processes into a single system (compatible with extended mind [Clark 2008](#), [this collection](#); [Menary 2007](#); [Rowlands 2010](#))

¹ Here we might take dependence simply to be a causal, and not a constitutive, relation. Perhaps my gesturing in a particular way causes my recalling a word.

Weakly embodied mind is just the old thesis that the mind is identical to the brain. One can be an individualist and hold to this form of embodiment, and I won't consider the implications of the view here. The work of some² embodied cognition researchers will fall under the moderate sense of embodiment. For example, those who attempt to show that concepts or word-meanings are causally dependent upon sensorimotor areas of the brain (Glenberg 2010; Gallese 2008) commit to a moderate sense of embodiment. The strong sense of embodiment focuses on how cognition is constituted by bodily interaction with the environment, and I shall focus on the discussion here. CI and enactivism occupy this region of the environment, but with different emphases on the nature of the interaction and the evolutionary continuity of simple and complex cognitive systems. CI also occupies the strongly-embedded region, but I shall deal with the relation between CI and cognitive extension in the next sub-section.

Enactivism (excluding its radical variant)³ allows that even simple living systems are cognitive. Enactivists are committed to the continuity of life and mind and so they propose cognitive and even mental states and processes⁴ for much simpler biological systems than would CI (Varela et al. 1991).⁵ Whilst I am sympathetic with the commitment to continuity between simple cognitive systems and complex cognitive systems, it is questionable whether we should argue that simply being a living organism provides sufficient cognitive complexity for conscious experience and sense (or meaning) making.

CI does not require us to think that complex cognitive and mental phenomena, such as conscious experience, are shared by all living or-

ganisms whatever their complexity or simplicity. This is to assume that the properties of complex cognitive systems will be found even in very simple cognitive systems. According to CI, this gets things the wrong way round: there is a continuity from very simple systems that interact with their environments, by having mechanisms that track or detect salient features of their environments, to complex systems that have a wider range of cognitive capabilities (traits) including memory, inference, communication, problem solving, social cognition, and so on. By contrast a phylogeny of cognitive traits would show the distribution of those traits (across species) and help us to understand both the evolutionary pressures that produce more complex kinds of cognitive systems and the innovations that bring about new traits.⁶

CI provides a phylogenetic and ontogenetic basis for when bodily interactions are cognitive processes. Along with niche constructionists (Laland et al. 2000), CI maintains a phylogeny of hominid cognition in terms their active embodiment in a socially constructed cognitive niche. Ontogenetically, neonates acquire cognitive abilities to create, maintain, and manipulate the shared cognitive niche, including tools, practices, and representational systems. Cognitive processing often involves these online bodily manipulations of the cognitive niche, sometimes as individuals and sometimes in collaboration with others. CI has a unique position on the 4E landscape, because it is the first framework to propose that the co-ordination dynamics of integrated cognitive systems are jointly orchestrated by biological and cultural functions. What, though, are the cultural functions in question?

2.1 Cognitive practices as cultural practices

Both CI and extended mind (EM) occupy the strong embedding region, but they do so in different ways. Here I will differentiate CI as a thesis of enculturation from Clark's organism-

² One could look at a classic paper on mind/brain identity such as Smart (1959).

³ See Thompson (2007) for an account of the life-mind continuity, Stewart et al. (2010) for a volume dedicated to enactivism, and Hutto & Myin (2013) for a self-proclaimed radical variant.

⁴ See for example Barbaras (2010), which argues that to live is to have intentional consciousness of living.

⁵ Interestingly, radical enactivists appear to agree with CI on this issue; see Hutto & Myin (2013, p. 35). However, the radicals have a problem bridging the gap between basic cognitive processes and enculturated ones, since they think that meaning, or content, can only be present in a cognitive system when language and cultural scaffolding is present (Hutto & Myin 2013). That, of course, doesn't sit well with evolutionary continuity.

⁶ See for example Sterelny's cognitive phylogeny in Sterelny (2003) and Godfrey-Smith's complexity thesis in Godfrey-Smith (1996). See MacLean et al. (2012) for an overview of the problems for a comparative phylogeny.

centred approach to EM. Cognitive integration is a model of how our minds become enculturated. Enculturation rests in the acquisition of cultural practices that are cognitive in nature. The practices transform our existing biological capacities, allowing us to complete cognitive tasks, in ways that our unenculturated brains and bodies will not allow. Cultural practices are patterns of action spread out across cultural groups (Roepstorff 2010; Hutchins 2011; Menary 2007, 2010, 2012). Cognitive practices⁷ are enacted by creating and manipulating informational structures⁸ in public space. This can be by creating shared linguistic content and developing it through dialogue, inference, and narrative; or it can be by bodily creating and manipulating environmental structures, which might be tools or public and shared representations (or a combination of both). Examples of linguistically mediated action include self-correction by use of spoken (or written) instructions, co-ordinating actions among a group, or solving a problem in a group by means of linguistic interaction. Examples of creating and manipulating public and shared representations include using a graph to represent quantitative relationships; using a diagram to represent the layout of a circuit or building; using a list to remember a sequence of actions; or to solve an equation, to mathematically model a domain, to make logical or causal connections between ideas, and so on. Practices can be combined into complex sequences of actions where the physical manipulation of tools is guided by spoken instructions, which are updated across group members. A simple example of a group brainstorming with one member writing out the answers would be an example of a complex of collaborative cognitive practices.⁹

Cognitive practices are culturally endowed (bodily) manipulations of informational structures.

Practices govern how we deploy tools, writing systems, number systems, and other kinds of representational systems to complete cognitive tasks. These are not simply static vehicles that have contents; they are active components embedded in dynamical patterns of cultural practice. Practices are public, and they are also embodied and enacted.¹⁰ We embody practices: they become the ways in which we act, think, and live. They structure our lifeways (although not exclusively).

CI does not deny that much thinking takes place offline in the brain, but it does take the online and interactive mode of thought to be adaptive. Again, this line of thought has precursors,¹¹ but CI, uniquely, takes interactive thought as a basic category,¹² which is then scaffolded by culturally evolved practices. Practices stabilise and govern interactive thought across a population of similar phenotypes. The stable patterns of action can then be inherited by the next generation, because the practices have become settled and are part of the developmental niche in which the minds of the next generation grow. Our brains co-adapted to the stable spread of practice and its role in ontogeny—resulting in the slow evolution of the cultural brain.

The focus upon practice and culture marks cognitive integration out from variants of extended cognition, such as Clark's organism-centred approach to extension (2008). Clark's organism centred approach takes the assembly of extended cognitive systems to be controlled by the discrete organism, and brain, at the centre of it. He thereby reduces the role of cultural practices in large or small groups of organ-

⁷ I don't mean to suggest that there can't be other effects of cognitive practices, but since practices are just the cultural formalisation of patterns of action across a population, or group, cognitive practices are tied directly to these patterns of action. I can't provide a detailed origin account for cognitive practices here, but see Menary (2007, Ch. 5) for an early attempt to do so. However, the account of mathematical cognition I give in the next two sections provides an example of how such an account would be likely to look.

⁸ The primary cases I am thinking of are public systems of representation, including spoken language. However, I don't want to rule out cases involving tools, bodily gestures, artistic or bodily adornments, and the intelligent use of space and objects.

⁹ For two very good overviews of collective or group cognition see Theiner (2013) and Huebner (2013).

¹⁰ Jennifer Windt helpfully pointed out that practices can be thought of as public, because they are embodied and enacted. I think that this is just right: practices are patterns of action spread across a population. However, I am inclined to think that practices are not simply reducible to the bodily actions of individuals. Whilst doing long multiplication requires a bodily action of me, what I am doing cannot be described exclusively in terms of those bodily actions. The practice is a population, or group level phenomenon, not an individual one.

¹¹ The classical pragmatists, particularly Peirce and Dewey, held that thought was interactive. See Menary (2011) for a description of pragmatist approaches to thought, experience and the self.

¹² See Menary (2007, Ch. 5), where I make a detailed evolutionary case.

isms in the explanation of cognitive assembly. “Brains are special, and to assert this need mark no slippery-slope concession to good old-fashioned internalism as an account of mind. It is fully consistent with thinking (as I do) that Hutchins is absolutely right to stress the major role of transmitted cultural practices in setting the scene for various neurally-based processes of cognitive assembly” (Clark 2011, p. 458). On Clark’s view, cultural practices only set the scene for the real work of integration to be done by the brain. Whilst it is arguable whether Clark’s position is a return to “good old fashioned internalism,” he certainly does not give cultural practices a central role in assembling and orchestrating cognitive systems.¹³ Hutchins, by contrast, is committed to a full-blooded enculturated approach:

[t]he ecological assemblies of human cognition make pervasive use of cultural products. They are always initially, and often subsequently, assembled on the spot in ongoing cultural practices. (2011, p. 445)

CI is the only variant of strong embedding (including EM) to explain the role of cultural practices in assembling integrated cognitive systems. Cognitive practices are inherited as part of the developmental niche and have profound transformative effects on our cognitive abilities. This leads us to the main concepts required to understand these transformations as a process of enculturation.

3 Enculturation: The main concepts

In this section I define and explain the main concepts required to understand enculturation, other than the already explored concepts of integration and practice. I will develop the concepts of evolutionary continuity, behavioural and neural plasticity, transformation and innov-

¹³ If this is an accurate portrayal of Clark’s position (and I have tried to carefully use his own words) then, despite his protestations to the contrary, it appears to be a return to internalism, at least for the most central and important cognitive processes. If the brain carries out all the important cognitive operations, then Clark’s position would be a moderate embedded cognition for core cognitive abilities and an extended approach only to some of the more peripheral cases.

ation, or novelty and uniqueness. In particular I will emphasise the phylogenetic and ontogenetic bases for modern human cognitive capacities.

3.1 Evolutionary continuity

The concept of evolutionary continuity results from the fact that evolution occurs gradually with complex structures evolving over many generations. Over long periods of time these gradual changes accumulate, resulting in large differences. Consequently, changes to a phenotype occur in slow cumulative steps over long periods of time and do not appear in a single mutational step. Evolutionary continuity demands that modern human minds evolved from earlier archaic variants. Doubtless modern minds differ from archaic minds in important respects, but these differences must have evolved over long periods of time, through slow cumulative mutational changes to the genotype. Even so, we should expect some of our archaic traits to remain, and for more modern variants to be built on top of them. One obvious example of this is the evolution of the human brain.

The evolution of the human brain can, to some extent, be seen in the gradual increase of cranial capacity, but some of the most important changes have been in the reorganisation of cortical circuitry and interconnectivity (Hoffman 2014). Although the evolution of the human brain can be understood in terms of increasing encephalization and increased connectivity between brain regions, the human brain has essentially the same set of structures as any other primate brain.¹⁴ Modern brains evolved from archaic brains and share the same evolutionary constraints as other primates: “the similarity in brain design among primates, including humans, indicates that brain systems among related species are internally constrained and that the primate brain could only evolve within the context of a limited number of potential forms” (Hoffman 2014, p. 5). Modern minds are still partly archaic.

¹⁴ “Although species vary in the number of cortical areas they possess, and in the patterns of connections within and between areas, the structural organization of the primate neocortex is remarkably similar” (Hoffman 2014, p. 4).

It is important to think of evolutionary continuity as running from archaic to modern. We should try to avoid anthropomorphic tendencies to project modern cognitive capacities backwards into the hominin lineage or across to primate species. For example, humans are excellent social cognisers, but it does not follow from this that we should expect other primates to have a theory of mind.¹⁵ The evolutionary pressures under which humans evolved and the capacities for complex social cognition might have been very different from those under which other primates evolved. Consequently, we should be searching for archaic precursors to modern cognitive capacities. For example, we might expect that given the increasing social pressures in hominid social groups there would be precursors to modern social cognition and that these precursors would have been adaptive solutions (Shultz et al. 2012). Modern human social cognition would then be an evolutionary consequence of increasing variation in the complexity of social organisation and interaction (Sterelny 2003).

I am committed to another sense of continuity: that between biology and culture. Culture is not, as a category, distinct from the biological. Although culture is sometimes thought of as floating free of our biological nature and sometimes as being highly constrained by it, I shall assume that genes and culture co-evolve¹⁶ mutually, influencing and constraining one another. Therefore I shall accept no culture–biology dualism in this paper. Indeed I shall adopt a cultural inheritance model of cognitive evolution (of the niche construction kind). However, I shall always do so with archaic origins in mind. Archaic origins matter to cognitive evolution and they matter to the way our brains develop during the lifespan.¹⁷

¹⁵ Indeed, it is questionable whether humans deploy a theory of mind, or at least, perhaps they only do so on rare occasions (Hutto 2008; Andrews 2012). Andrews has also argued that we may share a number of “mind reading” strategies with other primates that don’t involve theory of mind (2012).

¹⁶ See below for a niche construction account of gene–culture co-evolution. I favour such an account because it helps us to understand how a developmental niche could have cumulative downstream evolutionary effects on phenotypes (Sterelny 2003).

¹⁷ They matter because they are part of the developmental biases that produce a robust phenotype.

In the “modern synthesis” there is only one line of inheritance, and that is genetic inheritance. More recently, biologists (Odling-Smee et al. 2003) have proposed that there are other lines of inheritance: ecological inheritance and cultural inheritance (Boyd & Richerson 2005). Many organisms construct the niche in which they live, mate, hunt, and die. Niche constructors modify the ancestral environment, and these modifications are bequeathed to the next generation. Modifications encompass physical alterations, such as living in mounds or constructing hives, as well as cultural artefacts, practices, and institutions. Over long periods these alterations to the niche can have profound effects on the phenotype. For example, the ubiquitous niche constructions of termites, burrows and mounds, have profoundly altered their morphology and behaviour (Turner 2000).

Humans are also ubiquitous niche-constructors. They physically alter their environment and they also epistemically, socially, and culturally engineer the environment (Sterelny 2003, 2010; Menary 2007). Humans are born into a highly structured cognitive niche that contains not only physical artefact, but also representational systems that embody knowledge (writing systems, number systems, etc.); skills and methods for training and teaching new skills (Menary & Kirchhoff 2014); and practices for manipulating tools and representations. Inherited cultural capital is a real and stable feature of the socio-cultural environment, including a great variety of knowledge systems, skills, and practices across a variety of domains of human action. As such, human cultural niches provide neonates with rich developmental niches. It is in these developmental niches that humans acquire cognitive practices.

Cognitive practices are products of cultural evolution, evolving over faster timescales than biological evolution. Writing systems, for example, are only thousands of years old; consequently, it is highly unlikely that there is a “reading gene” or even an innate specialised “reading module.” This is important: cognitive capacities for reading and writing, mathematics, and other culturally recent forms of cognition could not be biological adaptations (that

evolved over long periods of time). The timescales for their evolution are too short. It follows that the capacity for culturally recent forms of cognition must be acquired through learning and training.

Although there are no innate specialized modules for these recent forms of cognition, cortical circuits with which we are endowed through evolution are transformed to perform new culturally recent cognitive functions, even though they evolved to perform different functions. Recent cognitive innovations aside, there are good reasons to expect that evolution has driven us to think by interacting with the environment and that this is adaptive (Sterelny 2003 2012; Menary 2007; Wheeler & Clark 2008). However, it is the scaffolding of cultural practices that orchestrates the interactions—as in the case of written language and mathematics.

Structured socio-cultural niches have had profound evolutionary consequences in the hominin lineage. Structured niches have co-evolved with human phenotypic and developmental plasticity. We have evolved to be a behaviourally plastic species (Sterelny 2012) as well as a cultural species. In this co-evolution we have developed all manner of skills, practices, and activities. Why, though, are we so peculiarly behaviourally plastic? One good answer to this question is that human behavioural and developmental plasticity is an adaptive response to the variability and contingency of the local environment (Finlayson 2009; Sterelny 2003, 2012; Davies 2012). This is an alternative to the view that we are adapted to a pleistocene hunting and gathering environment—a view relied upon by many evolutionary psychologists (Barkow et al. 1992).

Critical to a co-evolutionary account of cultural practices is the evolution of human plasticity. Given that there is such a variety of cultural activity, we need an account of human evolution that will allow for variability in human behaviour. Second, we need a model that explains how innovations in our cultural niche are inherited and propagated, leading to changes in behaviour over time. The niche construction model explains how both of these causal factors could come into play. In the sub-

sections below, I outline the importance of behavioural and neural plasticity, the concept of transformation, and those of novelty and uniqueness.

3.2 Behavioural and neural plasticity

In evolutionary terms, humans are capable of developing a wide range of skills that allow them to cope with a wide variety of environments (and their contingencies). For example, even where skills are (broadly) of the same type, such as hunting, they will vary in how they cope with the differences in local environments—think of the differences in environments between Aboriginal hunters in the Pilbara desert, hunter-gatherers in the Central American rainforests, and Inuit seal-hunters (Sterelny 2003, p. 167).

Development is extended in modern humans relative to other species. Humans take a long time to learn how to walk and talk, and much, much longer to develop fine-grained manual and cognitive skills such as reading and writing. Other primates have much faster developmental timescales. While this might make humans more dependent on their caregivers for longer, it also allows them to refine skills and acquire a greater array of them before entering adulthood.

Through cultural inheritance, knowledge, skills, and artefacts are passed on to the next generation, but learning environments and learning techniques are also passed on so that the next generation can acquire and be transformed by the inherited cultural capital. This last point is important for our purposes, because developmentally plastic humans need scaffolded learning environments in which to develop.¹⁸

How, though, are we capable of acquiring these new cultural capacities in development? Through neural plasticity. Rather than the process of synaptogenesis or lesion-induced plasticity,¹⁹ the kind of plasticity I will discuss here is

¹⁸ If the cognitive abilities for manipulating artefacts and representations are not innate, then a scaffolded learning environment helps to explain how we acquire them.

¹⁹ Many neurological studies of plasticity focus on synaptogenesis, the florid growth of grey matter and then the consequent pruning, or the

what I call learning driven plasticity (see [Menary 2014](#)). Learning driven plasticity (LDP) can result in both structural and functional changes in the brain. Structurally, LDP can result in new connections between existing cortical circuits. Functionally, LDP can result in new representational capacities (the ability to represent public symbolic representations such as alphabets and numerals) and new cognitive abilities, such as mathematics,²⁰ reading, and writing ([Dehaene 2009](#); [Ansari 2012](#)). It should come as no surprise that learning drives structural and functional changes in the brain, given the extended developmental period in humans and the late development of the cortex ([Thatcher 1991](#)). The brain changes, not just because of maturation, but also because of learning:

[w]hen children learn to read, they return from school ‘literally changed’. Their brains will never be the same again. ([Dehaene 2009](#), p. 210)

Famously, Dehaene argues that a region of the occipito-temporal junction (which he calls the VWFA, visual word form area) that is part of a wider network for recognising faces, objects, and even abstract shapes (such as chequer patterns), alters its function to recognise written symbols in alphabets and even logographic scripts such as kanji ([Dehaene 2009](#)). This is due to the plasticity of that area of the brain, where the functional shift is due to scaffolded learning.²¹ “Scanning of ‘ex-illiterate’ adults who learned to read during adulthood has demonstrated that the VWFA is highly plastic, even in adults, and quickly enhances its response to letter strings as soon as the rudiments of reading are in place” ([Dehaene & Cohen 2011](#), p. 259). Even those who are not convinced that a specialised region for “word recognition” is acquired once we learn to read admit that the oc-

cipito-temporal junction is part of a reading and writing circuit (e.g., [Price & Devlin 2011](#)).

We have evolved to be phenotypically and developmentally plastic. This is in no small part due to the plasticity of our brains. Our developmentally plastic brains exhibit learning-driven plasticity. When the brain is coupled to a highly scaffolded learning environment it is profoundly transformed, structurally and functionally, and consequently we are cognitively transformed in the profoundest way.

3.3 Transformation

The transformation thesis can be given a simple formulation: cognitive transformations occur when the development of the cognitive capacities of an individual are sculpted by the cultural and social niche of that individual. Cognitive transformations result from our evolved plasticity and scaffolded learning in the developmental niche. In the previous sub-sections an account was given of the effects of cultural inheritance and niche construction on hominid evolution. The result is phenotypic plasticity, and in the cognitive case the co-evolution of neural plasticity and scaffolded learning. However, the point of the transformation thesis is to drill down into the process of acquiring knowledge, skills, and cognitive abilities via learning-driven plasticity and scaffolded learning. It does this by showing how transformations are a result of the role of cognitive practices in development. Practices structure the niche; they transform plastic brains via learning driven plasticity and result in new cognitive abilities.

During the learning and training of a skill, such as flaking an arrowhead, or a shot in tennis or cricket, we are guided by the norms for the correct actions that make up the skilled practice. A parallel case can be made for cognitive abilities such as mathematics. The neophyte mathematician gains mastery over the cognitive norms²² by which numerals, operators, and other symbols are created and manipulated. Vygotsky expresses this in the claim that children, “master the rules in accordance with which ex-

synaptic death of many of those neurons in the so-called critical period of childhood. There are a large number of studies of neural damage, often by stroke or injury, where cortical circuitry becomes damaged and its function impaired, but where other areas of the cortex can take on the impaired function. (See [Huttenlocher 2002](#) for an overview.)

²⁰ I will be defending an account of mathematical cognition in section 4.

²¹ See [Menary \(2014\)](#) for a discussion of plasticity and the VWFA.

²² For an account of cognitive norms see [Menary \(2007\)](#), Chapter 6.

ternal signs must be used” (Vygotsky 1981, pp. 184–185). Initially the child masters the creation and deployment of spoken linguistic signs (and later written signs) through the scaffolding of parents and caregivers. However, this process is not simply a matter of gaining new representations; it is also one of gaining new abilities.

Neophytes go through a process of dual-component transformation: they learn how to understand and deploy public symbolic representations and they learn how to create and manipulate inscriptions of those symbols in public space (Menary 2010). In so doing, they learn mathematical and linguistic concepts and they learn how to manipulate inscriptions to complete cognitive tasks. When learning the manipulative techniques, the first transformation is one of the sensory-motor abilities for creating and manipulating inscriptions: we learn algorithms like the partial products algorithm²³ and this is an example of the application of a cognitive practice. This is something we learn to do on the page and in the context of a learning environment, in public space, before we do it in our heads. Our capacities to think have been transformed, but in this instance they are capacities to manipulate inscriptions in public space. This is a way of showing that the transformation of our cognitive capacities has recognisably public features. This ought not to be a surprise, given that the cognitive niche is socially and culturally constructed and is structured by socio-cultural practices. Symbol systems, such as those for written language and mathematics, are not impermanent scaffolds that we shrug off in adulthood, but are permanent scaffolds that indelibly alter the architecture of cognition.²⁴

The transformatory position is quite different from that held by Clark or Sterelny. In particular it holds that our basic cognitive capabilities are transformed in development and that the dual component transformation results in a distinct functional redeployment of neural circuitry and new abilities to bodily manipulate structures in public space. Cognitive tasks can be completed by manipulating written symbols in public space or by off-line strategies for completing algorithms, or a combination of both.

²³ I’ll look at this example in detail in section 5.

²⁴ I take this issue up again in section 4.1.

This conclusion sits happily with the idea that thought is interactive and governed by practices.

The main difference between the position outlined here and Clark’s (e.g., 2008), is that Clark does not explain cognitive extension in terms of the transformation of basic cognitive resources during development in a socio-cultural niche (although he does acknowledge the importance of symbolically structured niches). Rather, he thinks that basic biological resources are not really transformed but simply dovetail to external symbols (Clark 2008, 2011). Sterelny (2010) concentrates on cognitive scaffolding, but does not think that the manipulation of symbols in public space is constitutive of cognitive processing. The enculturated approach of CI answers questions that are problematic for both Clark and Sterelny:

1. How do we learn to complete cognitive tasks that require the manipulation of symbols in public space?
2. Assuming that cognitive processing criss-crosses between neural space and public space, how does it do this?

The first question is hard for Clark since he does not think that our basic cognitive resources get transformed, at least in the way that I have presented here. The second question is hard for Sterelny because he limits himself to a scaffolded view of cognition rather than an extended view. Consequently, manipulations of symbols in public space are not cognitive processes for Sterelny.²⁵

CI as a process of enculturation requires a robust transformation thesis. A robust transformation thesis is warranted by phenotypic and neural plasticity, in particular by learning driven plasticity. Novel and unique public systems of representation drive the transformation of our existing cognitive abilities.

3.4 Novelty and uniqueness

Sometimes symbols and tools provide us with novel functions: they radically extend our cap-

²⁵ Or they might be assuming that Sterelny does not care either way; in private communication Sterelny indicated that he does not think that boundary disputes are of much interest.

abilities in some sphere. Take the humble hand axe. Very crude hand tools have been discovered dating as far back as 2.6 mya (million years ago; [Toth & Schick 2006](#)), since then there has been evidence of a hominid capacity for cumulative cultural inheritance “which was ultimately to transform *Homo sapiens* into the richly cultural species we are today” ([Whiten et al. 2011](#)). However, the capacity for developing novel functions and transmitting them to the next generation with high fidelity appears to be a more recent innovation, as evidenced by the long periods of relative stability in technological development in the early hominids and archaic humans. It also appears to be an innovation unique to the homonin lineage ([Whiten et al. 2011](#)). The Oldowan period begins in the lower paleolithic with *Homo Habilis* around 2.6 mya, being taken up by *Homo Erectus* and *Ergaster* and ending at about 1.8 mya ([Lycett & Gowlett 2008](#)). The tool types and process of manufacture remain consistent during this period, with some refinement and novelty ([Lycett & Gowlett 2008](#)), where the main tool types were choppers and scrapers or mode 1 tools ([Semaw et al. 2003](#)).

Homo Habilis is unique in that it is the first hominid to make tools that were made to endure and be re-usable (it is likely that earlier anthropocines used naturally-occurring objects as tools that were disposable; [Jefferies 2010](#)).

Oldowan toolmaking involves the production of sharp-edged flakes by striking one stone (the core) with another (the hammerstone). Effective flake detachment minimally requires visuomotor coordination and evaluation of core morphology (e.g., angles, surfaces) so that forceful blows may reliably be directed to appropriate targets ([Stout et al. 2008](#), p. 1940).

There is a clear transition to Achulean technology at around 1.7 mya with the appearance of *Erectus*/*Ergaster*. The main innovation for Achulean technology was the bifacial handaxe—a handheld cutting tool with two cutting sides. The real explosion in novelty occurs in the upper paleolithic period, from 50,000 years ago (ya) to 10,000 ya (or to just before the advent

of agriculture and the neolithic period), with genuine novelty in tool production and use and cultural diversification. In this period we begin to see evidence of art, including paintings and sculpture, fishing, jewellery, burial, evidence of musical activity, and all the hallmarks of behaviourally modern humans. It is in this period that the combination of inherited cultural capital, with phenotypic and learning-driven plasticity, complex social relations and language results in an explosion of cultural and behavioural diversity.

It is also in this period that we begin to find evidence of proto-numerical and writing systems as novel representational innovations. Simple tally notch systems on bone fragments have been dated to between 35,000 and 20,000 ya, and may have been used for a variety of purposes, the most obvious being to keep track of economic exchanges. However, it is far easier and more economical to keep track of larger amounts using a single symbol, rather than a one-to-one correspondence of marks with things.

The complex social and economic pressures that required tracking exchanges involving increasingly large numbers would be the kind of socio-economic pressures that produced symbolisation of quantity. Social and cultural pressures can drive evolutionary novelty, in this case symbolisation and uniqueness—symbolic representations are unique in both type and property, no other animal produces written symbols to represent concepts. Symbols have unique properties that allow for operations—addition, subtraction, multiplication, division, and so on that are much harder (if not unlikely) without them.

Early symbolic number systems date from between 3000–4000 BCE, but genuinely abstract symbol systems are even more recent—about 1000–2000 BCE. The invention of symbol systems is too recent to be a genetic endowment, but is inherited as cultural capital and acquired through high-fidelity social learning (which is in turn dependent upon neural plasticity).

The phylogeny of hominid tool-use is one of hard-won innovation and retention. Modern humans have developed high-fidelity modes of transmitting cultural capital vertically and horizontally. The socio-cultural pressures that led to

humans innovating symbolic representational systems are unique and very recent. Fortunately, modern human minds are flexible enough to both innovate and reliably acquire those innovations in ontogeny.²⁶ This flexibility makes modern human minds unique, and in the case of mathematical cognition unique amongst all our primate relatives.

The next section outlines mathematical cognition as a case of enculturation, and there I will explore the example of mathematical cognition by deploying the concepts refined in the first two sections.

4 Numerical cognition

In this section I outline the phylogenetic basis of mathematical cognition. That basis is in our shared sense of quantity and our ability to estimate the size of small sets by making approximate judgements of the size of the set. This ancient endowment is the basis for our mathematical competence, but it is not all there is to mathematical cognition. This is because precise mathematics depends upon a very recent and acquired public system of exact and discrete mathematical thinking. The ancient system is analogue and approximate, but mathematics requires digital and discrete representations and exact operations. These are, of course, recent additions to inherited cognitive capital. I shall show why mathematical cognition requires our ancient capacity for numerosity and how it is constituted by cognitive practices—which transform our cognitive abilities, resulting in novel and unique modern human cognitive capacities. However, this transformation results in two partially overlapping systems—the approximate number system and the discrete number system—with the latter having unique properties acquired from cultural innovation. One of the puzzles is how it is possible to move from an inherited approximate system to an acquired exact system. The process of enculturation provides the mechanisms by which such a move takes place, from the ancient capacity for numerosity to development in a socio-cultural

niche, and the orchestrating role of practices in the assembly of the cognitive systems responsible for mathematical cognition.

4.1 Numerosity in animals and humans

There is strong evidence to suggest that we have a basic analogical and non-linguistic capacity to recognise quantity and number. I think that there is overwhelming evidence for an ancient evolutionary capacity to discriminate cardinality, and to determine in an approximate way the quantity of membership of sets. It is obvious how this capacity, for only very small sets, would be beneficial for activities such as foraging, hunting, and so on.

Recent studies have revealed that the neural populations that code for number are distributed in the intraparietal sulcus (Dehaene & Cohen 2007). A growing number of studies show that both animals and humans possess a rudimentary numerical competence, which is an evolutionary endowment. For example, red-backed salamanders have been shown to choose the larger of two groups of live prey (Uller et al. 2003). Single neuron activation studies in rhesus monkeys (Nieder et al. 2006) discovered that individual neurons respond to changes in number when presented visually (and non-symbolically). These neurons are also located in the intraparietal sulci, indicating a probable cross-species homology. The neurons peak at the presentation of a specific quantity of dots, but then decrease as the numbers presented differ from the original. So a neuron that peaks at the presentation of two dots responds less to three or four dots. The further the numerical distance of the array of dots is from the magnitude to which the neuron is tuned, the lower the firing rate of the neuron. Therefore, the ancient capacity for numerosity is an approximate function, not a discrete one (DeCruz 2008).

This is not yet counting; counting is exact enumeration. Subitizing is the ability to immediately recognise the size, or number, of a small set—usually <4 . Most animals subitize, rather than count. Infant humans also appear to be able to subitize (Rouselle & Noël 2008). This ancient or approximate number system (ANS)

²⁶ This section has put together a case for the flexibility of modern minds and the ability to acquire cultural innovations quickly and easily in ontogeny.

is a non-linguistic continuous representation²⁷ of quantities above 4; Dehaene calls it the number sense (1997). Take the following example. Whilst it is easy enough to determine which of the following two boxes contains the larger number of dots without having to count them:

Figure 1: Subitizing or counting?

It is less easy to do so for the following (you will probably need to resort to counting):

Figure 2: Subitizing or counting?

It is also possible to make estimations or approximate judgements of scale for numbers. Most people can quickly identify that 7 is larger than 3. Even for more complicated exact operations we can do this:

$$34 + 47 = 268 \text{ (is this right?)}$$

We readily reject this result, because the proposed quantity is too distant from the operands of the addition (Dehaene 2001, p. 28).

$$34 \times 47 = 1598 \text{ (is this right?)}$$

Approximation involving proximity and distance will not help here (unless you are very practised at mental multiplication), but you

²⁷ The appearance of the word representation here need not raise concerns; these are not representations with propositional contents and truth conditions. They are not symbolic and are not molecular constituents that can be combined to make more complex representations.

might resort to a multiplication algorithm (which might be routinized). It is clear that we have an ancient sense of quantity and are good at making judgements about more than and less than, but when it comes to precise and discrete quantities (particularly larger numbers) we need new capacities to be able to make judgements about operations on discrete numbers.

4.2 Two overlapping systems

The approximate numerical system is an analogue and approximate system for discriminating non-symbolic numerosities greater than 4, but the “representations” are approximate and noisy. The second system is acquired and concerns discrete symbolic and linguistic representation of individual numbers from our numeral system, including individual words for numbers. This system works with discrete, exact, symbolic representations of quantity and allows for the exact operations of arithmetic and mathematics. I will call this the discrete numerical system (DNS). There is disagreement about how much the two systems overlap. However, what is clear is that the internalisation of the public numeral system allows us to perform the kind of digital mathematical operations that are required for most arithmetic and mathematical operations (Nieder & Dehaene 2009, p. 197).

Dehaene and colleagues produced a series of experiments that demonstrate the separate functioning of the two systems. Russian–English bilinguals were taught a set of exact and approximate sums of two digit numbers in one of their languages (Dehaene et al. 1999, p. 970). Their tasks were split into giving exact answers to additions and giving an approximate answer to the addition task. The interesting result was that:

[w]hen tested on trained exact addition problems, subjects performed faster in the teaching language than in the untrained language, whether they were trained in Russian or English. (Dehaene et al. 1999, p. 971)

This provided evidence that knowledge of arithmetic was being stored in a linguistic format,

and that there was a switching cost between the trained and untrained languages. By contrast, there was equivalent performance in the approximation task, and no switching cost between the trained and untrained languages. Dehaene et al. conclude that this provides “evidence that the knowledge acquired by exposure to approximate problems was stored in a language-independent form” (1999, p. 971).

This leads us to the conclusion that there are two overlapping, but not identical, systems for mathematical cognition. The first is the ancient and approximate system, the second is a relatively new and acquired system for discrete and digital representations and operations. As Dehaene & Cohen put it:

The model that emerges suggests that we all possess an intuition about numbers and a sense of quantities and of their additive nature. Upon this central kernel of understanding are grafted the arbitrary cultural symbols of words and numbers [...]. The arithmetic intuition that we inherit through evolution is continuous and approximate. The learning of words and numbers makes it digital and precise. Symbols give us access to sequential algorithms for exact calculations. (2007, p. 41)

The two systems are overlapping but not identical because they have quite different properties. First, the ancient system is part of our phylogeny, whereas the discrete system is an acquired set of capacities in ontogeny. Second, the ancient system is analogue and approximate, whereas the discrete system is digital and exact. Third, the discrete system operates on symbols that don't map directly on to the ancient system.

When we consider very large numbers, such as 10,000,000, there is no obvious analogue in the ANS. Consequently, large or exotic numbers and operations on them do not map onto existing cortical circuitry for numerosity. Lyons et al. (2012) call this phenomenon “symbolic estrangement”. Symbols become estranged through a process of symbol-to-symbol mappings, rather than symbol-to-approximate-quantity mappings (Lyons et al. 2012, p. 635).

However, there appears to be a point of contention here: Dehaene expects there to be a more or less direct mapping of symbols to quantities (e.g., the mental number line). If symbolic estrangement does happen, then this would appear to be mistaken. Lyons, Ansari and Beilock propose a developmental resolution of this apparent disagreement. Children may start out in the acquisition of discrete number systems by a mapping to an existing approximate neural coding of quantity, but as the system matures and symbols become abstracted from the ancient system, the mature system splits into two (related but not entirely overlapping) systems: neural circuitry in the DNS tunes for discrete symbols,²⁸ whereas circuitry in the ANS tunes for approximate quantities, such that discrete symbols do not map directly onto approximate quantities. E.g., 10,000,000. The DNS has properties that are unique.

In the next section I return to the question of the role of practices in assembling the DNS.

5 Mathematical practices

The DNS is dependent upon mathematical practices, systems of number and algorithms for performing mathematical operations, complex mathematical concepts such as sets, functions, and so on. None of these practices, representations, or concepts are innate, and no one seriously thinks that they are. They are culturally inherited and acquired in the right learning niche with experts willing to teach. These new abilities are continuous with our cognitive phylogeny. How, though, can we put the whole package together? This section does that job.

5.1 Cognitive practices and the development of mathematical competence

Mathematics and writing systems are examples of culturally evolved symbol systems that are deployed to complete complex cognitive tasks. These systems are structured by rules and

²⁸ There is evidence of narrower tuning curves for Arabic numerals in the left intraparietal sulcus (Ansari 2008).

norms, but they are deployed as practices: patterns of action spread out across a population. In this case cognitive agents must gain mastery over the symbols, including numerals and operators, as well as the rules for their combination. However, they must also learn how to write and manipulate the symbols according to those rules in order to produce the right products—and this is proceduralised.

There may be more than one way of achieving a solution to the task. One can multiply by the partial products algorithm, or one can use the lattice/grid method or a number of others that have been developed by different cultures using different numerical systems. However, they all involve the same set of features: symbols, rules, operators, spatial configuration, and products, and they jointly constitute a practice for manipulating the symbols to complete mathematical problems. The practices are novel and unique to humans.

The methods apply equally to their off-line equivalents, so in the page-based version of the partial products algorithm we perform the multiplications from right to left and write down their products in rows, carrying numbers where necessary. In the off-line version we can perform the same operations on imagined numerals, multiplying numbers along the line and carrying any numbers as required. It is cognitively taxing to hold the products of the multiplications constant in working memory, though some people can train themselves to become quite good at it. Most people learn off-line multiplication by performing shortcuts; if I want to work out what 25×7 is, I just add 25 together 7 times.

On-line methods can change even within the same arithmetical systems, so the partial products algorithm works like this:

$$\begin{array}{r}
 23 \\
 \times 11 \\
 \hline
 23 \quad (1 \times 3 \text{ and } 1 \times 2) \\
 + 230 \quad (\text{carry } 0, 1 \times 2 \text{ and } 1 \times 3) \\
 \hline
 253 \quad (\text{add products together})
 \end{array}$$

However there is an equivalent algorithm that works like this:

$$\begin{array}{r}
 23 \\
 \times 11 \\
 \hline
 200 \quad (10 \times 20) \\
 30 \quad (10 \times 3) \\
 + 23 \quad (1 \times 23) \\
 \hline
 253 \quad (\text{add products together})
 \end{array}$$

The algorithms may differ, but they still involve the practice of spatially arranging the numerals, and performing operations on them and deriving a product, by performing the staged manipulations on the page. It appears then to matter how we manipulate symbols in public space, but is there any empirical evidence for this conclusion?

CI predicts that it matters how symbols are spatially arranged when they are being manipulated. Landy & Goldstone (2007) found that college-level algebraists could be induced to make errors by altering the layout of numbers that they were to manipulate. They did this by altering the spacing of the equations:

$$F+z * t+b = z+f * b+t$$

Although minor, the extra spacing was enough to induce errors. It matters how the symbols are spatially laid out, for this layout is the basis of how we manipulate those symbols. In this case the artificial visual groups created by the irregular spacing affected the judgement of the validity of the equation. If the visual groupings were inconsistent with valid operator precedence then they negatively affected the judgement.²⁹

Landy & Goldstone's work provides evidence that expert algebraists are practised at symbolic reasoning achieved via the perception and manipulation of physical notations (2007; Landy et al. 2014). Rather than an internal system of abstract symbols and rules for their combination (i.e., a language of thought), the system is composed of perceptual-motor systems and the manipulations of numerals. They are careful to say that the manipulations must conform to the abstract norms of algebra. Dutilh Novaes (2013) takes this to be evidence that mathematical competence is constituted by the

²⁹ In algebra multiplications are made before additions. E.g., $5+2*6 = 17$ (not 42).

capacity to manipulate inscriptions of mathematical equations. This fits very well with the CI approach.

Despite some interesting lacunae (savants and blind mathematicians), most mathematicians learn to manipulate numerals and other mathematical symbols on the page, and they continue to do so throughout their mature cognitive lives. Landy and Goldstone's evidence supports the thesis that mathematical competence is constituted, in part, by our capacity to manipulate symbols in public space; that competence is, properly, a matter of interaction.

5.2 Continuity and transformation

We have seen that there is an ancient evolutionary endowment for numerosity—an analogue and approximate system. This system is found in other primates and other species. It provides both the phylogenetic basis of mathematical cognition and the initial constraints for the development of the DNS. The DNS did not spring *sui generis* into the world. It did so because of a heady mixture of socio-cultural pressures, phenotypic and neural plasticity, social learning strategies, and cultural inheritance. These are the conditions for the scaffolding of the ANS, transforming our basic biological capacities into the DNS.

New cultural functions, discrete mathematical functions, and the practices for manipulating inscriptions transform existing circuitry in the brain. Once we learn how to recognise, understand, and manipulate mathematical symbols our brains undergo a profound transformation. There is a reproducible circuit for mathematical cognition involving a bi-lateral parietal based approximate estimation; a left lateralised verbal framework for arithmetic concepts (e.g., number words); and a occipito-temporal based symbol recognition system (e.g., Arabic numerals). The system also incorporates visual-motor systems for writing (manipulating, or pushing) symbols in public space.

A further important aspect of transformation is symbolic estrangement. As the DNS matures it becomes more abstract and less directly mapped onto the approximate functions of the

ANS. Interestingly, at the same time expert mathematicians become reliant upon visual-motor capacities for manipulating inscriptions. Transformation depends upon the novelty and uniqueness of mathematical symbols and practices.

5.3 Novelty and uniqueness

Symbolic number systems and sequential algorithms allow for mathematical and cognitive novelty. Once we have a public system, all manner of exotic numbers and operations can be discovered:³⁰ negative numbers, square roots, zero, sets, and so on. Its importance lies in the ability to perform computations that cannot be performed by ancient neural functions for numerosity. For example, the neural circuits responsible for numerosity cannot (on their own) represent -3 or $\sqrt{54}$, and yet this is simply represented in terms of public mathematical symbols (DeCruz 2008). This is because the symbolic representations are novel and unique. Initially, novelty results from the pressures of increasing social and economic complexity. Small roaming bands of foragers do not need to develop symbolic number systems; post-agricultural Neolithic societies settled in villages and towns do. A further issue is how novelty comes about from the ability to abstractly combine symbols and functions that apply to the symbols. I don't propose to try to answer that question here; however, we might think of this as a curiosity- and creativity-driven processes. Given uniquely human behavioural and neural plasticity and socio-cultural complexity we might expect an increasing drive towards cognitive innovation. This has certainly been the story of recent cultural evolution in modern human societies.

This concludes the discussion of mathematical cognition as enculturation. Now I turn to the objections.

6 The incredible shrinking system

Why not just shrink the cognitive system to brain-based systems? Is there a way to bridge
