³⁰ I will not address the issue of what discovery amounts to here and will remain neutral on whether discovery reveals a platonic mathematical system or simply the logical relations between concepts.

the impasse between moderate and strong embedding? One argument concerns whether it makes any difference to cognitive science to consider, for example, the manipulation of public symbols to be cognitive processes (Sprevak 2010). Ultimately, to give a decisive answer to that question we would need to change our conception of cognitive processes to on-going dynamical interactions with the environment that loop through brain, body, and environment. However, weak and moderate embedded approaches do not work with such a conception of cognitive process; they work with an input-process-output style sandwich model, where processes supervene on bodily states and processes. For them, there is no reason to accept strong embedding, and much of the discussion has been based around thought experiments or abstract definitions rather than concrete examples.

However, even on a scaffolded view of cognition we can't deny the difference-making role the manipulations of symbols make to the completion of cognitive tasks. Manipulating public symbols is unique; there is a difference between internalised strategies for completing mathematical tasks and strategies for manipulating mathematical inscriptions. Our cognitive capacities cannot cope with long sequences of complex symbols and operations on them. This is why we must learn strategies and methods for writing out proofs. Symbol manipulation makes a unique difference to our ability to complete mathematical tasks, and we cannot simply ignore their role. If we take the approach of CI, then mathematical cognition is constituted by these bouts of symbol manipulation, and we cannot simply shrink the system back to the brain. The case for a strongly embedded approach to mathematical cognition depends upon the novelty and uniqueness of mathematical practices and dual component transformations. Our evolutionary endowments of numerosity are not up to the task of exact symbolic arithmetic and mathematics. Without symbolic number systems and sequential algorithms there would be no mathematical innovation. Mathematical innovation includes representational novelty: negative numbers, square roots, zero, etc., but also novel functions: multiplication, division,

etc. Novelty comes about from the ability to abstractly combine symbols and functions that apply to the symbols.

Uniquely, symbols represent quantities discretely, but there is also the unique human capacity of manipulating symbols in public space. We learn to manipulate symbols in public space and we continue to do so when completing cognitive tasks.

The entire system of mathematics is not contained in a single brain. Symbol systems are public systems of representations and practices for their manipulation. Mathematical practices are part of the niche that we inherit—they are part of our cultural inheritance.

6.1 Impermanent scaffolds?

Another objection concerns the impermanence of the scaffolding required for mathematical cognition. Once we have internalised the scaffolding of symbolic number systems, we have no further need for it, except for communication purposes. This claim would be proven if we did not continue to manipulate numerals when completing cognitive tasks. Even if we think that transformation only results in new internal representational resources, and that this just amounts to moderate embedding/scaffolding, we must also concede that most mathematics is conducted on the page.

Scaffolding theorists, like Sterelny, can endorse this idea; indeed they can agree with the bulk of the framework provided by CI whilst avoiding the constitutive claim. What they cannot do is deny that mathematical practice and the manipulation of physically laid-out symbols on the page is a difference maker for mathematical cognition. If you remove it, the ability to complete mathematical tasks drops considerably. To do so is to fly in the face of the empirical evidence from psychology (Landy & Goldstone 2007) and cognitive neuroscience (Dehaene & Cohen 2007; Ansari 2012). Consequently, it is clear that cognitive practices transform our mathematical abilities, lending weight to the CI approach.

The case I have presented in this paper is that symbols are not simply impermanent scaffolds.

folds, they are permanent scaffolds. They become part of the architecture of cognition (and not simply through internalisation). Mastery of symbol systems results in changes to cortical circuitry, altering function and sensitivity to a new, public, representational system. However, it also results in new sensori-motor capacities for manipulating symbols in public space. The case can be made in terms of what a symbol system is:

A symbol is a physical mark (or trace), either in physical space, or as a digital trace. Symbol systems contain rules and practices for interpreting symbols, for combining them, and for ordering and manipulating them. A large body of often tacit practices for interpreting and manipulating symbols is acquired. Scaffolding is not simply an amodal symbol with an abstract designation that needs to be learnt (or mapped onto some innate symbol); scaffolding is also how the symbols are physically arranged, how symbols are pushed from one place to the next in a regular fashion. Finally, scaffolding is also how we use our own bodies, eyes, ears, and hands to create and manipulate symbols.

7 Conclusion

I have presented a case for CI as a process of enculturation, with mathematical cognition as an example of the process of enculturation at work. I began by laying out the 4E landscape and locating CI within it, relative to enactivism and EM. In particular I showed how CI shares the interactive stance of enactivism and the constitutive stance of EM, but how it also differs from these. The main difference between CI and enactivism is that CI does not equate life and mind in the way that enactivism does. The main difference between CI and EM is that CI takes cultural practices to play a central role in the assembly of cognitive systems, whereas EM does not.

I then went on to outline the central concepts required to make sense of enculturation. The CI framework embraces both evolutionary continuity and transformation of existing cognitive circuitry in development. Our modern minds are built on archaic precursors by slow

incremental changes. However, modern humans are behaviourally plastic and scaffolded learning drives functional changes in our plastic brains. The developmental change from the ANS to the DNS is an example of how learning-driven changes to cortical function result in new abilities, but this would not happen without the novelty and uniqueness of mathematical symbols and the practices for manipulating them.

I also countered two standard objections: impermanence and shrinkage. The defence of CI rested on the novelty and uniqueness of mathematical practices and symbols.

If the CI framework is on the right track, then human cognitive evolution has resulted in minds that are flexible and interactive. Furthermore, cultural evolution has resulted in written symbol systems and practices for manipulating symbols that can be acquired (in development) by minds like ours. The uniqueness of modern human minds lies in their capacity for transformation.

Enriching the Notion of Enculturation: Cognitive Integration, Predictive Processing, and the Case of Reading Acquisition

A Commentary on Richard Menary

Regina E. Fabry

Many human cognitive capacities are rendered possible by enculturation in combination with specific neuronal and bodily dispositions. Acknowledgment of this is of vital importance for a better understanding of the conditions under which sophisticated cognitive processing routines could have emerged on both phylogenetic and ontogenetic timescales. Subscribing to enculturation as a guiding principle for the development of genuinely human cognitive capacities means providing a description of the socio-culturally developed surrounding conditions and the profound neuronal and bodily changes occurring as a result of an individual's ongoing interaction with its cognitive niche. In this commentary, I suggest that the predictive processing framework can refine and enrich important assumptions made by the theory of cognitive integration and the associated approach to enculturated cognition. I will justify this suggestion by considering several aspects that support the complementarity of these two frameworks on conceptual grounds. The result will be a new integrative framework which I call enculturated predictive processing. Further, I will supplement Richard Menary's enculturated approach to mathematical cognition with an account of reading acquisition from this new perspective. In sum, I argue in this paper that the cognitive integrationist approach to enculturated cognition needs to be combined with a predictive processing style description in order to provide a full account of the neuronal, bodily, and environmental components giving rise to cognitive practices. In addition, I submit that the enculturated predictive processing approach arrives at a conceptually coherent and empirically plausible description of reading acquisition.

Cognitive integration | Cognitive transformation | Enculturation | Neural plasticity | Neuronal reuse | Predictive processing | Reading acquisition | Scaffolded learning

1 Introduction

In his target paper *Mathematical Cognition: A Case of Enculturation*, Richard Menary investigates the conditions under which phylogenetically recent, socio-culturally shaped target phenomena within cognitive science such as mathematics, reading, and writing have emerged.

Resting on his theory of cognitive integration (CI; e.g., [Menary 2007a](#)), he starts from the idea that these processes are fully continuous with phylogenetically older ones (*evolutionary continuity*). This type of continuity is justified by the assumption that the evolution of neur-

onal reuse mechanisms allows for the redeployment of cortical circuits for phylogenetically recent functions (Anderson 2010; Anderson & Finlay 2014). Ontogenetically, neuronal reuse is a precondition of *learning driven plasticity* (LDP), which “can result in both structural and functional changes in the brain” (Menary this collection, p. 8). That is, the human brain is assumed to be neuronally plastic so that its processing routines are altered as the individual acquires new cognitive abilities (Ansari 2012). However, the acquisition of new cognitive abilities takes place within

[...] a highly structured cognitive niche that contains not only physical artefacts, but also: representational systems that embody knowledge (writing systems, number systems, etc.); skills and methods for training and teaching new skills (Menary & Kirchhoff 2014); practices for manipulating tools and representations. (Menary this collection, p. 6)

It is this cognitive niche that provides the resources for *scaffolded learning*, which allows the individual to acquire new cognitive abilities through its ongoing embodied interaction with its socio-cultural environment. Together, LDP and scaffolded learning lead to cognitive transformations that augment the individual’s cognitive capacities through ontogenesis: “Cognitive transformations result from our evolved plasticity and scaffolded learning in the developmental niche” (Menary this collection, p. 8).¹ The result of cognitive transformation is the acquisition of a sufficient degree of expertise in performing a certain *cognitive practice*. Cognitive practices are normatively constrained to the extent that socio-culturally shaped procedures work in close interaction with the cognitive niche: They “[...] are culturally endowed (bodily) manipulations of informational structures” (Menary this collection, p. 4), such as manipu-

lations of tokens of a representational writing system, and they serve to complete a cognitive task. In order to describe the transformational processes by which cognitive practices are acquired, Menary introduces the notion of *enculturation*: “Enculturation rests on the acquisition of cultural practices that are cognitive in nature” (*ibid.*). That is, enculturation refers to any cognitive transformation that is rendered possible by LDP and the individual’s ongoing interaction with its cognitive niche. As a proof of concept, Menary (this collection) deals with mathematical cognition and describes the ways in which individuals acquire expertise in manipulating a public, socio-culturally developed mathematical symbol system. Relying on a set of empirical results, he arrives at the conclusion that precise mathematical operations are rendered possible by the recruitment of a neuronal sub-system during ontogeny. In contrast to the evolved approximate number system (ANS), which allows for subitizing and is also present in other animals, the neuronal realization of the discrete number system (DNS) heavily depends on LDP, the individual’s immersion into its cognitive niche, and its active participation in scaffolded learning routines. Thus, the acquisition of mathematical skills is an important example of enculturation.

The purpose of this commentary is to enrich and refine the enculturated approach. First, I will propose that the predictive processing framework provides conceptual and explanatory tools for describing and explaining the neuronal and extracranial bodily mechanisms underlying cognitive practices and enculturation. Thus, I will accept the challenge to combine “[...] the dynamical nature of causal commerce between world, body, and brain and the inferential free energy principle that allows their unification in one account” (Hohwy this collection, p. 18). I will argue that a new integrative framework that views CI and predictive processing as complementary is able to meet this challenge. Second, I will illustrate this by presenting reading acquisition as a paradigmatic case of enculturated cognition. In particular, I will demonstrate that a position that combines the enculturated approach with predictive processing,

¹ More precisely, according to Menary (2014, p. 293) it is scaffolded learning that renders LDP possible in the course of cognitive development of individuals: “Both structural and functional plasticity can result from both endogenous and exogenous sources, but here the focus is on structural and functional changes driven by scaffolded learning.”

which I call enculturated predictive processing, leads to a parsimonious and conceptually coherent account of reading acquisition that helps interpret and unify a vast array of recent empirical findings.

2 Towards a more complete approach to enculturation: Cognitive integration and predictive processing

In order to appreciate the descriptive power of the enculturated approach, it is necessary to specify the mechanistic underpinnings of the acquisition of cognitive practices. In his summary of the CI framework, Menary ([this collection](#), p. 2) argues that “[a]lthough the framework is unified by a dynamical systems description of the evolution of processing in the hybrid and multi-layered system, it recognises the novel contributions of the distinct processing profiles of the brain, body and environment.” However, the dynamical systems style approach to the acquisition and enactment of cognitive practices in the version first introduced in Menary (2007a, pp. 42-48) does not exhaustively specify the distinct, yet highly interactive neuronal and bodily components of cognitive processing. Furthermore, it does not account for LDP, simply because it remains neutral to the concrete realization of its neuronal component system. Finally, the dynamical systems approach, on Menary’s construal, helps illustrate what the interactive contribution of neuronal and extracranial bodily components to human cognition might amount to. Yet, it does not spell out the mutual influence that neuronal and extracranial bodily components have over each other.

This is where predictive processing (PP) enters the picture. In the remainder of this commentary I will argue that the PP approach provides the resources for a more detailed account of how human cognitive systems become enculturated and how they are subject to integrated cognition.

2.1 Cognitive integration: Five theses about human cognition

In its original version (cf. Menary 2007a), CI is constituted by five theses. They emphasize the

different aspects that are crucial for an integrationist approach to cognitive processing: 1. Human cognition is continuous with animal cognition on both diachronic and synchronic scales. However, it has a special status in that it is situated in a particular cognitive niche and heavily rests upon neural plasticity which is itself an adaptation (*continuity thesis*). 2. Certain cognitive processes are hybrid because they are constituted by neuronal and extracranial bodily components (*hybrid mind thesis*). 3. In the course of ontogenetic hybrid cognitive processing, both the constitutive neuronal and extracranial bodily functions are transformed (*transformation thesis*). 4. The bodily manipulation of specific environmental resources plays a crucial functional role in integrated cognitive processes (*manipulation thesis*). 5. These manipulations are constrained by cognitive norms, which are acquired through learning, and which realize socio-culturally developed habits for the interaction with cognitive resources (*cognitive norms thesis*).

In addition to the continuity thesis and the cognitive transformation thesis, which are given centre stage in Menary’s target paper, the hybrid mind thesis is important in that it acknowledges the close interaction of neuronal and extra-neuronal bodily sub-processes in the completion of cognitive tasks. In other words, certain cognitive processes “involve the integration of neural manipulations of vehicles and bodily manipulations of environmental vehicles” (Menary 2010, p. 236; see also Menary 2007b, p. 627). The notion of bodily manipulation as it is used here goes back to Mark Rowlands’ (1999, pp. 23f) account of *environmentalism*, which claims that “cognitive processes are, in part, made up of manipulation of relevant structures in the cognizer’s environment”. In this context, manipulation is defined as “any form of bodily interaction with the environment – manual or not, intrusive or otherwise – which makes use of the environment in order to accomplish a given task” (*ibid.*, p. 23). Thus, subscribing to the manipulation thesis amounts to the assumption that “[c]ognitive processing often involves these online bodily manipulations of the cognitive niche, sometimes as individuals and sometimes

in collaboration with others” (Menary [this collection](#), p. 3). Importantly, it is assumed that extracranial bodily manipulations causally interact with neural sub-processes, thereby stressing the hybridity of cognitive processes (cf. Menary 2007a, p. 138). In addition to highlighting the constitutive role of embodied engagements with “external” cognitive resources as proposed by Rowlands (1999), cognitive integrationists claim that the manipulation of these resources is constrained by cognitive norms. In this vein, Menary (2007a, p. 5; 2010, p. 233) argues that “[o]ur abilities to manipulate the extrabodily environment are normative and are largely dependent on our learning and training histories.” The idea that certain cognitive abilities are normatively structured thus concerns the individual’s interaction with specific resources provided by the cognitive niche. Importantly, the normatively constrained ways in which environmental resources are integrated into cognitive processes are shared by many individuals. Put differently, the normativity of cognitive practices helps “[...] stabilise and govern interactive thought across a population of similar phenotypes” (Menary [this collection](#), p. 4). Furthermore, the acquisition of a certain cognitive practice is tightly connected with the acquisition of the relevant cognitive norms in the course of scaffolded learning. This is because “we learn cognitive practices by learning the cognitive norms that govern the manipulation of vehicles” (Menary 2007b, p. 628).

From these five theses defended by CI it follows that there should be two distinct, yet interdependent levels of description for cognitive practices. First, there is the social level of description. On this level, cognitive practices need to be approached by highlighting the interactive, cooperative cognitive achievements of a large group of individuals sharing the same cognitive niche. Second, cognitive practices can be investigated by approaching them on an individual level of description. In this case, the acquisition and enactment of a certain cognitive practice is described with regards to a certain individual. However, any individual level description needs to acknowledge that certain cognitive capacities of an enculturated individual

are rendered possible only by the individual’s ongoing interaction with its socio-culturally shaped environment in normatively constrained ways. This means to do justice to the broader socio-cultural context of enculturated cognition, while being interested in a precise description of its neuronal and extracranial bodily sub-components. In this commentary I will operate on the individual level of description without denying that it is important to develop a fine-grained description on the social level by specifying the properties of a certain cognitive niche and the conditions under which it could have emerged.

To this end, I will now proceed by summarizing the most important features of the predictive processing (PP) approach that will help specify the mechanistic underpinnings of enculturated cognition.

2.2 An outline of predictive processing

Recently, the idea that human perception, action, and cognition can be described and explained in terms of hierarchically organized predictive processing mechanisms implemented in the human brain has enjoyed widespread attention within cognitive neuroscience (e.g., Friston 2005, 2010; Friston et al. 2012), philosophy of mind, and philosophy of cognitive science (e.g., Clark 2012, 2013, [this collection](#); Hohwy 2011, 2012, 2013, 2014, [this collection](#); Seth [this collection](#)). The overall epistemic goal of this emerging approach is to describe perceptual, sensorimotor, and cognitive target phenomena within a single framework by relying on unifying mechanistic principles. Accounts of PP generally assume that human perception, action, and cognition are realized by Bayesian probabilistic generative models implemented in the human brain. Since the human brain does not have immediate access to the environmental causes of sensory effects, it has to infer the most probable state of affairs in the environment giving rise to sensory data (cf. Seth [this collection](#), pp. 4f). PP approaches solve this *inverse problem* by assuming that generative models in accordance with Bayes’ rule are implemented in the human brain. On this construal, a generative model

“[...] aims to capture the statistical structure of some set of observed inputs by tracking [...] the causal matrix responsible for that very structure” (Clark 2013, p. 182). In order to be able to infer the causes of sensory effects, generative models encode probability distributions. Each generative model provides several hypotheses about the causes of a certain sensory input. The system has somehow to ‘decide’ which hypothesis needs to be chosen in order to account for the cause of the sensory effect. The descriptive power of Bayes’ rule lies in its capacity to capture the probabilistic estimations underlying these choices. Applied to the case of human perception, action, and cognition, Bayesian generative models are assumed to be realized in hierarchically organized structures comprising multiple, highly interactive low- and high-level cortical areas. This is referred to as the *Bayesian brain hypothesis* (cf. Friston 2010, p. 129). The hierarchical organization of probabilistic generative models is combined with a specific version of *predictive coding*, where predictive coding “depicts the top-down flow as attempting to predict and fully ‘explain away’ the driving sensory signal, leaving only any residual ‘prediction errors’ to propagate forward within the system” (Clark 2013, p. 182). That is to say, selected hypotheses inform prior predictions about the sensory input to be expected at each level of the hierarchy. These predictions fulfil the function of encoding knowledge about statistical regularities of patterns in the observable (or any imaginable) world. This hypothesis selection proceeds in accordance with Bayes’ rule. The processing of sensory input gives rise to prediction errors. Prediction errors carry neuronally realized information about “[...] residual differences, at every level and stage of processing, between the actual current signal and the predicted one” (Clark this collection, p. 4). Importantly, it is only prediction errors, and not sensory input *per se*, that are fed forward within the hierarchy (cf. Clark 2013, pp. 182f; Hohwy 2012, p. 3, 2013, p. 47, 2014, p. 4). The overall aim of this multi-level processing mechanism is to *minimize prediction error*, that is, to reduce or to ‘explain away’ the discrepancy between predictions and the actually given sensory input

that is an effect of environmental (or bodily) causes (cf. Clark 2013, p. 187; Hohwy 2011, p. 269, 2013, p. 88). This is known as *prediction error minimization*.²

Prediction error minimization is a special way of minimizing *free energy* in accordance with the principle “that any self-organizing system that is at equilibrium with its environment must minimize its free energy” (Friston 2010, p. 127). Applied to human perception, cognition, and action, minimizing free energy means minimizing the amount of unbound energy available to the perceiving, cognizing, and acting organism. This is where prediction error enters the picture. As Andy Clark (2013, p. 186) puts it, “[p]rediction error reports this information-theoretic free energy, which is mathematically constructed so as always to be greater than ‘surprisal’ (where this names the sub-personally computed implausibility of some sensory state given a model of the world [...]).” The relationship between free energy and surprisal then is that “[...] free energy is an upper bound on surprise, which means that if agents minimize free energy, they implicitly minimize surprise” (Friston 2010, p. 128). Suprisal, however, cannot be estimated directly by the system, because “there is an infinite number of ways in which the organism could seek to minimize surprise and it would be impossibly expensive to try them out” (Hohwy 2012, p. 3). The solution to this problem lies in implicitly minimizing surprisal (and its upper bound, i.e., free energy) by minimizing prediction error (cf. Hohwy 2013, p. 85, this collection, 3; see also Seth this collection, p. 6). It is exactly here where prediction

2 On a neuronal level of description, hierarchical generative models are assumed to be neuronally realized by multiple connections across low- and high-level cortical areas. Each level within the cortical hierarchy is connected to the next subordinate and supraordinate level, thereby ensuring effective inter-level message passing (cf. Hohwy 2013, pp. 67f). According to Clark (2013, p. 187), predictive generative models are implemented in “a kind of duplex architecture”. This means that there are distinct neuronal units dedicated to the representation of predictions of environmental (or bodily) causes, so-called *representation units*, on the one hand, and those dedicated to the encoding of prediction error, so-called *error units*, on the other (cf. *ibid.*; Friston 2005, p. 829). To date, a detailed account of the concrete neuronal realization of these functionally distinct units of message-passing is still missing (cf. *ibid.*). However, it is hypothesized that representation units might correspond to superficial pyramidal cells, while error units might correspond to deep pyramidal cells (cf. Friston et al. 2012, p. 8; see also Clark 2013, pp. 187f).

error minimization avails itself as a tractable expression of more general life-sustaining mechanisms.

Prediction error minimization can be achieved in two distinct, yet complementary ways. The first of these is *perceptual inference*, which can be described as

[...] an iterative step-wise procedure where a hypothesis is chosen, and predictions are made, and then the hypothesis is revised in light of the prediction error, before new and hopefully better predictions are made on the basis of the revised hypothesis. (Hohwy 2013, p. 45)

That is, prediction errors are propagated up the hierarchy leading to an adjustment of the initial hypothesis, thereby achieving an approximation of the hypothesis generating the predictions and the actually given input. The adjustment of predictions and hypotheses in the face of feed-forward prediction error occurs at every level of the hierarchy until any prediction error is accommodated. This complex process comprising multiple levels is known as perception: “Perception thus involves ‘explaining away’ the driving (incoming) sensory signal by matching it with a cascade of predictions pitched at a variety of spatial and temporal scales” (Clark 2013, p. 187; see also Clark 2012, p. 762).

On Andy Clark’s account of PP, one important consequence of this is that the traditional distinction between perception and cognition becomes blurred. It is replaced by a reconceptualization of perceptual and cognitive processes as a continuous employment of the same prediction error minimizing mechanism on multiple scales:

All this makes the lines between perception and cognition fuzzy, perhaps even vanishing. In place of any real distinction between perception and belief we now get variable differences in the mixture of top-down and bottom-up influence, and differences of temporal and spatial scale in the internal models that are making predictions. Top-level (more ‘cognitive’) models

intuitively correspond to increasingly abstract conceptions of the world, and these tend to capture or depend upon regularities at larger temporal and spatial scales. Lower-level (more ‘perceptual’) ones capture or depend upon the kinds of scale and detail most strongly associated with specific kinds of perceptual contact. (Clark 2013, p. 190)

Consequently, processes typically associated with perception or cognition can only be distinguished by considering the temporal and spatial resolution of the instantiation of PP mechanisms and the levels at which model revision ensues, respectively. This relationship between perception and cognition becomes important once we consider how enculturated cognition has been rendered possible on both phylogenetic and ontogenetic time scales. For it helps specify how evolutionary continuity could have been rendered possible in the first place. The evolutionary development of perception and cognition (and, as we shall see, of action too) may have proceeded from more perceptual generative models present in many other animals to more cognitive generative models exclusively realized in humans. This is in line with Roepstorff’s (2013, p. 45) observation that “[t]he underlying neural models are basically species-unspecific, and the empirical cases move back and forth between many different model systems.” Referring to this observation, Clark (this collection, p. 14) emphasizes that “[t]he basic elements of the predictive processing story, as Roepstorff (2013, p. 45) correctly notes, may be found in many types of organism and model-system.” Thus, while certain (lower-level) model parameters and processing stages of prediction error minimization are shared by many organisms, there certainly are specific (higher-level) processing routines that are shared only by enculturated human organisms in a certain cognitive niche.

Furthermore, the idea that perception and cognition are continuous is relevant for considerations of the ontogenetic development of enculturated cognitive functions. This is because it anchors higher-order cognitive operations in

more basic perceptual processes and thus allows for a fine-grained description of a certain developmental trajectory leading to cognitive transformation. Bearing in mind the hierarchical structure of generative models, another interesting consequence of the PP style approach to perception and cognition is that lower (i.e., more perceptual) levels of the generative model influence higher (i.e., more cognitive) levels by means of fed-forward prediction error. Vice versa, higher levels of the hierarchical generative model influence lower levels by means of fed-backward predictions (cf. Hohwy 2013, p. 73). This will become more important when we explore how reading acquisition can be described as an ongoing enculturating process of prediction error minimization.

Perceptual inference is only one way of minimizing prediction error. The second is *active inference*, where “[...] the agent will selectively sample the sensory input it expects” (Friston 2010, p. 129). The idea is that the system can minimize prediction error by bringing about the states of affairs (i.e., the environmental hidden causes) that are predicted by a certain hypothesis. This is achieved by performing any type of bodily movements, including eye movements, that make the selected prediction come true. The predictions at play in active inference are *counterfactual*, because

[...] they say how sensory input *would* change if the system *were* to act in a certain way. Given that things are not actually that way, prediction error is induced, which can be minimized by acting in the prescribed way. (Hohwy 2013, p. 82; italics in original; see also Clark this collection, p. 6; Friston et al. 2012, p. 2)

Accordingly, in active inference the selected prediction is held constant and leads to bodily activities that minimize prediction error by altering the sensory input such that it confirms the prediction. Therefore, active inference is of crucial importance for prediction error minimization, “[...] since it provides the only way (once a good world model is in place and aptly activated) to actually alter the sensory signal so as

to reduce sensory prediction error” (Clark 2013, p. 202).

This suggests that perceptual and active inference, or perception and bodily action for that matter, mutually influence each other, thereby minimizing prediction errors and optimizing hypotheses generating ever new predictions. However, perceptual and active inference have a “different direction of fit” (Hohwy 2013, p. 178; see also Hohwy this collection, p. 13; Clark this collection, p. 7).³ This is because in perceptual inference, predictions are aligned to the sensory input, while active inference is a matter of aligning the sensory input to the predictions. It follows “[...] that to optimally engage in prediction error minimization, we need to engage in perceptual inference and active inference in a complementary manner” (Hohwy 2013, p. 91). Since both perceptual and active inference are aimed at minimizing prediction error and optimizing generative models, “[p]erception and action [...] emerge as two sides of a single computational coin” (Clark 2012, p. 760).

As emphasized earlier, perception and cognition are deeply related to the extent that both phenomena are the result of the same underlying functional and neuronal mechanisms. By extension, action is also deeply intertwined with cognition. This follows from the assumptions that 1. perception and cognition are continuous and 2. perception and action are subject to the same principles of prediction error minimization. As Seth (this collection, p. 5) puts it, both ways of prediction error minimization “[...] unfold continuously and simultaneously, underlining a deep continuity between perception and action [...]” Yet, perceptual and active inference fulfil distinct functional roles in their ongoing attempt to minimize prediction error. This becomes even more obvious once we take the free energy principle into account: “The free energy principle [...] does not posit any fundamental difference between perception and action. Both fall out of different reorganizations of the principle and come about mainly as different direc-

3 The notion of two functions having “a different direction of fit” originates in J. L. Austin’s (1953, p. 234) speech act theory and in G. E. M. Anscombe’s (1963, p. 56) example illustrating how words and states of affairs can relate to each other. I would like to thank Thomas Metzinger for pointing out the philosophical history of this notion.

tions of fit for prediction error minimization [...]” (Hohwy this collection, p. 13). Active inference plays a crucial role in cognition (understood as prediction error minimization comprising many higher-level predictions), for it helps minimize prediction error throughout the cortical hierarchy by bringing about the states of affairs in the environment that are predicted on higher levels. Therefore, on Clark’s (2013, p. 187) account, which he dubs *action-oriented predictive processing*, prediction error minimization “[...] depicts perception, cognition and action as profoundly unified and, in important respects, continuous.”

PP accounts of human perception, action, and cognition distinguish between first-order and second-order statistics. In contrast to first-order statistics, which amount to minimizing prediction error by means of perceptual and active inference, second-order statistics are concerned with estimating the *precision* of prediction error. In second-order statistics, the influence of feed-forward prediction error on higher levels of the hierarchical generative model is dependent upon its estimated precision. Neuronally, the estimation of precision is captured in terms of increasing or decreasing the *synaptic gain* of specific error units (cf. Feldman & Friston 2010, p. 2). That is, “[t]he more precision that is expected the more the gain on the prediction error in question, and the more it gets to influence hypothesis revision” (Hohwy 2013, p. 66; see also Friston 2010, p. 132). Conversely, if the precision is expected to be poor on the basis of second-order statistics, the synaptic gain on the error unit is inhibited such that the prediction on the supraordinate level is strengthened (cf. *ibid.*, p. 123). It has been proposed that precision estimation is equivalent to attention. This means that “attention is nothing but optimization of precision expectations in hierarchical predictive coding” (Hohwy 2013, p. 70; see also Feldman & Friston 2010, p. 2). For current purposes, it is sufficient to focus in the main on first-order statistics. However, it is important to bear in mind the crucial modulatory role precision estimation plays in prediction error minimization.

2.3 Combining cognitive integration and predictive processing

To what extent is it feasible to describe the mechanisms underlying cognitively integrated processes and enculturated cognition in terms of prediction error minimization? After having summarized CI and the core ideas of the PP framework I will argue in this section that there are many aspects of the CI approach that can be enriched by making a crucial assumption, namely that PP can account for many components constituting cognitive practices on at least functional and neuronal levels of description.

First, a major conceptual consequence of PP is that perception, action, and cognition are both continuous and unified, if this approach proves correct. This is because they follow the same principles of prediction error minimization, yet are characterized by important functional differences. This kind of complementarity fits neatly with the *hybrid mind thesis* defended by CI. Recall that the hybrid mind thesis claims that cognitive processes are constituted by both neuronal and extracranial bodily components. By taking prediction error minimization into account, this claim can be cashed out by assuming that the neuronal components are equal to perceptual inferences at multiple levels of the cortical hierarchy, while the bodily components are mechanistically realized by active inferences. The hybrid mind thesis emphasizes the indispensable, close and flexible coordination of neuronal and bodily components responsible for the completion of a cognitive task. The PP framework, or so I shall argue, provides the resources for a careful description of the underlying mechanisms at play. It does so by depicting human organisms as being constantly engaged in prediction error minimization by optimizing hypotheses in the course of perceptual inference and by changing the stimulus array in the course of active inference.

A second advantage of the prediction error minimization framework is that it helps cash out the *manipulation thesis*. This thesis, recall, states that “the manipulation of external vehicles [is] a prerequisite for higher cognition and embodied engagement [is] a precondition

for these manipulative abilities” (Menary 2010, p. 232). In terms of the PP framework, bodily manipulation can be understood as an instance of active inference occurring in specific contexts. That is, in order to complete a certain cognitive task, the system changes its sensory input by altering certain components of its cognitive niche. This becomes even more obvious once we take into account that embodied activity is also a means of increasing confidence in sensory input by optimizing its precision. As suggested by Hohwy (this collection, p. 6), “expected precision drives action such that sensory sampling is guided by hypotheses that the system expects will generate precise prediction error.” Applied to an organism’s interaction with its socio-culturally shaped environment, Hohwy (2013, p. 238) argues “[...] that many of the ways we interact with the world in technical and cultural aspects can be characterized by attempts to make the link between the sensory input and the causes more precise (or less uncertain).” However, bodily manipulation is more than just a contributing factor to prediction error minimization (and precision optimization). In order to acknowledge this, we need to take into account that bodily manipulations are a crucial component of the performance of cognitive practices. In the performance of a cognitive practice, the minimization of prediction error and the optimization of precision is not an end in itself. Rather, it serves to facilitate the completion of a certain cognitive task. Furthermore, the concrete bodily manipulations given in terms of active inference are subject to cognitive norms that constrain the ways in which human organisms interact with cultural resources, such as tokens of a representational writing system. That is to say that the performance of a cognitive practice is not an individualistic enterprise. Rather, in completing a cognitive task, the individual is deeply immersed into a socio-cultural context which is shared by many human organisms.

Third, it is the normative constraints on cognitive practices that render their performance efficient and, in many cases at least, successful. This is because compliance with these norms induces what Andy Clark (2013, p. 195)

calls “path-based idiosyncrasies”. That is, one of the reasons why the coordination of neuronal and bodily components in the manipulation of cultural resources is beneficial certainly is that it takes place in a normatively constrained “multi-generational development of stacked, complex ‘designer environments’ for thinking such as mathematics, reading, writing, structured discussion, and schooling” (ibid.). That is to say that the performance of cognitive practices in compliance with certain norms has the overall advantage of reducing cognitive effort, which can be captured as the minimization of overall prediction error and the optimization of precision on a sub-personal level of description. At the same time, however, cognitive practices themselves can be described, or so I shall argue, as having prediction error minimization as their underlying mechanism. This double role of cognitive practices, described in terms of prediction error minimization, can be fully appreciated once we consider the cognitive transformations brought about by the ongoing interaction with cultural resources.

Fourth, our cognitive capacities and the various ways we complete cognitive tasks are profoundly augmented by our neuronal and bodily engagements with the socio-culturally structured environment through ontogenesis (cf. Menary 2006, p. 341). Put differently, “cognitive transformations occur when the development of the cognitive capacities of an individual are sculpted by the cultural and social niche of that individual” (Menary this collection, p. 8). This niche includes mathematical symbol systems, representational writing systems, artifacts, and so forth. It is this immersion and, importantly, the scaffolding provided by other inhabitants of the cognitive niche that ideally lead to the transformation of neuronal and extracranial bodily components constituting cognitive processes, to enculturation that is. The PP framework, or so I shall argue, offers a highly promising account of learning that is most suitable for a sub-personal level description of cognitive transformation. On the construal of PP, learning flows naturally from the mechanism of prediction error minimization. For learning can generally be construed as a sub-personally real-

ized strategy of optimizing models and hypotheses in the face of ever new prediction error: “Learning is then viewed as the continual updating of internal model parameters on the basis of degree of predictive success: models are updated until they can predict enough of the signal” (Hohwy 2011, p. 268). Broadly understood, ‘learning’ thus figures as an umbrella term referring to the ongoing activity of prediction error minimization and model optimization throughout the lifetime of a human organism. This is because potentially ever new and “surprising” sensory signals need to be “explained away” by perceptual and active inference. For current purposes, however, “learning” can also be understood in a rather narrow sense as the acquisition of a certain skill, which is also subject to prediction error minimization through perception, action, cognition, and the modulation of attention. It is the individual’s socio-culturally structured environment that delivers new sensory signals helping optimize parameters of the generative model:

But those training signals are now delivered as part of a complex developmental web that gradually comes to include all the complex regularities embodied in the web of statistical relations among the symbols and other forms of socio-cultural scaffolding in which we are immersed. We thus self-construct a kind of rolling ‘cognitive niche’ able to induce the acquisition of generative models whose reach and depth far exceeds their apparent base in simple forms of sensory contact with the world. (Clark 2013, p. 195)

However, complex skills that are targeted at the completion of cognitive tasks cannot be learned simply by being exposed to the right kind of “training signal” in the cognitive niche. What is additionally needed is engagement in activities that are scaffolded by inhabitants of that cognitive niche who have already achieved a sufficient degree of expertise. This is what Menary (this collection) calls “scaffolded learning”. From the perspective of PP, this amounts to the strategy of exposing predictive systems to

highly structured, systematically ordered patterns of sensory input in the cognitive niche. This, however, needs to be complemented by a fine-grained personal-level description of the kind of interactions between experts and novices that is needed in order to pass on the right set of cognitive norms. Furthermore, the kind of cognitive transformation at play here requires a description of the neuronal changes that are correlated with the acquisition of a certain cognitive practice. That is, we need a more fine-grained account of LDP and how it might be realized in the human cortex. From the perspective of the PP framework, one plausible conjecture at this point is that LDP can be captured in terms of *effective connectivity*. Effective connectivity reports the causal interaction of neuronal assemblies across multiple levels of the cortical hierarchy (and across different brain areas) as a result of attention in terms of precision estimation. This line of reasoning is implied by Clark (2013, p. 190) who argues that “[a]ttention [...] is simply one means by which certain error-unit responses are given increased weight, hence becoming more apt to drive learning and plasticity, and to engage in compensatory action.” This last point is important, since it stresses that it is not only perceptual inference that drives learning and contributes to the improvement of generative models, but also active inference. However, this approach to the acquisition of action patterns in concert with an optimization of precision might raise the worry that learning is depicted here as being a rather internalistic, brain-bound affair. But once we acknowledge that it is the performance and ongoing improvement of embodied active inferences that play an indispensable functional role in the completion of cognitive tasks, it becomes obvious that this worry is not warranted. For it is the efficient interaction of neuronal and extracranial bodily components (i.e., perceptual and active inferences in terms of PP) that results from learning and the efficient engagement of human organisms with their environment. Furthermore, LDP can now be considered in terms of the precision-weighted optimization of hypotheses throughout the cortical hierarchy and the ever new patterns of effective con-

nectivity, as new cognitive practices are acquired and successfully performed. The sub-personal description of cognitive transformation in terms of prediction error minimization also does justice to neuronal reuse as a guiding principle of the allocation of neuronal resources for phylogenetically recent cognitive functions such as arithmetic or reading.

From this, the following question arises: What is the actual relationship between CI and PP supposed to be and what is the scope of this theory synthesis? First of all, the position developed in this commentary is neutral with regards to metaphysical consequences that may or may not result from the idea that CI and PP can be integrated into a unified theoretical framework. Rather, this position has an instrumentalist flavour to the extent that it tries to answer the question by which means socio-culturally shaped target phenomena can be best investigated both conceptually and empirically. Thus, the combination of CI and PP is valid only to the extent that it displays great descriptive as well as predictive power and is supported by many results stemming from empirical research. As such, the new approach on offer here is contingent upon the current state of research in cognitive science. It is falsifiable by new empirical evidence or convincing conceptual considerations that directly speak against it. Furthermore, it sidesteps the concern that PP and the underlying free energy principle might be trivial because they can be applied to any target phenomenon by telling a “just-so story”. This is because the combination of CI and PP is applied to specific domains, namely to classes of cognitive processes that count as cognitive practices, with reading being the paradigm example.⁴ Thus the approach advocated can be seen as a modest contribution to the project aiming at a “[...] translation into more precise, constricted applications to various domains, where predictions can be quantified and just-so stories avoided” (Hohwy [this collection](#), p. 14).

The idea that CI and PP can be combined can lead to different degrees of commitment.⁵

First, I do not assume that CI *necessarily requires* PP. Hypothetically, it is conceivable that another theory of neuronal and bodily functioning might be more suited to cashing out cognitive practices and enculturation more convincingly and more extensively. To date, PP appears to be the best unifying framework that helps specify exhaustively the functional and neuronal contributions of bodily and neuronal sub-processes giving rise to cognitive practices and enculturation. This is because PP offers a fine-grained functional and neuronal description of perception, action, cognition, attention, and learning that does justice to the complex interactions stipulated by CI and the associated approach to enculturation.

Second, it could be assumed that CI and PP are merely compatible. This would mean that CI and PP were self-sufficient and co-existent theoretical frameworks whose claims and key assumptions do not necessarily contradict each other. This compatibility assumption is too weak for various reasons that have been presented in this commentary so far. For it is the purpose of the theory synthesis sketched here to enrich and refine the notion of enculturation and the associated theses defended by CI. Furthermore, to the extent that PP directly speaks to complex cognitive phenomena and learning, it benefits from the effort of CI to do justice to the socio-culturally shaped context in which these phenomena can be developed. This is to say that CI and PP can be directly referred to each other in ways that I have started to illustrate in this section.

Finally, from this it follows that both frameworks are more than just compatible – they are *complementary*. Taken together, they provide us with complex and far-reaching conceptual tools for investigating complex cognitive phenomena that are shaped by the individual’s immersion in its cognitive niche. Thus, the complementarity of CI and PP leads to a new integrative framework that I dub enculturated predictive processing (EPP).

2.4 Defending enculturated predictive processing

At first glance, the EPP framework might appear to be unwarranted. For prediction error

⁴ Thanks to Jennifer M. Windt for raising this point.

⁵ Thanks to an anonymous reviewer for helpful suggestions on this issue.

minimization could be construed as being a purely internalistic, brain-bound affair that does not leave any room for the idea that cognitive processes are constituted both by neuronal and extracranial bodily components that are normatively constrained, socially scaffolded, and deeply anchored in a socio-culturally structured environment.

First, consider a position that takes for granted that cognitive processes can be coherently described in terms of prediction error minimization, but which denies that cognitive processes are co-constituted by neuronal and bodily sub-processes operating on socio-cultural resources. Such a position is defended by [Jakob Hohwy \(2013, p. 240\)](#) who argues that “[...] many cases of situated and extended cognition begin to make sense as merely cases of the brain attempting to optimize its sensory input so it, as positioned over against the world, can better minimize error.” In particular, according to his interpretation of the prediction error minimization framework, “[...] the mind remains secluded from the hidden causes of the world, even though we are ingenious in using culture and technology to allow us to bring these causes into sharper focus and thus facilitate how we infer to them.” (*ibid.*, p. 239)

For Hohwy, this directly follows from the causal relations holding between the predictive system and the environmental causes it constantly tries to infer. According to him (*ibid.*, p. 228), this relation needs to be characterized as “direct” and “indirect” at the same time:

[...] the intuition that perception is indirect is captured by its reliance on priors and generative models to infer the hidden states of the world, and the intuition that perception is direct is captured by the way perceptual inference queries and is subsequently guided by the sensory input causally impinging on it.

Since the causal relation that holds between a predictive system comprised of inverted generative models and the world is partly indirect, so the argument goes, the system is in constant embodied interaction and direct contact with its

environment only insofar as it tries to make the effects of hidden causes fit the predictions. This precludes the theoretical possibility of depicting prediction error minimizing systems as being situated, scaffolded, integrated, or extended.

However, this line of reasoning fails to acknowledge the conceptual necessity of emphasizing the functional role of embodied active inference in terms of its contribution to the minimization of prediction error and the optimization of predictions. For even if the causal relations holding between a predictive, generatively organized system and environmental causes are mediated by hypotheses, predictions, prediction errors and precision estimation as encoded in the cortical hierarchy, it does not follow that this system is just a passive receiver of sensory input that informs it about remote states in the environment. Similarly, it does not necessarily follow from the prediction error minimization framework that it “[...] creates a sensory blanket – the evidentiary boundary – that is permeable only in the sense that inferences can be made about the causes of sensory input hidden beyond the boundary”, as [Hohwy \(2014, p. 7\)](#) claims. Rather, the predictive system is part of its socio-culturally structured environment and has many possibilities for bodily acting in that environment in order to facilitate its own cognitive processing routines. Considering embodied active inference, it turns out that the causal relation holding between embodied action (in terms of bodily manipulation) and changes of the set of available stimuli in the environment is as direct as any causal relation could be. This is because these changes are an immediate effect of these very prediction error-minimizing and precision-optimizing actions, which in turn contribute to the performance of cognitive tasks. Furthermore, we need to take into account that genuinely human cognitive processes occur in a culturally sculpted cognitive niche, which is characterized by mathematical symbol systems, representational writing systems, artifacts, and the like, and other human organisms with whom we interact. These cognitive resources have unique properties that render them particularly useful for the completion of cognitive tasks.⁶ For example, consider the regularity of line

⁶ Thanks to Richard Menary for raising this important point in personal communication.

arrangements and the orderliness of succeeding letters in an alphabetic writing system. Once learned and automatized, following these normative principles facilitates several types of cognitive processing routines. That is to say that it is the socio-culturally shaped sensory input itself that has an important impact on the concrete realization of prediction error minimization. This cannot be accounted for if we assume that the predictive processing of cognitive resources is an internalistic, secluded endeavour.

Second, consider a line of reasoning that goes against the compatibility of CI with the prediction error minimization framework, that might be put forward by an integrationist. She might agree that we need a mechanistic description of the neuronal and bodily components which jointly constitute cognitive processes in the close interaction with socio-cultural resources. But she might continue to argue that the performance of cognitive practices is more than just the minimization of prediction error and the optimization of precision.⁷ From the perspective of PP, it needs neither to be denied that human cognitive systems as a whole aim to fulfil cognitive purposes by completing cognitive tasks and that they do so by engaging in cognitive practices. Nor should it be rejected that cognitive practices are normatively constrained and that cognitive systems are deeply immersed in a socio-culturally structured environment, which in turn provides these very norms through scaffolding teaching. However, the important theoretical contribution made by the prediction error minimization framework is its providing of a sub-personal, mechanistic description of the underlying neuronal and bodily sub-processes that turns out to be parsimonious, conceptually coherent, and empirically plausible. In addition, PP also offers a description of the close interaction of the neuronal and bodily components constituting cognitive practices by offering a concise description of the ongoing, mutually constraining interplay of perceptual and active inferences. More generally, this section should have established that all important claims and assumptions made by CI in favour of cognitive

practices, such as the hybridity, the transformative efficacy, and the enculturated nature of cognitive processes, can be supplemented and refined by taking the prediction error minimization framework into account.

The arguments in favour of the EPP framework directly speak to the current debate within philosophy of mind and philosophy of cognitive science about the relationship between the prediction error minimization framework and approaches to situated, distributed, integrated, or extended cognition. On the one hand, [Jakob Hohwy](#) (2013, 2014) denies on both methodological and metaphysical grounds that there is anything like these types of cognition from the perspective of prediction error minimization. According to him, this is because predictive systems have only indirect access to the world. Furthermore, there is “the sensory boundary between the brain and the world” which prohibits predictive systems from engaging in any variant of situated, distributed, integrated, or extended cognition including CI ([Hohwy 2013](#), p. 240). On the other hand, [Andy Clark](#) (2013, p. 195) argues that the PP framework at least “[...] offers a standing invitation to evolutionary, situated, embodied, and distributed approaches to help ‘fill in the explanatory gaps’ while delivering a schematic but fundamental account of the complex and complementary roles of perception, action, attention, and environmental structuring.” Once we take the arguments and considerations in favour of EPP into account we have reasons to think that EPP lends support to Clark’s construal of the PP framework. This will become even more persuasive once we take empirical data and a paradigm case of EPP into account.

3 Reading acquisition: A case of enculturation

So far, I have argued that the notion of enculturation and key claims made by CI can be enriched by taking the PP framework into account. In particular, the hybridity, embodiedness, and transformative character of enculturated cognition can be mechanistically described in terms of prediction error minimization. How-

⁷ This consideration was put forward by Richard Menary in personal communication.

ever, cognitive practices cannot be fully reduced to prediction error minimization, since they have a normative dimension that needs to be investigated on a personal level of description.

This section serves to illustrate the validity of the line of reasoning put forward in this commentary. This will be done by showing that reading acquisition, understood as another case of enculturation next to mathematical cognition, can be fruitfully described from the perspective of EPP.

3.1 Scaffolded learning and the acquisition of cognitive norms

One crucial aspect of learning to perform a cognitive practice is the acquisition of the relevant cognitive norms, where this class of norms “govern[s] manipulations of external representations, which aim at completing cognitive tasks” (Menary 2010, p. 238). In the case of reading, these norms concern the recognition and identification of tokens of a representational writing system. In alphabetic writing systems, important cognitive norms are derived from the so-called *alphabetic principle*, where this principle amounts to the “mapping [of] written units onto a small set of elements – the phonemes of a language” (Rayner et al. 2001, p. 33; see also Snowling 2000, p. 87). Specifically, the correspondence of graphemes to phonemes puts culturally established, normative constraints on the ways in which individual letters (and combinations thereof) are related to phonological units. The normative scope of these correspondences is best illustrated by differences across languages and orthographies. As pointed out by Ziegler & Goswami (2006, p. 430), “[i]n some orthographies, one letter or letter cluster can have multiple pronunciations (e.g. English, Danish), whereas in others it is always pronounced in the same way (e.g. Greek, Italian, Spanish).”⁸ This demonstrates that the degree of consistency or transparency of *grapheme-phoneme correspondences* is subject to arbitrary stipulations by a linguistic, literate community employing a specific orthographic system. These stipulations are

normative insofar as they constrain the ways in which combinations of letters are pronounced and written words are correctly related to spoken words. The acquisition of this normative knowledge needs “explicit instruction in the alphabetic principle” (Rayner et al. 2001, p. 57).⁹ It follows that learning these norms is socially structured and dependent upon the cooperation of experts with novices. This fits neatly with Menary’s (2013, p. 361) following assumption:

Manipulative norms and interpretative norms apply to inscriptions of a public representational system and are never simply dependent on an individual. Indeed, it is the individual who must come to be transformed by being part of the community of representational system users.

Acquiring knowledge about grapheme-phoneme correspondences, especially in an inconsistent orthography such as English, puts demands not only on the novice, but also on the teachers who assist her in learning these correspondences. For the teachers, being experts in reading, need to break down their automatic identification and recognition skills in order to be able to teach the norms underlying the relationship between graphemes and phonemes. As Sterelny (2012, p. 145) points out more generally, “[e]xpert performance is often rapid and fluent, without obvious components. Learning from such performance is difficult. It becomes much easier if the task is overtly decomposed into segments, each of which can be represented and practiced individually.” In the present context, the most successful strategy of teaching grapheme-phoneme correspondence has turned out to be so-called *phonics instruction* (cf. Rayner et al. 2001, pp. 31f): “[...] teaching methods that make the alphabetic principle explicit result in greater success among children trying to master the reading skills than methods that do not make it explicit” (ibid., p. 34). This goes along with teaching novices that spoken language consists of phonemes. That is, children’s reading acquisi-

⁸ This phenomenon is also known as orthographic depth. For a recent review, see Richlan (2014).

⁹ See also Dehaene (2010, p. 219), Dehaene (2011, p. 26), and Frith (1985, p. 307).

tion is dependent upon, or at least co-develops with *phonological awareness*, where this is understood as “[...] the ability to perceive and manipulate the sounds of spoken words” (Castles & Coltheart 2004, p. 78). The *metalinguistic awareness* that spoken language consists of phonemes must be explicitly acquired and allows the novice to learn that these units correspond to letters, or combinations thereof. It is still debated whether phonological awareness is a prerequisite for learning to read or whether it is co-emergent with basic letter decoding skills. However, as suggested by Castles & Coltheart (2004, p. 104), “[...] it may not be possible for phonemic awareness to be acquired at all in the absence of instruction on the links between phonemes and graphemes.” Thus, it seems safe to assume that phonological awareness clearly facilitates the ability to relate graphemes to phonemes. There are other components of metalinguistic awareness that influence the successful application of norms governing alphabetic representational writing systems. Beginning readers are already proficient speakers of their native language and are able to fluently apply syntactic, semantic, and pragmatic norms in their everyday conversations. However, they are usually unable to explicitly represent that utterances are made up of sentences and that sentences are made up of combinations of words (cf. Frith 1985, p. 308; Rayner et al. 2001, p. 35). To novices, these basic properties must be made explicitly available in order to put those novices in the position to apply knowledge about them automatically and fluently at later stages of reading acquisition. Furthermore, novices need to be acquainted with the convention, which is fairly obvious to expert readers, that alphabetic writing systems are decoded from left to right and from the top to the bottom of a page. These basic personal-level components of the acquisition of reading skills provide the cognitive norms necessary for the development of reading understood as a cognitive practice. It is these norms that govern the successful manipulation of representational vehicles belonging to an alphabetic writing system that need to be established by social interaction between learners and teachers. Thus, be-

coming proficient in applying the alphabetic principle, getting to grips with phoneme-grapheme correspondences, and developing phonological and metalinguistic awareness are cases of scaffolded learning.

3.2 Reading acquisition and neuronal transformation

Next to scaffolded learning, another crucial aspect of cognitive transformation is LDP (cf. Menary 2013, p. 356, [this collection](#), p. 8). Indeed, in the case of reading acquisition, there is unequivocal evidence pointing to “[...] plastic changes in brain function that result from the acquisition of skills” (Ansari 2012, p. 93). By the same token, Ben-Shachar et al. (2011, p. 2397) emphasize that “[...] culturally guided education couples with experience-dependent plasticity to shape both cortical processing and reading development.” As Schlaggar & McCandliss (2007, p. 477) point out, the application of knowledge about grapheme-phoneme correspondences in novice readers “[...] implicates the formation of functional connections between visual object processing systems and systems involved in processing spoken language.” The left ventral occipitotemporal (vOT) area appears to play a crucial role in establishing these connections.

As mentioned by Menary ([this collection](#)), there has been consensus on the contribution of the vOT area to a neuronal reading circuit. In a series of experiments, Stanislas Dehaene, Laurent Cohen and their colleagues have made the remarkable discovery that neuronal activation in one particular region of the left vOT area is reliably and significantly associated with visual word recognition in adult, non-pathological readers (Cohen & Dehaene 2004; Dehaene 2005, 2010; Dehaene & Cohen 2011; Dehaene et al. 2005; McCandliss et al. 2003; Vinckier et al. 2007). This region, especially the left ventral occipito-temporal sulcus next to the fusiform gyrus, frequently responds to visually presented words regardless of the size, case, and font in which they are made available (cf. Dehaene 2005, p. 143; McCandliss et al. 2003, p. 293). This consistent finding has led these researchers

to call it the visual word form area (VWFA), since it crucially contributes to “[...] a critical process that groups the letters of a word together into an integrated perceptual unit (i.e. a ‘visual word form’)” (McCandliss et al. 2003, p. 293). However, it is debatable whether the left vOT area is almost exclusively dedicated to visual word recognition in expert readers, or whether this area serves several functions having to do with the (visual) identification of shapes more broadly construed (see Price & Devlin 2003, 2004, for a discussion). Nevertheless, the findings by Dehaene and his colleagues that the left vOT area plays a crucial role in the overall visual word recognition process is important and widely acknowledged, although the interpretations of its functional contribution differ.

An important motivation for research on the overall function of the left vOT area stems from considerations on the phylogenetic development of visual word recognition. Considering that writing systems were invented only approximately 5400 years ago, it is unlikely that the ability to read is the result of an evolutionary process (cf. Dehaene 2005, p. 134, 2010, p. 5; McCandliss et al. 2003, p. 293). In a nutshell, the crucial question is how visual word recognition is possible given “[...] that the human brain cannot have evolved a dedicated mechanism for reading” (Dehaene & Cohen 2011, p. 254). This is also referred to as the “reading paradox” (Dehaene 2010, p. 4). The solution to this paradox proposed by Dehaene and his colleagues is to assume “[...] that plastic neuronal changes occur in the context of strong constraints imposed by the prior evolution of the cortex” as a result of the human organism being exposed to tokens of a certain writing system (Dehaene & Cohen 2011, p. 254). Specifically, the idea is “[...] that writing evolved as a recycling of the ventral visual cortex’s competence for extracting configurations of object contours” (*ibid.*). This view, which has been dubbed the *neuronal recycling hypothesis* (cf. Dehaene 2005, p. 150), suggests that existing neuronal functions associated with visual cognition are “recycled” for the phylogenetically recent, ontogenetically

acquired capacity to recognize visually presented words (cf. Cohen & Dehaene 2004, p. 468; see also Menary 2014, p. 286). This “recycling” is in turn constrained by the overall evolved neuronal architecture and already existing processing mechanisms (cf. Dehaene 2010, pp. 146f). Thus, neuronal recycling is just a special type of neuronal reuse (see Anderson 2010, for a discussion). There are certain conditions that need to be met if a specific cortical area is to be ‘recycled’ for a phylogenetically recent cognitive function (see Menary 2014, p. 288). In the case of visual word recognition, the left vOT area is assumed to exert certain “functional biases” that make it most suitable for the recognition and identification of visually presented words: “(1) a preference for high-resolution foveal shapes; (2) sensitivity to line configurations; and (3) a tight proximity, and, presumably, strong reciprocal interconnection to spoken language representations in the lateral temporal lobe” (Dehaene & Cohen 2011, 256). These “functional biases”, however, do not preclude that the left vOT area is still engaged in other cognitive processes such as object recognition in skilled adult readers (cf. Carreiras et al. 2014, p. 93; Dehaene & Cohen 2011, p. 257; Price & Devlin 2004, p. 478). Rather, it helps explain why this area is found to be well-equipped for contributing to the overall process of visual word recognition. However, the question arises what the contribution of the left vOT area to the overall visual word recognition process is supposed to make. According to Cathy Price’s & Joseph Devlin’s (2011) Interactive Account (IA), the contribution of the left vOT area can be best described and explained in terms of PP. In line with the general principles of the PP framework presented above, they generally hold the following assumption: “Within the hierarchy, the function of a region depends on its synthesis of bottom-up sensory inputs conveyed by forward connections and top-down predictions mediated by backward connections” (Price & Devlin 2011, p. 247). In other words, the suggested synthesis equals the prediction error that results from the discrepancy

between top-down predictions and bottom-up sensory information. Applied to the patterns of neuronal activation associated with visual word recognition, this assumption is specified as follows:

For reading, the sensory inputs are written words (or Braille in the tactile modality) and the predictions are based on prior association of visual or tactile inputs with phonology and semantics. In cognitive terms, vOT is therefore an interface between bottom-up sensory inputs and top-down predictions that call on non-visual stimulus attributes. (Price & Devlin 2011, p. 247)

Accordingly, the vOT area is supposed to be associated with a distinct level of the hierarchical generative model responsible for visual word recognition mediating between higher-level, language-related predictions and bottom-up visual information. It follows that “[...] the neural implementation of classical cognitive functions (e.g. orthography, semantics, phonology) is in distributed patterns of activity across hierarchical levels that are not fully dissociable from one another” (*ibid.*, p. 249). Specifically, IA proposes a neuronal mechanism that is able to demonstrate how linguistic knowledge about phonology and semantics, encoded in top-down predictions, causally interacts with bottom-up information. This is because it is held that a prediction error is generated each time bottom-up information diverges from the associated top-down prediction. In turn, the resulting prediction error is associated with significant activation in the left vOT area. Empirical evidence supporting this approach to the functional contribution of the left vOT area to visual word recognition in expert readers is widely available (see, e.g., Bedo et al. 2014; Kherif et al. 2011; Kronbichler et al. 2004; Schurz et al. 2014; Twomey et al. 2011).

In reading acquisition, the left vOT area appears to be an equally important contributor to visual word recognition. According to Price & Devlin (2011, p. 248), the activation level of the vOT area develops in a non-linear fashion,

as the proficiency in visual word recognition increases:

In pre-literates, vOT activation is low because orthographic inputs do not trigger appropriate representations in phonological or semantic areas and therefore there are no top-down influences [...]. In early stages of learning to read, vOT activation is high because top-down predictions are engaged imprecisely and it takes longer for the system to suppress prediction errors and identify the word [...]. In skilled readers, vOT activation declines because learning improves the predictions, which explain prediction error efficiently [...].

That is, IA assumes that the level of activation within the left vOT area is dependent upon the general establishment and refinement of a generative model comprising both lower-level areas associated with visual processing and higher-level cortical areas associated with phonological and semantic knowledge. If this account turns out to be correct, the blurredness of the distinction between perception and cognition as suggested by Clark (2013) becomes vitally important. For it is the mutual interplay of lower-level processing stages (traditionally associated with visual processing) and higher-level processing stages (traditionally associated with phonological and semantic processing) that renders the successful acquisition of visual word recognition possible in the first place. Evidence in favour of IA comes from studies demonstrating that there is a significant increase of activation in this area as a result of exposure to visually presented words in beginning readers across different research paradigms and methodologies employing fMRI (e.g., Ben-Shachar et al. 2011; Gaillard et al. 2003; Olulade et al. 2013). Furthermore, two longitudinal ERP studies (Brem et al. 2010; Maurer et al. 2006) demonstrate that the left-lateralized occipito-temporal N1 effect, an effect associated with print sensitivity, does not develop in a linear fashion in the course of reading acquisition. Rather, Maurer et al.’s (2006, p. 756) comparison of their results obtained from their child participants with an adult control

group indicates that “[i]nstead of a linear increase with more proficient reading, the development is strongly nonlinear: the N1 specialization peaks after learning to read in beginning readers and then decreases with further reading practice in adults following an inverted U-shaped developmental time-course.” In this vein, [Brem et al. \(2010, p. 7942\)](#) interpret their results by suggesting that “[t]he emergence of print sensitivity in cortical areas during the acquisition of grapheme-phoneme correspondences is in line with the inverse U-shaped developmental trajectory of print sensitivity of the ERP N1, which peaks in beginning readers [...]”

Another consequence of [Price’s & Devlin’s \(2011\)](#) PP account of reading acquisition is that the activation level within the vOT should be associated with the degree of accuracy of top-down predictions in the face of bottom-up signals. This is supported by various studies demonstrating that higher-level activations of cortical areas associated with language processing are also present in beginning readers. For example, [Turkeltaub et al. \(2003, p. 772\)](#) report that “[a]ctivity in the left ventral inferior frontal gyrus increased with reading ability and was related to both phonological awareness and phonological naming ability. [...] Brain activity in the anterior middle temporal gyrus also increased with reading ability”, where this area is associated with semantic processing. Similarly, [Gaillard et al. \(2003\)](#) report activation in the middle temporal gyrus, which is frequently associated with semantic processing in expert readers (e.g., [Bedo et al. 2014, p. 2](#); [Price & Mechelli 2005, p. 236](#); [Vogel et al. 2013, p. 231](#); [Vogel et al. 2014, p. 4](#)). Furthermore, they report significant activation patterns in left IFG, which is associated with both phonological and semantic processing.

In the light of much empirical evidence in favour of [Price’s & Devlin’s \(2011\)](#) approach to the neuronal changes corresponding to reading acquisition, it seems safe to assume that it is empirically plausible and can account for many data derived from experiments in cognitive neuroscience. However, to what extent can this approach be conceptually enriched? Recall that learning a new skill such as reading is just a

special case of overall prediction error minimization according to the PP framework. On this construal, learning to read means becoming increasingly efficient in predicting linguistic, visually presented input as a result of long-term exposure to types of this input and the optimization of hypotheses through perceptual inference. The careful instruction in relating graphemes to phonemes, phonological and metalinguistic awareness, and the normatively constrained alphabetic principle provides the environmental conditions for efficient and progressively more accurate prediction error minimization. The signals delivered by this highly structured learning environment are estimated as being precise, such that the synaptic gain on error units reporting the discrepancy between (still inaccurate) predictions and prediction error is high. As learning to read proceeds, the predictions become more accurate and the overall influence of prediction error shows a relative decrease. This line of reasoning is supported by [Price’s & Devlin’s \(2011, p. 248\)](#) following suggestion: “At the neural level, learning involves experience-dependent synaptic plasticity, which changes connection strengths and the efficiency of perceptual inference.” Understood this way, LDP and the associated neuronal transformations can be understood as being realized by prediction error minimization in the context of scaffolded learning, which allows a beginning reader to become ever more efficient and successful in this particular cognitive practice.

3.3 Reading acquisition and bodily transformation

Starting from the hybrid mind thesis defended by CI, which states that certain cognitive processes are constituted by both neuronal and extracranial bodily sub-processes, it seems natural to assume that reading acquisition also is associated with the transformation of bodily sub-processes. That is, in the course of enculturation it is the enactment of bodily manipulation that is transformed in addition to the neuronal changes occurring as a result of LDP. In terms of PP, this assumption leads to the suggestion that it is not only perceptual inferences that are

causally relevant for learning described in terms of prediction error minimization, but also active inferences that allow for ever more efficient sub-personally employed strategies for “explaining away” incoming sensory input. Recall that eye movements are just a special case of active inference (see e.g., [Friston et al. 2012](#)). Their functional contribution to prediction error minimization becomes vitally important for a complete account of visual word recognition and its acquisition. This is because visual word recognition, in both novices and experts, is rendered possible by the coordination of perceptual and active inference. From the perspective of CI, the idea here is that the ways in which an individual bodily manipulates a certain cognitive resource is importantly improved in the course of cognitive transformation. Applied to reading acquisition, this leads to the assumption that specific eye movement patterns become more efficient as a result of reading instruction and iterate exposure to a certain type of cognitive resource (say, sentences printed on a piece of paper).

Recently, it has become possible to investigate eye movements in beginning readers by employing eye-tracking methodologies. Converging evidence suggests that beginning readers make more fixations (i.e., acquisition of visual information in the absence of oculomotor activities), saccades (i.e., oculomotor activities), and regressions (i.e., backward saccades), and exhibit longer fixation durations and smaller saccade amplitudes than proficient and expert readers (cf. [Joseph et al. 2013](#), p. 3; [Rayner et al. 2001](#), p. 46). More specifically, these tendencies are assessed in a longitudinal eye-tracking study reported by [Huestegge et al. \(2009\)](#). They measured eye movements during an oral reading task in second and fourth graders of a German primary school and additionally assessed overall reading skills and oculomotor behaviour beyond reading (cf. [Huestegge et al. 2009](#), p. 2949). Their results indicate that the fourth graders, in comparison to the second graders, show a decrease of fixation duration, gaze duration, total reading time, refixations, and saccadic amplitudes (cf. [ibid.](#), p. 2956). [Huestegge et al. \(2009](#), p. 2958) attest that the younger, less

proficient readers show a “[...] refixation strategy, with initial saccade landing positions located closer to word beginnings.” Similarly to [Huestegge et al. \(2009\)](#), [Seassau et al. \(2013\)](#) report a longitudinal study comparing the performance of 6- to 11-year-old children in a reading task and a visual task. In line with the empirical evidence already mentioned, their results indicate that “[w]ith age, children’s reading capabilities improve and they learn to read by making larger progressive saccades, fewer regressive saccades and shorter fixations [...]” ([Seassau et al. 2013](#), p. 6). Furthermore, it is demonstrated that the eye movement patterns employed in reading and in visual search diverge with increasing reading proficiency (cf. [ibid.](#), p. 9).

An explanation of these results in terms of PP is straightforward. In beginning readers, the predictions initiating active inference occurring in a highly-structured linguistic environment are inaccurate, such that the generation and execution of eye movements in terms of active inference is not as efficient as it is in the case of expert readers. By the same token, the inaccuracy of the currently selected prediction makes it necessary to sample the visually available linguistic environment more thoroughly, explaining the “refixation strategy” and the execution of comparatively more saccades. As reading skills improve, resulting from increasingly efficient prediction error minimization through perceptual inference as already suggested, the accuracy of predictions becomes increasingly optimal, therefore allowing for more efficient active inference. More efficient active inference, in turn, allows for more efficient perceptual inference, since both types of inference mutually influence each other. This line of reasoning is supported by [Huestegge et al.’s \(2009](#), p. 2957) claim informed by the results of their study “[...] that only linguistic, not oculomotor skills were the driving force behind the acquisition of normal oral reading skills.” Thus, the increase in efficiency of eye movements in beginning readers does not result from an increase in oculomotor capabilities *per se*, but works in tandem with higher-level linguistic knowledge encoded in predictions, which are associated with representa-

tions in higher-order cortical areas. As a result, the improvement of active inference in the course of reading acquisition works in tandem with the improvement of perceptual inference. This highlights that learning to read does not only result in neuronal, but also in bodily transformations. As such, the optimization of eye movements in the course of reading acquisition highlights the importance of bodily manipulation in the efficient enactment of reading understood as a cognitive practice. This also means to suggest that a complete account of enculturation should not only pay attention to scaffolded learning and LDP, but also to the developmental trajectory of bodily manipulation.

4 Concluding remarks

This commentary on Richard Menary's paper *Mathematical Cognition: A Case of Enculturation* started from the assumption that the general outline of enculturation and the associated claims made by CI provide important conceptual tools for the description of ontogenetically acquired, socio-culturally shaped cognitive processing routines. However, I have argued that the idea of enculturation and its most important aspects, namely cognitive transformation and scaffolded learning, need to be enriched by providing a detailed functional and neuronal description on a sub-personal level of description. In addition, it needs to be born in mind that enculturation is rendered possible by normative constraints developed by a large group of individuals sharing the same cognitive niche. To this end, I have suggested that the notion of enculturation and its associated constitutive aspects can be complemented in important ways by taking the PP framework into account. The result is what I call enculturated predictive processing. Thus, the PP framework is capable of providing the conceptual resources necessary for a thorough description of the mechanistic underpinnings of cognitive practices and their acquisition. Lending further support to this line of reasoning, I have dealt with reading acquisition as a paradigmatic case of enculturated predictive processing. This should have been sufficient to establish that the CI framework is well-suited

for a conceptually coherent description of the interaction between brain, body, and environmental cognitive resources. However, it needs to be supplemented by a sub-personal level description in terms of prediction error minimization in order to be able to specify the neuronal and functional underpinnings of the hybrid mind thesis, the bodily manipulation thesis, and the transformation thesis as defended by CI. At the same time, the approach to reading acquisition put forward in this commentary suggests that a vast array of empirical findings from cognitive neuroscience and cognitive psychology can be unified for the first time by interpreting them from the new perspective of enculturated predictive processing. Thus, I submit that we can only appreciate the cognitive assets rendered possible by our socio-culturally structured environment once we account for the enabling conditions of sophisticated, neuronally and bodily realized cognitive processes such as mathematical cognition and reading. These conditions include socio-culturally established ways of learning and teaching, LDP, and the ability to adapt action patterns to the needs and requirements of a certain cognitive task. My overall claim is that we need the EPP framework to be able to approach the entire spectrum of these factors, whose complex interplay ultimately leads to truly enculturated cognition.

Acknowledgements

The author wishes to thank the Barbara Wengeler Foundation for its generous financial support. In addition, she is indebted to Thomas Metzinger, Jennifer M. Windt, and an anonymous reviewer for their helpful feedback on earlier versions of this commentary.

What? Now. Predictive Coding and Enculturation

A Reply to Regina E. Fabry

Richard Menary

Regina Fabry has proposed an intriguing marriage of enculturated cognition and predictive processing. I raise some questions for whether this marriage will work and warn against expecting too much from the predictive processing framework. Furthermore I argue that the predictive processes at a sub-personal level cannot be driving the innovations at a social level that lead to enculturated cognitive systems, like those explored in my target paper.

Keywords

Active inference | Cognitive integration | Enculturation | Learning driven plasticity | Mathematical cognition | Perceptual inference | Predictive processing | Reading

1 Introduction: What? Now.

I'd like to thank Regina Fabry for her excellent and detailed response to my paper. She articulates an important account of reading acquisition as a process of enculturation and describes how a Cognitive Integration/Enculturated Cognition (henceforth CI/ENC) account can be combined with a predictive processing account of neural processing. She shows, in impressive detail, how CI/ENC can benefit from Predictive Processing (henceforth PP), primarily as a way of explaining the neural-level details of processes that conspire with bodily interactions with the local environ-

ment to complete cognitive tasks. Since Fabry's response suggests an important way of cashing out some of the details of an enculturated approach, I would like to take this opportunity to look at some of the potential pitfalls in the proposed Enculturated Predictive Processing style (henceforth EPP). Primarily I want to focus on the differences in explanatory emphasis between CI/ENC and PP, especially where CI/ENC proposes the importance of the population-level effects of normative patterned practices (henceforth NPP), such as mathematical practices.

PP is all about predictions, happening in the here-and-now¹; however CI/ENC occurs at different levels and over much longer time-scales. It turns out that this difference is important, because if the brain is engaged in predictive error minimization (as sub-personal processing) in the here-and-now, then it cannot be driving the innovation of new NPP over many generations. This is because the pressures driving those innovations are found at the social, or populational, level², not at the level of neural processing where ‘what?’ is answered in the now.

I also raise several issues concerning the nature of the PP project, particularly whether, as a theory of general brain architecture, all processing can be cashed out in terms of predictive processes. I’m also sceptical about Fabry’s claim that PP can provide the “mechanistic underpinnings of the acquisition of cognitive practices” (Fabry this volume, p. 3) on its own, without help from what I call learning-driven plasticity (LDP) and neural redeployment. Finally, I comment on the promising research path down which Fabry is headed.

In the first section I remind the reader of some of the leading ideas of the CI/ENC framework, highlighting, in particular, the different levels of explanation and how this matters to the proposed marriage of ENC-PP. In the second section I raise several problems for the PP approach in general and for the ENC-PP approach in particular. My main concerns are to push away from an ‘isolated brain’ interpretation of PP and to place EPP within a much broader context of explanation.

2 CI and enculturation

As I point out in my contribution to this volume, cognitive integration should be understood as a thesis about the enculturation of human cognition. It is a thesis about how phylogenetically earlier forms of cognition are built

upon by more recent cultural innovations (e. g., systems of symbolic representation). This results in a multi-layered system with heterogeneous components, dynamically interwoven into a co-operative of processes and states an integrated cognitive system (henceforth ICS). The co-ordination dynamics of the system are, at least in part, understood in terms of the physical dynamics of brain–body–niche interactions in real-time; however, they are also to be understood in terms of NPP that govern and determine those interactions (over time). NPP operate at both social/population levels and individual, even sub-personal, levels. They originate as patterns of activity spread out over a population of agents; consequently they should be understood primarily as public systems of activity and/or representation that are susceptible to innovative alteration, expansion, and even contraction over time. They are transmitted horizontally across generational groups and vertically from one generation to the³ next. At the individual level they are acquired, most often by learning and training, and they manifest themselves as changes in the ways in which individuals think, but also the ways that they act (intentionally) and the ways in which they interact with other members of their social group(s) and the local environment. NPP, therefore, operate at different levels (groups and individuals) and over different time-scales (intergenerationally and in the here-and-now).

Given this, it is clear that What? Now⁴ processes that reduce prediction errors on their own could not drive the innovation of NPP; nor could they determine the properties of NPP on their own. Less obviously, I would argue, they do not drive the acquisition of NPP, because scaffolded learning requires both a physically and temporally-structured learning environment and the capacity for functional changes to cortical circuitry to be driven by the structured learning environment. The mechanism of acquisition includes both neural and environmental processes working in concert and over long periods of ontogenetic time. What? Now processes may help us to understand the here-and-now

¹ I mean predictions on incoming sensory input relevant to immediate action in the environment.

² I think that these levels are real. There is a level of entire populations, social groups, individual organisms and there is a level of individual brains. Cognition takes place within and across (at least the final three) levels.

³ See my target article for examples.

⁴ Predictions on sensory input in the here-and-now.

processes by which we enact NPP; they may even tell us something about the neural mechanisms for learning and plasticity; but we should be wary of making prediction and error minimization the driving factors behind the why and how of enculturation.

Fabry's commentary focuses on the neural level, functioning in real-time, where the primary aim is to give a mechanistic account of how cognitive capacities can be transformed by learning and training in rich socio-cultural niches. Rather than looking at the origin of ICS in cultural inheritance, phenotypic plasticity, and learning driven plasticity, Fabry argues that a version of the PP framework can provide the neural mechanisms by which ICS are (partly) constructed. My contribution to this volume focused primarily on the origin of ICS in the recent cultural evolution of NPP and then explored how mathematical practices could be learnt and how this process of learning could drive functional changes to circuitry in the brain. Consequently, the CI/ENC framework pursues the phylogenetic and ontogenetic basis of the larger brain-body-niche nexus. What, though, of the neural mechanisms of transformation?

I don't agree with Fabry's starting premise that CI/ENC lacks a mechanism of transformation: the mechanism of transformation is learning-driven plasticity (LDP) with neural redeployment in a scaffolded learning environment. The fundamental plasticity of the brain explains the nature of neural transformations and why the brain is open to scaffolded learning driven by the environment. (E)PP does not have the resources to explain redeployment (this is a theme I take up in the next section). Why would it, since PP is not a framework for explaining redeployment. It might be the case that PP fits with a certain conception of scaffolded learning such as path-dependent learning, but I have yet to see a thorough working-through of the details and it's not clear to me that all scaffolded learning should be reduced to a predictive form of path-dependent learning.

Fabry claims that a dynamical systems approach to integration "does not spell out the mutual influence that neuronal and extra-cra-

nial bodily components have over each other" (2015, p. 3). The EPP approach is supposed to fill in the details here. However, I suspect that this judgement is made a little too quickly, because the dynamical systems description of brain-body-niche interactions is in one sense a higher-level description of those interactions. The dynamical interactions are described as being part of a larger system comprising brain, body, and niche. We can zoom in and focus upon the dynamics of brain or body, but we shouldn't confuse the dynamics of the brain for the dynamics of the overall system. I have highlighted and outlined the neural dynamics required for enculturation in a number of places. For example, in the account of body schema dynamics and in the case of NPP for symbolic cognition, I have outlined the case for dual component transformations (e. g., Menary 2007, pp. 78–83; 2010; 2013 and 2014). Let's take these two cases in order.

In a now famous series of studies, Maravita & Iriki (2004) studied the bimodal interparietal neurons in trained Japanese macaque brains. These neurons respond both to tactile stimulation on the hand (tactile receptive field) and visual stimuli in the same vicinity as the tactile receptive field (the visual receptive field). The visual receptive field was centred on the hand following it through space. When macaques were trained to use a rake to pull food towards them on a table, the observation that struck Maravita and Iriki was that when the macaques used the rake the receptive fields of the bimodal neurons extended along the axis of the rake, including its head. Iriki's interpretation of this is that "either the rake was being assimilated into the image of the hand or, alternatively, the image of the hand was extending to incorporate the tool" (Iriki & Sakura 2008, p. 2230). The extension of the body schema (receptive field) to include the tool happened only during active holding; it reduced to just the hand during inactivity. The interesting result of these experiments is that the existing body schema has the latent capacity to extend to incorporate the tool. LDP can be cashed out in terms of functional changes as the result of scaffolded learning even in the case of

macaques, let alone the notoriously plastic brains of humans.

Functional changes can be cashed out in terms of neural redeployment and cortical connectivity. Returning to the case of mathematical cognition, inherited systems for numerosity are evolutionary endowments; we can be reasonably sure of this because they are constant across individuals and cultures and they are shared with other species. The numerosity systems are “quick and dirty”; they are approximate and continuous, not discrete and digital. By contrast, discrete mathematical operations exhibit cultural and individual variation; there is a big difference between Roman numerals and Arabic numerals. They are subject to verbal instruction (they actually depend on language); one must learn to count, whereas one does not learn to subitise. Mathematics depends on cultural norms of reasoning (mathematical norms). The ability to perform exact mathematical calculations depends on the public system of representation and its governing norms. We learn the interpretative practices and manipulative practices as a part of a pattern of practices within a mathematics community, and these practices transform what we can do. They are constitutive of our exact calculative abilities. Mathematical practices get under our skins by transforming the way that our existing neural circuitry functions.

The relationship between the evolutionarily earlier system and the recent development of public mathematical systems, norms, and symbols comes down to the redeployment of the cortical territories that are dedicated to evolutionarily older functions by novel cultural artefacts (e. g., representations, tools). The transformation results in new connections between the frontal lobe for number-word recognition and association, the temporal lobe for the visual recognition of number form, and the parietal lobe for the approximate recognition of magnitudes across both left and right hemispheres (Dehaene 1997).

The deeply transformative power of our learning histories in the cognitive niche relates to the development of our capacities for understanding symbolic representations and for phys-

ically manipulating inscriptions in public space. In learning to understand symbols, the first transformation involves our sensorimotor abilities for creating and manipulating inscriptions (the transformation of the body schema). This is something we learn to do on the page and in the context of a learning environment, in public space, before we do it in our heads. Our capacities to think have been transformed, but in this instance they are capacities to manipulate inscriptions in public space.

It looks like PP can provide models of some of the fundamental processing principles at work at the sub-personal neural level, but it is not obvious that it would replace LDP and neural redeployment in the mechanism of transformation. However, Fabry may be right and PP may add another string to the bow of our understanding of how the brain exhibits the plasticity required for cognitive transformation. In that case it provides extra explanatory depth to the account of enculturation, but only as part of a much broader explanatory framework.

3 Some worries for enculturated predictive coding

Fabry provides a persuasive case for how PP could provide the neural underpinnings of enculturation. In this section, however, I will raise some problems for the proposed marriage of CI/ENC and PP. The main issues I will address are as follows:

1. The incompatibility of the isolated brain interpretation (Hohwy 2013) and the active inference interpretation (Clark 2013) of PP.
2. The attempt to explain all cognitive processing in terms of prediction error.
3. The redeployment of neural circuitry as not being explained by PP.
4. The role of NPP as not being explained by the reduction of prediction error.

1. Isolating the brain

If CI/ENC has one central commitment, it is that we should not think of cognition as isolated from the environment. And yet this is ex-

actly how we ought to understand the predictive brain, according to a prominent interpretation of the PP framework. Whenever the PP framework is introduced, it is almost always introduced in the following way: “Accounts of PP generally assume that human perception, action, and cognition are realized by *Bayesian probabilistic generative models* implemented in the human brain. Since *the human brain does not have immediate access to the environmental causes of sensory effects, it has to infer the most probable state of affairs in the environment* giving rise to sensory data” (Fabry 2015, p. 4; my emphasis). The two main motivations for the PP framework are that the brain is isolated from the environment and must make a best guess as to what it is perceiving, and that this kind of probabilistic inference-making results in internal (neurally realized) models of the environment. Putting aside the probabilistic nature of the inferences, this just is old-fashioned individualism. There is a perceptual interface to an environment of hidden variables; the internal system creates internal models (representations) of those hidden environmental variables, which then causally produce behaviour. The internal states must predict the external variables via sensory input, but they have no direct access to the causal ancestry of the sensory input. This form of individualism is used as an explanation for why models and predictions are required: “Because the brain is isolated behind the veil of sensory input, it is then advantageous for it to devise ways of optimizing the information channel from the world to the senses” (Hohwy 2013, p. 238). Hohwy describes the mind–world relation as “fragile” because of the isolation of the brain, and this is why active inference is required.

The saving grace of the PP framework, from the perspective of CI/ENC, is active inference. In Clark’s version of PP active inference and cultural props help to minimize prediction errors (Clark 2013); and because of this, there is a deep continuity between mind and world mediated by active inference and the cultural scaffolding of our local niche. Curiously, Hohwy agrees with Clark’s interpretation, but at a cost. Hohwy agrees that active inference and the cul-

tural scaffolding of the environment help to change sensory input so as to minimize prediction error, but also “by increasing the precision of the sensory input” (Hohwy 2013, p. 238). According to Hohwy, the primary role of PP is perceptual inference; as a matter of “second order statistics” active inference helps to optimise sensory input so that perceptual inference is less error-prone.

Note the cost. First, active inference and cultural scaffolding is relegated to the secondary role of reducing prediction error for the primary cognitive job of perceptual inference, which is carried out wholly by matching statistical models to sensory input in the brain. Second, Hohwy shows that this interpretation of active inference should be understood against the background of the isolated brain. “The key point I am aiming at here is that this is a picture that accentuates the indirect, skull-bound nature of the prediction error minimization mechanism” (Hohwy 2013, p. 238). Organizing and structuring our environments makes sense if the mind–world relation is fragile in the way that Hohwy presents it, and also because this structuring makes perceptual inference more reliable. I take it that Fabry and Clark would deny this interpretation of the role of active inference and cultural scaffolding. Indeed, Fabry denies Hohwy’s ‘isolationist’ interpretation in her commentary.

However, Fabry does so by playing up the roles of NPP, which go far beyond prediction minimization: “Furthermore, we need to take into account that genuinely human cognitive processes occur in a culturally sculpted cognitive niche. [...] These cognitive resources have unique properties that render them particularly useful for the completion of cognitive tasks” (Fabry 2015, p. 12). She also nods to the sub-personal, mechanistic role of PP in the entire brain–body–niche nexus: “[T]he important theoretical contribution made by the prediction error minimization framework is its providing of a sub-personal, mechanistic description of the underlying neuronal and bodily sub-processes” (Fabry 2015, p. 13). It is therefore not clear to me that PP does anything more than provide the functional details of *some* of the neural processing in the brain–body–niche nexus. It cer-

tainly should not be taken to provide a comprehensive account of what cognition is and why there is cultural scaffolding, or what its interesting cognitive properties are.⁵ It is to these issues that I shall now turn.

2. Everything is predicted

One of the main concerns with the PP approach is that it is used both to try to explain all of cognition and as an explanation of why there is cultural scaffolding. We've already seen a brief hint of this in Hohwy, Clark, and Fabry's work above.⁶ The first worry can be found in the expression of PP as originating in the free energy principle:

The free-energy considered here represents a bound on the surprise inherent in any exchange with the environment, under expectations encoded by its state or configuration. A system can minimise free energy by changing its configuration to change the way it samples the environment, or to change its expectations. These changes correspond to action and perception, respectively, and lead to an adaptive exchange with the environment that is characteristic of biological systems. This treatment implies that the system's state and structure encode an implicit and probabilistic model of the environment. (Friston & Stephan 2007, p. 417)

PP is primarily a model of the way in which top-down processing 'predicts' bottom up sensory input and which samples the environment to change its expectations. These correspond to perception and action respectively.⁷ However, it seems odd to build a cognitive theory on the basis of the prediction of sensory sig-

nals. This is because much of cognition is not about sensory signal prediction; nor about actions as sampling the environment. Indeed much of cognition isn't about 'prediction' at all. So whilst I agree that at least part of the mechanisms of cognition can be fruitfully modelled by PP, not all of them will be. In enculturated systems, the really important work is being done by the processing governed by normative patterned practices whose properties are understood primarily at the social or populational level. I agree that at the individual level, the mechanisms of ICS can partly be explained by PP, but the main explanatory work will not be a matter of predictions of sensory input⁸.

The examples from Landy & Goldstone (2007) may be partly explained by prediction errors, but again this only makes sense in the context of sensorimotor processing governed by mathematical norms. If the norms function as priors in the system, then this might help explain the errors made by the test subjects.

3. Phenotypic plasticity and neural redeployment

PP can't explain the redeployment of neural circuitry to new cognitive functions. And it is not supposed to, since this isn't the job it was designed to do. However, this is a considerable weakness if PP is supposed to be the primary mechanism of enculturation. I've already canvassed the reasons why in section 1.

4. NPP and prediction error minimization

Enculturated PP plays a role in the multi-layered and interwoven ICS, but it neither determines nor implements the entire system. My argument in this response has been that the dynamics of ICS are not determined by the predictive processing of parts of the system: if any-

⁵ CI/ENC provides just these motivations and details. Clark himself proposes that the PP framework "offers a standing invitation to evolutionary, situated, embodied, and distributed approaches to help 'fill in the explanatory gaps' while delivering a schematic but fundamental account of the complex and complementary roles of perception, action, attention, and environmental structuring" (Clark 2013, p. 195).

⁶ See also their contributions to [this volume](#).

⁷ There are also theories of attention based upon PP, but I won't address those here.

⁸ Thomas Metzinger has raised an interesting question for me here: whether there is continuity between the levels? My argument has been that there is continuity between the levels, but this continuity is made possible by NPP's, LDP and neural redeployment. PP explains how we make perceptual inferences about the environment and it might explain something about the hierarchical organisation of neural architecture. However, it should be seen as playing a role in the organisation and enculturation of the brain, not the *only* role.

thing PP is enslaved to the processing needs of the entire enculturated system. The PP framework takes perceptual inference as its primary mode of processing, which is the top-down matching of predictions to sensory input. However, it is not obvious that this is the right model for all cognitive processing, since it is not obvious that all cognitive processing is just a matter of predictions about sensory input, nor a hierarchically organised system which minimises prediction errors.

For example Hohwy (2013, p. 238) argues that “many of the ways we interact with the world in technical and cultural aspects can be characterized by attempts to make the link between the sensory input and the causes more precise (or less uncertain).” This would be a very impoverished account of the evolution of public systems of representation. Public systems of representation did not simply evolve to “make the link between the sensory input and the causes more precise (or less uncertain)”; this would be to ignore the social pressures that would have caused representational innovation.⁹ It might be true that the history of the refinement of notation has something to do with making input more easy to ‘predict’; however, this would not be an *ultimate* explanation for why there are notations in the first place, nor how they function in our cognitive lives. It *might* be a *proximal* explanation of the neural mechanisms for the processing of notations and as such, it might explain some of the causal conditions that explain how notations have developed, but it doesn’t explain the conditions under which notations evolved. For further reasons why see section 3.4 of my target article, on evolutionary novelty and uniqueness (this volume).

For example, the idea that the brain predicts the product of two numerals makes sense, and the surprise at a product too distant from the operands lends further credence. Remember

the example from section 4.1 of my target article (this volume) : $34 + 47 = 268$. However, it is not obvious that predictions will help with the second example: $34 \times 47 = 1598$. What is required in this instance is the serial working through of the multiplication according to an algorithm. Furthermore, this is not simply a case of sensory predictions: when it comes to recognising the numerals on the page in front of you, PP can explain top-down predictions about sensory input, but that is not at all the same thing as the working through of a mathematical problem. So mathematical cognition could not, it seems to me, be reducible to error minimization.

4 Conclusion: Where now?

Despite some of my concerns about how the PP framework can be interpreted and its relation to the CI/ENC framework, I think that Fabry’s account of the enculturation of reading using a hybrid of CI and EPP is really compelling. This leads me to think that an EPP account might be workable for other cases, such as mathematical cognition. Having said this, the division of labour between PP and evolutionary accounts of the origin of NPP and ICS must be in place. The role of scaffolded learning and neural re-deployment should not be replaced by error minimization processes. The ‘isolationist’ reading of PP should be resisted, and a more situated cognition friendly approach embraced. PP is a sub-personal account of neural processes that fits within a larger account of the brain–body–niche nexus. If one embraces CI/ENC then there’s more to the mind than What? Now.

Acknowledgements

Thanks to Thomas Metzinger and Jenny Windt for comments and to Regina Fabry for her excellent commentary.

⁹ I take it that Hohwy is claiming that cultural representations function so as to make perceptual inferences more precise. This would be another way of reducing socio-cultural phenomena to a role that is complementary to the brain, with the processing needs of the brain dictating the evolutionary path that culture must take. The externalist perspective takes it that there are social and cultural pressures that require cognitive innovations (sometimes even new phenotypes).

Understanding Others

The Person Model Theory

Albert Newen

According to Interaction Theory (IT), neither Theory Theory (TT) nor Simulation Theory (ST) give an adequate account of how we understand others. Their shared defect, it is claimed, is that both focus on third-person observation of the other, and neglect the role of social interaction. While interaction theory is made to account for the latter, it has problems doing justice to explicit attributions of propositional attitudes, especially from an observational stance. The latter received a new explanation by the Narrative Practice Hypothesis (NPH) which focuses on story-based explanations and tends to underestimate the relevance of nonlinguistic intuitive understanding. In this paper, I first try to do justice to what is plausible about each of the four approaches by accepting that each account introduces one plausible epistemic strategy for understanding others, which leads us to a multiplicity view about the epistemic strategies for understanding others. But it will then be argued that an adequate theory of understanding others needs further adjustment and correction because we need to account for the fact that we usually understand others on the basis of specific background knowledge that becomes more enriched during our life; I thus propose Person Model Theory (PMT) as a fruitful alternative. On my account, understanding turns on developing “person models” of ourselves, of other individuals, and of groups. These person models are the basis on which we register and evaluate persons as having mental as well as physical properties. I argue that person models can be either implicitly represented or explicitly available. This is accounted for by describing two kinds of person model, corresponding to the two ways of understanding others; very early in life we develop implicit *person schemata*, where a person schema is an implicitly-represented unity of sensory-motor abilities and basic mental phenomena related to one human being (or a group of humans); and we also develop *person images*, where a person image is a unity of explicitly-registered mental and physical phenomena related to one human being (or a group). I argue that the person model theory has more explanatory power than the other candidates.

1 Introduction

A key question for social cognition is: Can we provide an adequate theoretical analysis of the process of understanding other human beings? For over twenty years, there have been only two possible answers to this question—that offered by “Theory Theory”, and that of “Simulation Theory”. The central claim of TT is that one’s understanding of another essentially relies on a folk-psychological *theory*, where some take the position that the relevant folk psychology is in-

born (e.g., [Baron-Cohen 1995](#)), while others claim that it is acquired ([Gopnik 1993](#)). In contrast, ST holds that we understand others by means of *simulation* (e.g., [Goldman 2006](#)), where simulation can take place at two levels, referred to as low-level and high-level simulation ([Goldman 2006](#)). In recent years, however, it has become clear that both positions have significant limitations. One central problem is claimed to be that both TT and ST take a

primarily observational stance towards the other when analysing understanding:¹ critics maintain that this observational stance is a nonstandard, intellectual perspective, and that in fact we are normally involved in *interaction* when we try to understand others. Developing this line of thought, [Gallagher's](#) interaction theory (2001) combines involvement in interaction with a direct perception thesis, such that we can directly perceive the mental states of others and do not have to infer them. Another alternative proposal is [Hutto's](#) *narrative* account of social understanding (2008), on which understanding others relies centrally on telling or understanding stories. These idealized positions are the bases for a wide range of mixed positions, with which I will engage shortly. Yet even if we consider only these idealized positions, a new central defect quickly becomes clear: namely, that these positions offer answers to rather different questions. Thus, in a first step, I aim to reorganize the field of the main positions and use this framework to situate my own view, which I refer to as the *person model theory* ([Newen & Schlicht 2009](#); [Newen & Vogeley 2011](#)): this account is characterized by the claim that we understand others by essentially relying on person models of individuals, or of groups.

2 Reshaping the field of positions by distinguishing central questions

The question “How do we understand other human beings?” has to be divided into several subquestions, the first of which is: What epistemic strategy do we adopt to register or assess the other's cognitive states? To reach any kind of assessment of the other we need to obtain information within a concrete situation. The second question is: Once obtained, how is this prior information stored and organized? This

second aspect is important, because we always rely on prior background knowledge in our assessments of others. One main defect of the debate thus far has turns on the failure to distinguish these two questions. The debate between the two classic positions, ST and TT, can roughly be described as a misunderstanding stemming from their dealing with different questions: while ST insists that the use of simulation is the standard epistemic strategy, TT insists that the prior information we have about others is organized as a folk-psychological theory. Concerning their main claims, these accounts are not in opposition. The opposition only becomes visible if for each account we consider their favoured answer to both questions. The classic opposition between ST and TT can then be described as follows: TT claims that the epistemic strategy relies upon theory-based inferences, and that the prior information is organized as a folk-psychological theory; while ST claims that the strategy for information-processing involves simulation (to put oneself into the other person's shoes) which draws only on my own experience as the source of data for simulation, leaving it open as to whether these data form a theory.

Before turning to the question of which information-processing strategy we use to understand others, I first provide a brief survey of the field. Thus, in addition to TT and ST, we have [Gallagher's](#) IT, which focuses only on the strategy question; it claims that we understand others through social interaction and/or by direct perception, i.e., we can directly perceive mental phenomena; we also have [Hutto's](#) account, which is given in terms of story-telling. Their more elaborate joint account combines these claims ([Gallagher & Hutto 2008](#)), maintaining that we can distinguish three epistemic strategies for understanding others, depending on the stage of cognitive development in ontogeny: direct perception in very early childhood, followed by interactional understanding, and finally narrative understanding ([Hutto 2008](#)). In contrast, my aim will be to show that we actually use a multiplicity of information-processing strategies to understand others, depending on the context; the proposed account, then, is even

¹ This is a simplified view. A closer look into [Gopnik & Meltzoff \(1997\)](#) shows that their version of TT accounts for interaction as part of the development of an understanding of action and agency (Chap. 5). But interaction is not accounted for in the further dimensions of understanding others. From a bird's eye view this characterization is not inadequate, although it needs qualification. As the reader will see, my person model theory integrates this initial understanding of action and agency as elements of forming implicit person models that at the beginning may not be rich and abstract enough to warrant being called a theory (see n. 6 below).

richer than the three strategies proposed by the joint account of Hutto and Gallagher.

3 The epistemic strategy for understanding others

3.1 What about simulation?

According to Goldman's (2006) elaborate simulation account, we must distinguish between low-level and high-level mindreading. "Mindreading", in his view, comprises all cases of evaluating the mental state(s) of another person that normally lead to a language-based attribution of a mental state to a person. In the case of high-level mindreading, this is

[...] mindreading with one or more of the following features: (a) it targets mental states of a relatively complex nature, such as propositional attitudes; (b) some components of the mindreading process are subject to voluntary control; and (c) the process has some degree of accessibility to consciousness. (Goldman 2006, p. 147)

The paradigmatic case of high-level mindreading is understanding another person's decision. Third-person attribution of a decision consists of:

- imagining propositional attitudes in a form of *enactment imagination*;
- using (the same) decision-making mechanisms (as in the first-person case);
- projecting the result of using that mechanism onto a third person by attributing a decision.

We can easily present cases in which these proposed essential steps are not involved. For (i), to understand a person suffering from a delusion of persecution, we are not able to deploy enactment imagination: Their case is just too different from our own experience. And the same may be true in cases of deep cultural difference. For (ii), if I have experience with the other person such that I know that he has idiosyncratic, non-rational decision-making habits

when making weekend plans, I can use this knowledge to model his decision and not my own decision-making apparatus, since I have experience that my own apparatus differs from his (at least concerning weekend plans). For (iii), grant for the sake of argument that we have a plausible candidate for the beliefs and desires of the other and we use this for enactment imagination as well as input for my own decision-making apparatus, thus reaching a decision to do action A. Then, according to Goldman, I should project this decision onto the other person. Yet there remains an essential gap, which is noted by Goldman but not adequately addressed by him: He observes the necessity of "quarantining" my idiosyncratic background beliefs if I want to come to an adequate projection of the decision to do action A. Suppose I am warranted in presupposing that the other wants an ice-cream, has money, and that there is a nearby cafeteria where he can get one: then the decision-making apparatus may come to the decision to buy an ice-cream. If, however, I am a person who is extremely parsimonious with money, then my own background desire to save money may prevent me from buying the ice-cream in the same situation, and so this intervenes and I do not attribute the decision to buy an ice-cream to the other. But it seems that the desire to save money is—often, at least—an idiosyncratic desire that I should not use in my projection. Yet how do I know which of my own beliefs and desires are idiosyncratic and do not relate to the person I aim to understand? To solve this problem, I must already possess some view about the attitudes of the other as compared to me; yet this was what we were aiming to understand. In general, then, Goldman's theory of high-level mindreading has difficulties even getting off the ground: It starts by making presuppositions about the beliefs and desires of the other person, where this is exactly what we were aiming to understand. The same problem appears again in the projection phase, as just illustrated. Thus, high-level mindreading is a very special case of simulating a decision of the other, specifically when I already know a lot about the other, which I can use as input. This leaves open the question of how we get this in-

formation at all. Goldman tries to account for problems of this kind by accepting the importance of inference-based strategies and the organization of the prior information in form of a theory. Thus he is no longer developing a pure simulation theory but rather a hybrid account. Nevertheless, the counterexamples are not rare but in fact quite typical, and thus they cast doubt on the typicality and pervasiveness of high-level simulation in mindreading decisions.

Goldman may, however, appeal to his strategy of low-level mindreading, which is characterized as an activity that is “comparatively simple, primitive, automatic, and largely below the level of consciousness” (2006, p. 113). Goldman uses as a paradigmatic case face-based recognition of emotion, and he makes an additional appeal to “mirror neurons”, proposing that mirror neurons are not only relevant in the case of understanding motor activities (in both observing and doing them) but also for recognizing mental phenomena like pain and disgust. The most elaborate case relevant to this area of discussion concerns the study of disgust: It has been shown that experiencing disgust and observing disgust are dependent on certain mirror neurons that are activated in both cases (Wicker et al. 2003). Yet what exactly can we learn from this observation? I develop a critical position on the explanatory potential of mirror neurons in two steps. First, I argue that if mirror neurons could provide us with the whole story of how we understand others, this story would not be given as a case of simulation. Second, I cite evidence that mirror neurons do not provide the core part of the story of understanding others in cases of understanding emotions. Let us start with criticism of the claim that low-level mindreading is a case of simulation. Here I mainly rely on lines of criticism worked out by Gallagher (2007), who claims that “simulation is a personal-level concept that cannot be legitimately applied to subpersonal processes” (p. 363). Even if we do not accept Gallagher’s claim, the two core features of simulation would be lacking in the case of resonance processes implemented by mirror neurons: There is neither a first-person perspective involved nor

a type of pretence that includes a projection from a first-person perspective to a third-person perspective: “Thus, according to ST, simulation involves the instrumental use of a first-person model to form a third-person ‘as if’ or a ‘pretend’ mental state. For subpersonal processes, however, both of these characterizations fail” (Gallagher 2007, p. 360). Why are mirror neurons not an essential part of understanding others? They represent a type of action or emotion that is independent from a first- or third-person perspective; but the distinction between self and other is an essential part of understanding others. Thus a simulation process cannot be fully captured in its essential aspects by the mirror-neuron processes (see Vogeley & Newen 2002).

This criticism of high-level and low-level mindreading does not imply that simulation processes never take place: rather, it suggests that it is only so-called high-level simulation that we can characterize as simulation, and also that it is implausible that simulation is the standard strategy for everyday understanding of others. The latter claim is also based on the observation that we often rely on automatic, intuitive understanding of others without any conscious considerations.

3.2 What about theory-based inferences?

The same general line of criticism can be developed with respect to theory-based inferences. Such inferences may sometimes be relevant, but are not always so; neither are they the standard strategy for understanding others. Theory-based inferences are important when we are confronted with cases that we find strange or surprising, i.e., situations where we meet another person suffering from a mental disease which we know nothing about, or where the person belongs to a culture that is radically different from ours. In such scenarios, we consciously build hypotheses about the relevant mental phenomena, as well as about the best behavioural strategy to adopt. But most everyday scenarios in which we understand others are not of this type; quite the contrary, we are generally in-

volved in well-known situations with individuals or types of persons with whom we are familiar. There is an effortless application of our know-how regarding dealing with other humans, without any need to rationalize through theory-based inferences. The reply of the advocate of TT would be: Even if the relevant knowledge-how does not involve an explicit theory-based inference, it is only applicable because we rely on *implicit theory-based inferences*. The criticism of this line of thought is twofold: The status of *implicit inferences* is very unclear, because inferences are defined as relations between propositions; and there is evidence that implicit information processes are often non-propositional in nature. For example, in the case of experts, very often the epistemic strategy in their field is complex visual pattern-matching without any inferences; with their superior organization of knowledge, for instance, a chess expert can rapidly perceive a promising move, or a medical expert can quickly notice an inconsistency in a suggested diagnosis. The process of smoothly using this information mainly relies on fine-grained pattern-discrimination and pattern-matching (Gobet 1997) in the relevant situation, rather than on drawing inferences (which only becomes the case if the expert has to consider problematic situations). This is supported by observations of the way people recall chess positions: When seeing a chess board that contains a real, meaningful arrangement, chess experts excel as compared to novices in recalling positions, but perform no better for scrambled, impossible positions (Gobet & Simon 1996). This indicates that they are able to “see” meaningful patterns that a novice cannot see. They may use this ability in addition to making inferences, but inferences are not so much their basic access strategy as an additional one.² If neither the strategy of simulation nor the strategy of theory-based inferences is the standard strategy upon which our smooth, everyday understand-

ing of others is based, what form does epistemic access to others’ mental states take?

3.3 What about direct perception?

In recent years Gallagher (2008) has argued that our epistemic access to others’ mental phenomena is essentially based on direct perception. The mental states of others are not hidden, and need not be inferred on the basis of perceiving others’ behaviour; rather, behaviour is an expression of the mental phenomena that, in seeing the behaviour, is also seen directly. What does the claim of direct perception involve? Gallagher explains his main idea with an analogy: I can directly see my car. It would be inadequate to claim that I only directly see the colour, the shape, and the material, and then have to infer that it is my car. This is also supported by the fact that, when seeing the car, I at the same time see its drivability. This view does not deny that object-perception involves complex and partially hierarchically-organized brain processes, but it introduces the notion of “smart” perception: If I have learned the concept CAR and I am used to driving cars, I can see a car directly; and in seeing my car I may also see concomitant affordances such as its drivability. The same is true in the case of understanding others: according to Gallagher, by seeing their face and body posture in a specific situation, I can directly see that someone fears an aggressive dog. This can be realized by visual pattern-matching without inferences (see footnote 3 and Newen et al. forthcoming). This is a convincing comparison, especially as regards its potential to give a unified account of both basic perception and what Gallagher calls “smart” perception. The latter are cases in which it appears plausible to accept that perception can be modulated by conceptual information, these usually being described as cases of cognitive penetration (see Macpherson 2012; Vetter & Newen 2014).

Let us illustrate both the basic and the smart perception of an emotion. Basic perception of an emotion takes place when we see fear, joy, anger, or sadness in the face of a person while relying mainly on a single feature, or

² It is important to note that I leave it open whether we have to rely on a package of knowledge we are warranted in calling a theory, since I only discuss the strategy of information processing, not the organization of prior knowledge in experts.

small group of features, connected with facial expression (Ekman et al. 1972).³ This can be done through a bottom-up perceptual process that involves almost no top-down influences, especially if the facial expression is very characteristic of an emotion pattern. In the case of smart perception, the perception of the emotion is modulated by higher-order cognitive processes. To show this, we need a case in which the same facial input leads to a different perception of an emotion as a result of conceptual input. Such cases have indeed been discovered: If we first hear a story describing a very unjust situation that makes us expect the person we are going to see to be angry, we have a strong tendency to see a typical “Ekman” fearful face as an angry face: for example, if I am told that the relevant person made a reservation at the restaurant, waited for an hour while many other people who had come in later were served first, and that after a further hour was informed that she would have to wait for at least another hour, then I have a strong expectation of seeing anger. This has been shown to make us see a typical fearful face as an angry face (Carroll & Russell 1996). Smart perception of an emotion is a cognitively-penetrated perception of an emotion, and it is also important for seeing more complex emotions that do not have the typical Ekman facial expressions: if I know that John is jealous of Peter, because he told me so, and I have seen several episodes of Peter behaving intimately towards John’s wife Anne, and the next day I see another episode of John flirting with Anne while Peter observes them, I can directly see the jealousy in Peter’s face. There is no need for inference-based evaluations. This is parallel to Gallagher’s case of seeing one’s car:

3 Although our basic perception mainly relies on certain central cues—e.g., wide-open eyes for fear—the fearful face is not recognized only in one central feature of the face. It requires the integration of several facial features, and not static ones alone. The perceiver also benefits from noticing dynamic visual features like gaze direction: If the gaze is directed away from the perceiver instead of towards her, then this makes the recognition of fear occur faster (see Adams & Kleck 2003; Sander et al. 2006). Together with colleagues I have argued elsewhere that emotion recognition is essentially a process of pattern recognition (Newen et al. forthcoming). This is true for these basic perceptions of emotions. The face is integrated with body posture, since facial expressions are categorized as expressing a specific emotion most rapidly when they are paired with emotionally congruent body postures (Meeren et al. 2005; van den Stock et al. 2007).

we may describe both cases as cases of *seeing as*: seeing my car as a car (by knowing which affordances come with it) and seeing John’s face as evincing jealousy. I illustrated these cases of direct perception because I think Gallagher makes an important point when he claims that the main source of understanding others is direct perception (whether basic or smart). Nevertheless, there are clear limits to direct perception as a form of epistemic access.

Although Gallagher has in the past shown a tendency to overgeneralize the importance of the role of direct perception (2008), he is well aware that there remain cases that cannot be accounted for without going beyond direct perception. This is the case especially concerning our understanding of propositional attitudes—e.g., someone’s desire to take a summer holiday with his elder brother in western Turkey. Propositional attitudes are normally radically underdetermined by expressive elements such as facial expressions, gestures, body postures, etc., in a given situation. In general, therefore, complex human cognitive phenomena of this underdetermined type are communicated by linguistic exchange, or else have to be inferred or simply guessed on the basis of available information. The latter often happens in situations of non-transparent communication due to norms in social situations, or due to the fact that at least one person wants to hide her beliefs and intentions. Since these situations are also part of our everyday life, inferential processes remain part of our everyday understanding of others. Thus, although direct perception is a very important epistemic strategy that we may use in cases of face-based perception of emotion, even “smart” direct perception is not the basic strategy employed to understand complex beliefs, desires, and intentions of others. The latter require inferential processes as well. Thus, we are left with three strategies (simulation, theory-based inferences, direct perception), where none is a clearly dominant standard strategy relevant to all mental phenomena.

But there is at least one further candidate we should take into account, namely *understanding through primary interaction* (Gallagher & Hutto 2008). All the epistemic strategies dis-

cussed so far can apply to situations in which I am simply observing the other without being involved in any interaction. As we have already mentioned, Gallagher views this as a radical defect of such accounts; intuitive understanding of others is part of our everyday life, and this is especially the case if I am not in a purely observational situation but am directly involved in some kind of interaction. Intuitive understanding may then be characterized just by the fact that I notice a social act being directed towards me and so start to interact, such that a standard social interaction is realized, which may be non-linguistic but may also involve linguistic communication—e.g., friendly greetings exchanged while arranging ourselves in line at the office coffee machine. Such a strategy of understanding can only be dominant if the interaction is situated within many conventions, such that smooth understanding can take place without theoretical considerations about the others' beliefs and intentions (de Bruin et al. 2012). But is understanding through primary interaction, as it already takes place in neonate imitation (Meltzoff & Moore 1977, 1994), really the main or the standard strategy for understanding others? Again, even if we grant that this is an important strategy in basic understanding of others, even in adults—e.g., in minimal understanding deployed by smoothly interacting with a stranger who is taking the same bus—we need more advanced strategies to frame estimations about the ramifications of the situation—e.g., whether taking this bus in an unknown city, by night, and with such people on board, is a reasonable risk to take.

3.4 The multiplicity view

To summarize thus far. We use at least four epistemic strategies to understand others, and we learn to use these strategies on the basis of evidence of successful application in the past in relevantly similar situations. We prefer to use simulation strategies where we have evidence that the other is similar to us in respect of many features that are relevant to the situation of evaluation. We typically use theory-based inferences if we need to account for complex men-

tal phenomena or if an intuitive understanding is, for whatever reason, not available. We use understanding by primary interaction in cases in which we are involved in interaction with the other and only need to understand her or him to a limited degree, such that acting according to conventions is sufficient for a smooth interaction. Finally, we normally rely on direct perception of mental phenomena when we are in an observational stance towards the other and have a rich, well-organized body of experience that allows us to recognize mental phenomena as patterns. This is rather easy in cases of emotion recognition, more complex in recognizing intentions, and almost impossible in understanding complex propositional attitudes of others. Only the combination of all four strategies, in full sensitivity to the context and applied on the basis of our experience in successfully using the strategies, makes us experts in understanding others. Thus, we have reached a first main conclusion concerning strategies of understanding, this being what I call the multiplicity view:

The multiplicity view =_{Def} There is no standard default strategy of understanding others, but in everyday cases of understanding others we rely on a multiplicity of strategies that we vary depending on the context and on our prior experiences (and which are eventually also triggered by explicit training).⁴

This thesis is also supported by a closer look at mental disorder such as Asperger's syndrome, which is a variant of autism (Fiebich & Coltheart under review). People with Asperger's syndrome lack an intuitive understanding of others. They are unable to directly perceive emotions on the basis of facial expressions, and they tend to avoid social interaction (Vogeley 2012). Thus intuitive understanding by primary interaction or direct perception is not available for them. Since they also tend to experience themselves as being different (Vogeley 2012), they do not use simulation as a strategy: so

⁴ This view was worked out in parallel by Anika Fiebich in her PhD thesis, under my supervision. She applied the thesis in discussing the case of autism (defended January 2013).

they are left principally with theory-based inferences (Kuzmanovic et al. 2011). And this is what we can observe: persons who are autistic try to understand others by asking for theoretical guidance; thus they might ask how long one is allowed to look into the eyes of another person (Kai Vogeley, personal communication; his expertise is based on regular treatment of more than 300 patients). They also learn what people think in typical situations, but become lost in new situations. Since we have to deal with new situations almost every day, autistic people notice their tendency to get lost and many of them avoid social encounters. This special situation is explained by the fact that in contrast to the usual multiplicity of strategies of understanding, they are left with theory-based inferences alone. People with Down's syndrome are in a contrary kind of situation: they have a good intuitive understanding of others' emotions, but, due to typically very constrained cognitive abilities, they lack any theory-based inferences. In the early years of childhood—where cognitive skills are not so important as in kindergarten or school—their social life is very similar to the social life of children without Down's syndrome; but in later life the interdependence of social interaction with cognitive abilities leads to more problems in building an inclusive social life (Buckley et al. 2002). Thus, the normal multiplicity of strategies may be strongly constrained in some conditions of mental disorders. Furthermore, we can roughly cluster direct perception and interaction as the main epistemic access for *an intuitive understanding* of others, while *inference-based understanding* is based mainly either on a (high-level) simulation strategy or theory-based inferences (including inferences from narratives, see below). Since in our everyday life most of what is going on is intuitive understanding of others, it is especially important to highlight the relevance of social perception. In what follows, I will argue that the most important unit of clustering information about others is neither a facial unit nor an emotion type (or some other sub-personal unit), but the *whole person*—and thus a primary aspect of epistemic access is our ability to perceive persons. We *perceive persons* and

their mental settings mainly by directly perceiving them, and/or interacting with them. In addition, we can come to *judgments regarding persons* by simulating them and/or through inference-based understanding.

4 The organization of relevant background knowledge about others

We can now address the second independent question concerning understanding others: How do we organize the information about other people that we already have? This question presupposes that in standard cases of understanding others we are not in a situation in which we are bereft of relevant background knowledge. Quite the contrary: most of the time, we interact with people about whom we have a lot of background knowledge—family members, colleagues, friends, etc. Furthermore, we have background knowledge about the general needs of human beings, the special needs of students, homeless people, etc. It seems clear that we are relying on this type of knowledge in an essential way when we understand others. There may be very short period as a newborn baby when we start from scratch, armed only with certain inborn minimal mechanisms such as neonate imitation. Even the social smile developed with two months is dependent on external stimulation and learning processes, and babies very quickly start to react selectively towards familiar and foreign individuals. They also expect a typical behavioural interactive pattern from the caregiver. If a mother stops reacting intuitively through normal facial expressions and gestures, and instead reacts with a “still face”, then the baby quickly starts to cry (Bertin & Striano 2006; Nagy 2008). The baby is irritated by the unexpected pattern of reaction. How, then, are all these different types of background information about the other organized and used in social understanding?

4.1 Are we organizing our prior knowledge in folk-psychological theories?

The question of whether we are organizing our knowledge according to folk-psychological theor-

ies has received a number of different answers. According to TT, this is exactly what happens. In understanding others we rely on folk-psychological rules such as: “If she desires an ice-cream and she believes that she can get one with her money at the cafeteria, then she will go to the cafeteria”. No doubt folk-psychological rules, organized according to a belief–desire psychology, are an important instrument for understanding others; but they are by no means the only one. Often it is sufficient to know the conventions in a society to understand what someone is doing and will do next, e.g., if someone is in Japan and he enters a restaurant, he will first take off his shoes, then take a seat, and then will be asked to order. So, seeing someone entering a restaurant who looks like a guest (and not a waiter) allows us to expect a specific conventionally-regulated sequence of behaviour. If one has a liberal notion of folk-psychological theory, then we may add such behavioural conventions into that theory. But even then the question remains whether our understanding of others always relies on knowledge organized as a folk-psychological theory. A counterexample can be proposed by reference to cases of basic intuitive understanding: e.g., the still-face reaction by the caregiver, instead of a typical smiling facial expression and gestural response, makes the baby start to cry (as we saw above). There is thus an intuitive recognition of basic emotions like fear, anger, happiness, or sadness. This may rely on inborn emotion recognition mechanisms, or mechanisms learned very early, which may be evolutionarily anchored, since recognizing such basic emotions is essential for survival (Griffiths 1997; Panksepp 2005). There are two ways in which the counterexample might be blocked: (i) It could be maintained that some folk-psychological theories are inborn (Baron-Cohen 1995) and that intuitive understanding such as face-based recognition of emotion already involves a theoretical package. The problem with this line of reasoning is that the notion of theory, stretched that far, starts to look very implausible. A theory is constituted by a minimal package of systematically interconnected beliefs; and even if a belief is understood in a liberal way such that it does not presuppose linguistic rep-

resentations, it remains highly questionable whether basic cases of face-based recognition can be characterized as a systematically interconnected set of beliefs. The standard descriptions of face-based recognition of emotion (e.g., Goldman 2006) on a neural level highlight the relevance of mirror neuron mechanisms and characterize the underlying mechanism as a rather basic and partially independent pattern-recognition process, and thus as not forming a theory. A defect in recognizing disgust does not automatically lead to a defect in recognizing other basic emotions like happiness or sadness (Calder et al. 2000). (ii) A more promising move is to claim that the folk-psychological theory is learned (Gopnik 1993). This view is compatible with some basic processes of understanding which do not yet form a theory, but are developed into one as they are integrated step by step into a systematically-organized body of knowledge. This is a plausible and to some extent empirically grounded view (Gopnik & Meltzoff 1997; Newen & Vogeley 2003).⁵ One shortcoming of this view, however, is that its proponents tend to appeal to examples that have a strong focus on general folk-psychological rules, such as: “All humans need to drink, thus if someone picks up a glass in the kitchen, he intends to pour into it some liquid to drink”. This neglects a very important phenomenon, namely that we mostly interact not with complete strangers but with persons we know at least partly and often very well. For example, if Michael observes his son in the kitchen grasping a glass he does not appeal to the folk-psychological rule at all, since he knows that his son—despite his education—still only drinks from a bottle when at home, and that if he takes up a

5 Gopnik and Meltzoff insist that the basic registration of objects—e.g., their being sensitive to object permanence, as well as the basic registration of agents rooted in their being able to distinguish inanimate objects and living beings—which babies develop very early on, shows that they already have an *initial theory* of objects and agents. They argue that the already innate “structures are rich enough and abstract enough to merit the name of theories themselves” (Gopnik & Meltzoff 1997, p. 82). But it is questionable whether the notion of theory really has any fruitful role here, because, for example, explanations and predictions of the behaviour of a baby when seeing an object are extremely constrained. The developmental story told by Gopnik and Meltzoff is of course very plausible and at some point turns into a theory, because the transformation of the representation in the context of new cognitive abilities comes with a rich and systematic package of explanations and predictions.

glass it is just because he wants to use it for practising magic tricks. This indicates that all the theories canvassed thus far have a blind spot: so far it seems simply to have been neglected that we rely extensively on knowledge of properties of individuals, which is organized as belonging to one specific individual (the son, the partner etc.) or to a group (students, managers, etc.). The general worry concerning the organization of this knowledge, according to TT, can also be expressed as follows: How are we able to apply a general theory of typically human features in a *specific social* situation? If we want to integrate our prior background knowledge of persons as individuals or as belonging to a group, e.g., to a profession, then we can characterize the organization of this knowledge as *person models*. Person models of individuals and groups are by far the most important source of understanding others, I will argue, and since they involve specific knowledge, they are the natural candidate for enabling adequate deployment of more general knowledge of human psychology in concrete everyday situations. It remains to be discussed, then, whether person models have the status of a folk-psychological theory or not. To adumbrate my line of argument: no doubt some elaborate person models are systematically-interconnected sets of beliefs, but not all of them have to be, because some person models only involve very sparse and basic properties that are not highly interconnected.

4.2 Do we organize our prior knowledge in narratives?

As we saw earlier, one recent account of understanding others, proposed by [Dan Hutto \(2008\)](#), holds that understanding others mainly relies on telling stories and using this knowledge to understand individuals. The core claim of his NPH (Narrative Practice Hypothesis) is

[...] that direct encounters with stories about persons who act for reasons—those supplied in interactive contexts by responsive caregivers—is the normal route through which children become familiar

with both (1) the basic structure of folk psychology and (2) the norm-governed possibilities for wielding it in practice, thus learning both how and when to use it. ([Hutto 2008](#), preface, p. x)

One focus of his theory is not so much how the prior background knowledge of others is organized, but rather how children are able to acquire it. His developmental claim is that the central route for learning relevant background knowledge is listening to stories about persons. I grant that this is an important additional route of epistemic access to relevant knowledge about others; but it is already an advanced method, not normally used before the second year of life. Furthermore, in such cases the focus is not epistemic access to knowledge used to understand the other in the situation (i.e., when listening to the storyteller), but rather to gain new background knowledge with an eye to future understanding of others. In a follow-up paper written together with Gallagher ([Gallagher & Hutto 2008](#)), Hutto and Gallagher enrich their views about epistemic access through appeal to direct perception and interaction (see above) in addition to learning by narratives. It is important to note the difference between epistemic access to information that allows me to understand the other in the actual situation (see section 3) and epistemic access to background knowledge relevant for future usage. Thus, by granting that narratives are an additional instrument for learning about important properties of persons, I can enrich my multiplicity claim as characterized above. In integrating this idea, one should also generalize it: we not only learn important background information that helps us to understand others by listening to stories told by a caregiver, but also by reading stories, especially novels.

Let us now briefly discuss the NPH considered as a claim about the organization of our background knowledge. If I have elaborate and explicit knowledge of a person, I may have acquired it by listening to or reading a story, and I may tell a story if someone asks me about this person. But, as the interaction view highlights, sometimes my knowledge may be anchored in

the interaction, yet still be non-linguistically represented, and only activated in similar interactive situations. Our rich non-linguistic knowledge about other human beings, which we acquire when directly perceiving them (tone of voice, what they look like) or interacting with them, or when realizing a joint action, etc., are often not linguistically coded and thus not memorized as a linguistic story. If we widen the notion of a story such that it includes any sequence of memorized events, we lose track of any interesting notion of “story”. In fact, we are instead going in the direction that I propose, i.e., that we organize our prior knowledge about others through unifying it in person models. Some such models may include properties of a person that are connected as or with stories, but the core of a person model is a unity of features of a person that are grouped together as belonging to one individual or to a group, where the features may be as primitive as the tone of voice of a person, and have no connection to any story, even in a wide sense.

Although our prior knowledge about others is the main component of our understanding of others in a specific situation, most of the theories canvassed above did not present any clear view on how this knowledge is organized.⁶ We found only two suggestions: relevant prior knowledge is organized either as a folk-psychological theory or as a narrative. Neither proposal covers all relevant cases: neither accounts for the innate or very-early-learned (nontheoretical) basic background knowledge that enables us to effect smooth interaction and allows us to rely on a basic intuitive understanding of others. And, furthermore, as I argue in the following, there is an alternative view, the person model theory, which is able to integrate the plausible aspects of these two suggestions, and additionally allows us to explain a variety of phenomena that the alternative views did not or cannot take into account—especially the integration of features of

other human beings that allow us to realize an intuitive understanding of them.

5 The person model theory

Before expounding the new account, let me highlight two main criteria of adequacy for any plausible candidate theory and some open questions. (i) The theory should account for two levels of understanding others from a phenomenological perspective, namely intuitive understanding and inference-based understanding. This was first clearly discussed by [Gallagher \(2001\)](#), while [Goldman \(2006\)](#) described it in his distinction between low-level and high-level mindreading. What, we may then ask, would be an adequate way of establishing this distinction? (ii) We learned from [Gallagher \(2005\)](#) that we should distinguish understanding others by observation from understanding by interaction.

There are also a number of open research questions that can potentially be answered in developing the alternative account: (a) What is the relation between understanding oneself and understanding others? Here the ST claims that understanding oneself is the basis for all understanding of others, while TT is neutral; [Carruthers](#), for example, has famously argued that understanding others is the source of our self-understanding ([2009](#)). (b) What is the relation between understanding persons and understanding objects or situations? (c) How can we best account for the difference between understanding a well-known person, on the one hand, and a complete stranger, on the other?

The new alternative theory, which promises to deal with these open questions, is the person model theory. The central claim of this theory is that we organize our prior knowledge that is used to understand others into something we can call person models, and that accounting for our way of using person models is the most informative factor when analyzing our everyday understanding of others. A person model⁷ is a unity of properties or features that

⁶ This includes, e.g., the ST, which mainly offers a claim about how we use our knowledge to understand others, and that the main source of this knowledge—in addition to situational input—is one’s own experience. But a representative of ST can easily grant that relevant prior knowledge is organized in a folk-psychological theory. She only insists that the strategy of application of this knowledge in a situation is a simulation process.

⁷ An important question which I cannot discuss in this paper is the question of the development of person model and the limits of application. Some very sketchy remarks may be of help here for urgent

Table 1: Varieties of person models

Person models	Self	Other: Individuals	Other: Groups
Person schema	Self schema	Individual person schema	Group person schema
Person image	Self image	Individual person image	Group person image

we represent in memory as belonging to one person or a group (resp. type) of persons. To account for the difference between two types of understanding others (intuitive versus inference-based understanding), I suggest that there are two types of person models in use: implicit person models,⁸ which we shall call person schemata; and explicit person models, which we shall call person images. Very early in life we develop *person schemata*: a person schema is an implicit person model and can typically be described as a unity of sensory-motor abilities and basic mental phenomena⁹ realized by basic representations and associated with one human being (or a group of humans), where the schema typically functions without any explicit considerations and is activated when directly seeing or interacting with another person. A person

schema is thus the unity of implicitly-available information about a person that is thus not easily accessible in terms of being reportable but is nevertheless used in a specific situation. In other words, a person schema is the basic unit that enables a practical knowledge (a *knowledge how*) for dealing with another human being while this ability relies mainly upon social perception and interaction. Person schemata can be developed step by step into *person images*. A person image is a unity of explicitly represented and typically consciously available mental and physical phenomena related to a human being (or a group of people). Thus, a person image is the unity of rather easily and explicitly available information about a person, including the person's mental setting. Both person schemata and person images can be developed for an individual, e.g., one's mother, brother, best friend, etc., as well as for groups of people, e.g., medical doctors, homeless people, managers, etc. Furthermore, person models are created for other people but also for oneself.¹⁰ In the case of modelling oneself we can speak of a self-model that we develop implicitly as a self-schema and explicitly as a self-image. Thus, we have the following varieties of person models (see Table 1).

Person models are characterized here as memorized units of person features, ignoring the difference between long-term or short-term memorization.¹¹ Person models are distinguished

questions: Concerning the development I suggest that person model unfolds gradually from an early model of living agents which is based on sensitivity for clusters of features indicating animacy and agency. This "agent models" enfold into person models which are systematically enriched by the features I describe as belonging to person schemata and person images. Furthermore, a creation of a person model (which is a unity of information clustered together) does not presuppose a concept of a person. Person models are developed in fact if some typical features of adult healthy human beings are clustered to model an individual or a group of entities which are relevantly similar to adult healthy human beings. Typical core features are e.g., 1. being an agent, 2. being a sentient being, 3. having some minimal control of action. We use person models to understand babies and pets since we usually perceive them as having a minimal amount of core features.

⁸ I am only presupposing a minimal consensus on using the distinction of implicit versus explicit. It indicates a (gradual) difference in epistemic access such that paradigmatic cases of explicit contents are easily accessible (by the subject's experience, memory, thinking, imagining etc.) while paradigmatic cases of implicit contents are very difficult to access by the subject while they nevertheless influence the subject's cognition and behaviour. Intuitively, explicit content are correlated with our intuitive understanding of *conscious accessibility*, but since the latter is scientifically pretty unclear, I do not want to ground the implicit/explicit distinction on the difference between being or not being consciously accessible.

⁹ Mental phenomena have different ontological types: states, events, processes, and dispositions. So not only are stable mental phenomena included but so are situational experiences (like tokens of perceptions, emotions, attitudes, etc.).

¹⁰ The distinction between *person schema* and *person image* is based on Shaun Gallagher's distinction between *body schema* and *body image*. Establishing a *person schema* of my own body amounts to Gallagher's *body schema*, while a *person image* of my own body is similar to what he introduces as *body image* (2005, p. 24).

¹¹ In a more detailed explication of the theory, it would indeed be useful to distinguish short-term person models (only stored in working memory) and long-term person models (stored in a long-term memory). In addition, other established distinctions in memory can be used to characterize the content of person models, such as procedural and declarative contents as well as episodic and semantic contents. I will, however, ignore these distinctions in this paper.

from the result of understanding in a situation, which may be either a person impression that mainly relies on person schemata, or a person judgment that mainly relies on person images. Let me illustrate one clear virtue of adopting the distinction between person schema and person image by reference to the fact that it can account for the difference between intuitive understanding and inference-based understanding of others.

5.1 Person schemata

In detail, then, what are person schemata? A *person schema* is an intuitively formed, implicit model of a person; it is a memorized unity of characteristic features of a person including facial features and expression, voice, moving pattern, body posture, gestures, and other perceivable features of a person. The function of clustering these features is to allow us to evaluate a person very quickly in a situation according to evolutionarily-important aspects: is a person familiar, dangerous, aggressive, helpful, or attractive? The evaluation is either expressed in a type of interaction, or it can simply be memorized in an implicit unitary structure for future retrieval, including recognizing the person and activating the former evaluation (Reddy 2008). Our main access to others in everyday life is through perceiving a person and forming an impression (see the review published as a book chapter by Macrae & Quadflieg 2010). To form a person impression, (i) we typically pick up these basic features by means of a quick visual evaluation, even when seeing a person for the first time, where (ii) most features are directly associated with socially-relevant information, and (iii) they are clustered at the level of perceiving the whole person. Let me offer some support for all three characteristics of the process of forming a person impression in a situation that is memorized as a person schema:

(i) *Quick evaluation even with parsimonious information*: Evaluations of threat (which is of strong evolutionary relevance) can be made on the basis of exposure to an unfamiliar face lasting as little as 39 milliseconds (Bar et al. 2006). If the exposure to the unfamiliar face

lasts about 100 milliseconds, we are able to evaluate likeability, trustworthiness, competence, and aggressiveness with subjective reliability levels that are similar to those generated under longer viewing times (Willis & Todorov 2006).¹²

(ii) *Most features are associated with socially relevant information*: looking into the face is a very rich source of information about a person. Between 3 and 7 months of age, infants learn to recognize the face of the mother and to distinguish it from the faces of strangers, and they start to categorize people according to emotional expression and sex (Nelson 2001). One important source of information that children use from 4 months onwards is the gaze-direction of a person, it having been shown that they can distinguish a direct from an averted gaze (Vecera & Johnson 1995). From 9 months onwards, infants learn to register the joint attention of the infant and an adult as directed towards an object (Cleveland & Striano 2007). Thus, on the basis of gaze-interaction they evaluate whether joint attention towards an object has been established or not, and learn to direct the attention of the other if necessary (Tommasello 1999). Between the ages of 9 and 18 months, children start to use gaze-information to register the *goal* of the action of the other human: they attend immediately to the eyes when the intentions of an actor are ambiguous (Phillips et al. 1992).

Let me now pick out some results based on studies of adults that illustrate the informational value of single cues. To start with facial expression: in emotion recognition, highly in-

¹² The time course can be observed in ERP studies. These studies all support claims about the early information processing of faces, although there is an ongoing debate about how best to interpret the results. The main observations are enhanced responsiveness to faces relative to a variety of other objects with peaks at approximately 100 milliseconds (Herrmann et al. 2005; Liu et al. 2002; Pegna et al. 2004), 170 milliseconds (Bentin et al. 1996; Eimer & McCarthy 1999; Itier & Taylor 2004), and 250 milliseconds (Bentin & Deouell 2000; Schweinberger et al. 2004) after stimulus onset. (For review see Macrae & Quadflieg 2010). Whole bodies (without faces) are evaluated with a delay of 20 milliseconds compared to the evaluation of faces (Gliga & Dehaene-Lambertz 2005). Concerning faces with emotional expressions, the following rather stable result is reported: there is a frontocentral positivity as early as 120 milliseconds after stimulus onset and a later more broadly distributed positivity beyond 250 milliseconds; both are modulated by emotional facial expressions (Eimer & Holmes 2002; Holmes et al. 2003; Vuilleumier & Pourtois 2007; Williams et al. 2006).

formative features include knitted eyebrows for sadness, a smile for happiness, and a frown for anger (Ekman 1972, 1999). To prevent this remark giving the wrong impression, I here highlight some individual features and will argue in the next step that they are part of an integrated view at the level of persons. Salient biological visual markers allow us to easily identify the “big three” categories in person perception (Brewer 1988; Fiske & Neuberg 1990), i.e., sex, race, and age. In the same way, we can illustrate highly informative single features such as body posture: if the other is bending her head in a communicative context, this is unconsciously registered as signalling sympathy (Frey 1999).¹³ One important data source here is biological motion-detection as investigated by point light studies. If a person has lights on her hands, feet, and ankles, and some other significant parts of her body, we can videotape her bodily movement in the dark. Such artificial pure biological movement information allows us to register social features, e.g., we can recognize emotions (Ambady & Rosenthal 1992) and attribute personality features (Heberlein et al. 2004) on the basis of seeing dynamic movements alone. Furthermore, there is evidence that social information can be taken from the combination of gesture and body posture alone. In an intercultural study (Bente et al. 2010), an interaction between an employer and an employee (played by two students of one type of culture) was filmed for a short period. Then the film was edited to show only gesture and body posture. This was realized by showing idealized wooden puppets, representing the real interaction while abstracting from facial information, speech, clothing etc. The question to be addressed was, what we can read from seeing the body postures and gestures. The interactions were filmed with students from UAE (United Arab Emirates), Germany, and the United States; and the test subjects were also drawn from all three countries. With this film, people could determine whether the people in the scene were nervous or not, as well as the dominance relation, i.e., they

could see who was the boss. This is an interculturally-shared social understanding of otherwise culturally variable cues of body posture and gesture (the US students moved a lot while the UAE students moved rarely). They furthermore could perceive the level of friendliness in the interaction, although the study showed that we are good at this only in assessing our own culture.¹⁴ Furthermore, there are many more complex culturally-dependent visual features that (according to other studies) we use for evaluating the other—e.g., physical attractiveness, where attractive people are evaluated as possessing more desirable characteristics than their less attractive counterparts, a phenomenon that has been labelled the *beauty-is-good stereotype* (Dion et al. 1972; Eagly et al. 1991). These kinds of stereotypes are especially connected with racial classifications: African-Americans are stereotypically assumed to be lazy, criminal, and uneducated, but also musical and athletic (Devine & Elliot 1995), whereas Asian-Americans are considered to be intelligent, industrious, conservative, and shy (Lin et al. 2005). Most observers in our culture assume that people with stylish hair and extravagant clothing are highly extrovert (Borkenau & Liebler 1992). We live with a lot of these deeply culturally-anchored stereotypes, and they are often applied without the perceivers’ intention or conscious awareness (Macrae & Bodenhausen 2000). This last point relates to the third aspect of person schemata. Person schemata are unities of characteristic features integrated at the level of persons. All these singular features are integrated into person models that enable us to develop detailed and extensive expectations of behaviour.

(iii) *Integration of characteristic features at the level of perceiving the whole person:* Although I have presented evidence that some single features are very salient for transferring social information, there is also much evidence that these features are normally combined with a variety of others to form an integrated impres-

¹⁴ Interestingly, Germans could perceive the friendliness of students from the US and UAE partially (as well as the other way around), while students from UAE and USA could not read the level of friendliness from the other culture at all (Bente et al. 2010).

¹³ We leave the question open as to what extent person schemata are constituted by innate or by learned dispositions. The examples mentioned above indicate that they involve properties of both kinds.

sion of a person that I call a person schema. We have seen evidence for the key role of gaze detection in registering another person's direction of attention (see ii). But there is further evidence that gaze alone is not the critical source of information; we actually seem to rely on an integrated evaluation on the basis of perceiving gaze, head, and body position (Frischen et al. 2007). The same holds for evaluation of the basic features sex, race, and age. Although isolated facial features are often sufficient to determine a person's sex, research has indicated that sex categorization is based on the integration of several features (Baudoin & Humphreys 2006; Bruce et al. 1993; Brown & Perrett 1993; Roberts & Bruce 1988; Schyns et al. 2002). Concerning face, the best available theory of face recognition seems to be Haxby's account (Haxby et al. 2000), according to which there are two distinguishable processes, one leading to face identification by focussing more on invariant core features, and the other leading to registering facial expression by relying on varying features. Furthermore, there is evidence that there are two different neural circuits for face perception and body perception (see the review by Macrae & Quadflieg 2010), both playing a core role in registering face or body identity, and playing an extended role in registering face or body expression in a given situation. And the integration processes are not limited to this level (Martin & Macrae 2007). Since we know that information about facial and bodily features is integrated, e.g., in the evaluation of emotional expression, we can therefore characterize a sequence of integration processes as leading finally to a person impression in a situation, which may be stored as a person schema in memory.

5.2 A model of forming a person schema

How can we best describe this process of forming a person schema? In general terms, the same complex process takes place in the case of perceiving a person and forming a person impression in a given situation as takes place when we perceive an object. I describe the process according to the model of object

perception developed by Ernst & Bühlhoff (2004), and I have already shown in detail that it can do justice to our recognition of emotions (Newen et al. forthcoming). The overall process comprises bottom-up processes starting with basic visual features that are modulated either by feature combination (if two features provide complementary information), or by feature integration. The latter can be modelled as a Bayesian weighting process that leads to the most probable intermediate estimate given the input. Further integration processes then lead from the most probable estimate to a stable percept of an object in the case of object perception, and to a stable person impression in the case of person perception. This model explicitly accounts not only for bottom-up but also for top-down processes, in the form of so-called cognitive penetration. I have sketched a plausible but in no way complete model of the formation of a person impression (see figure below). According to the evidence I have presented so far, it is plausible to suggest that at the level of intermediate estimates in the process of forming an impression of a person, we find (a) an estimation of a core person identity, (b) an estimate of situational emotions, intentions, and actions, as well as (c) an estimation of social status, person abilities, and individual personality traits. An important step in the model is the association of visual features with socially-anchored stereotypes (see above) which allows us to develop rich intermediate estimates, e.g., of the other's emotional situation, social status, etc.

Numerous lines of research (Albright, Kenny, & Malloy, 1988; Ambady & Rosenthal, 1992; Behling & Williams, 1991; Borkenau & Liebler, 1992; Kenny, Horner, Kashy, & Chu, 1992; Norman & Goldberg, 1966; Secord, Dukes, & Bevan, 1954) have provided compelling evidence that trait evaluations are readily drawn from a person's physiognomy (i.e., facial features), outer appearance (i.e., clothing), or demeanor (i.e., posture, walking, style). (Macrae & Quadflieg 2010, p. 433)

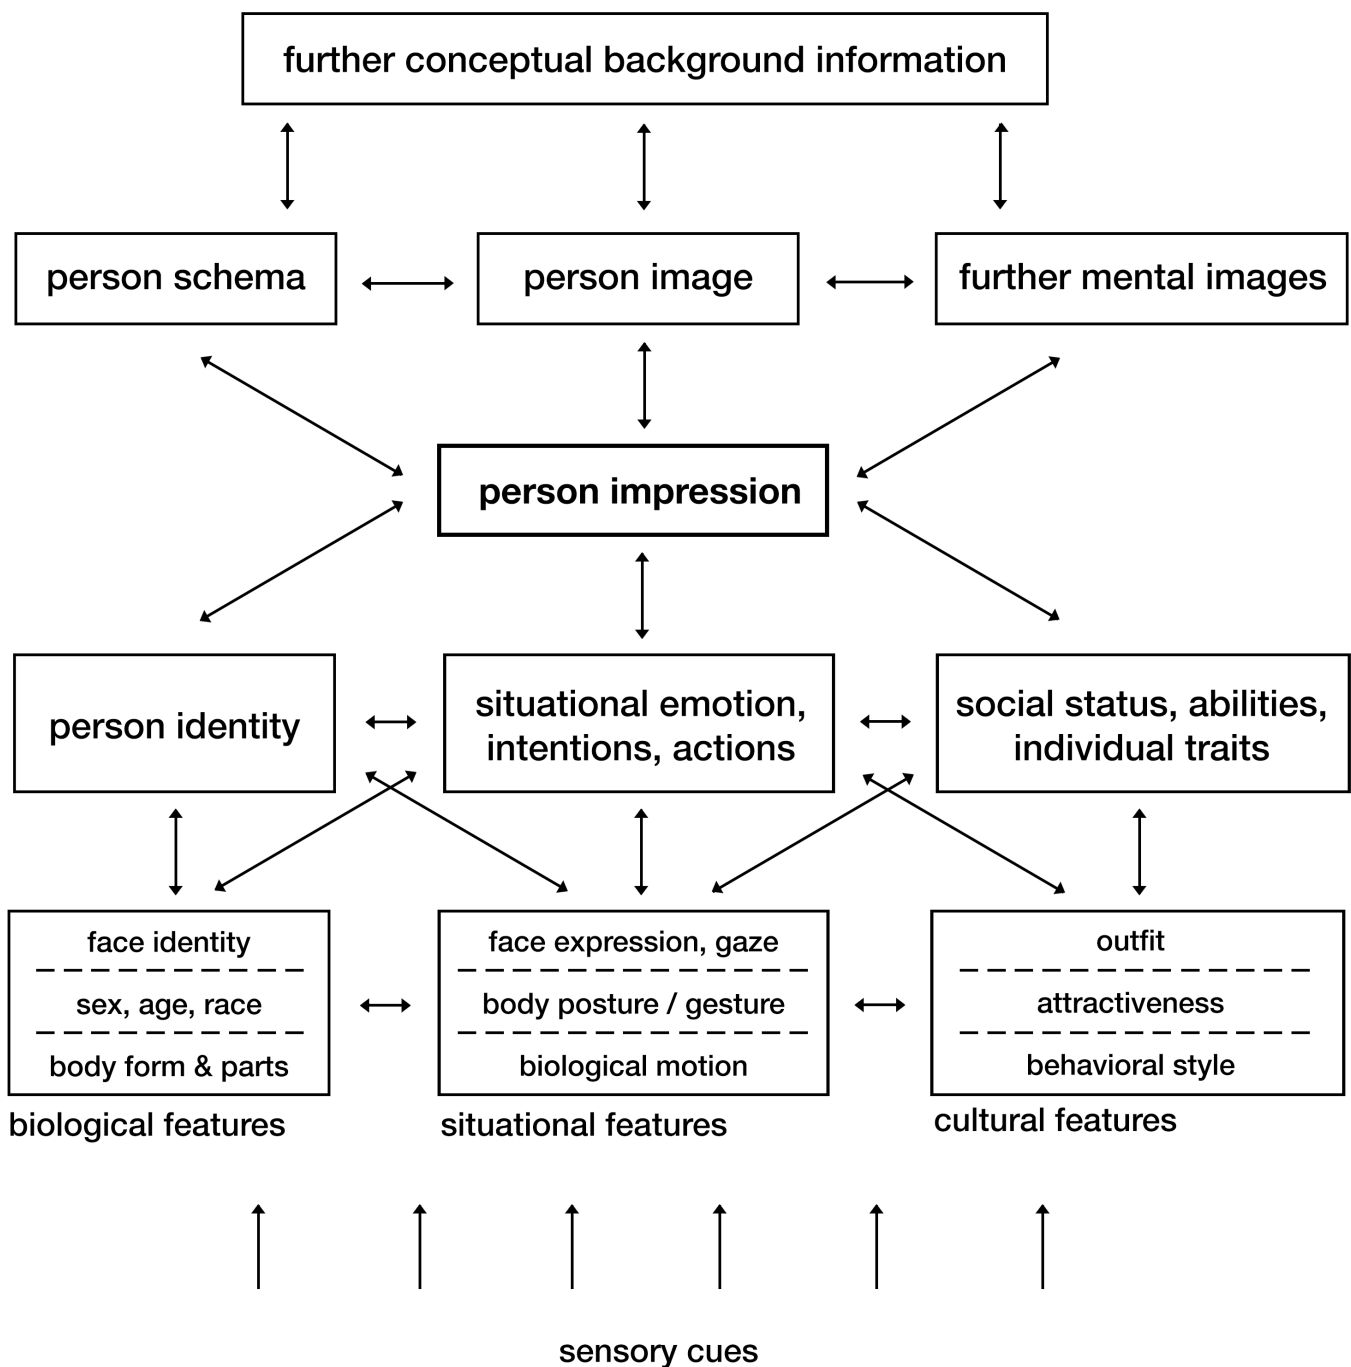

Figure 1: A model of the dynamics of bottom-up and top-down processes leading to a stable person impression by relying on person images and/or person schemata

Finally, I highlight that the top-down processes are able to interfere in this process of combination and integration very early in the visual information processes: for example, it has been shown that the activation of a race concept on the basis of the form of a face (African versus European face format) changes the perception of colour in the face, while colour is known to be represented in V4 as part of early visual

brain processes. The same hue of colour is seen as more dark in the African face than in the European face (Levin & Banaji 2006). Thus we have to admit that the process of feature-combination and integration is highly dynamic, involving simultaneous activation of features rooted in bottom-up and top-down processes, finally reaching the most probable and usually stable person impression. The dynamic is de-

scribed in detail for the case of object perception in Vetter & Newen (2014); it is postulated for person categorization in Macrae & Martin (2007), and analysed according to the levels of processing that lead to person construal in Freeman & Ambady (2011). Figure 1 is a sketch of the formation of a person impression according to my account.

A person schema emerges as the result of direct perception of a person, where this may be either basic or relatively smart perception; yet it usually remains implicit, and is not amenable to linguistic description. A typical example of person schema based on basic perception is the everyday experience of seeing a person only briefly in a single situation, whereupon it is difficult for us to describe the person—particularly her face. While we can often easily recognize the person, it may take hours with a professional to end up with an adequate “identikit” picture such as those produced at police stations. A person schema based on smart perception might be, for instance, a person schema that includes a lot of top-down activation—for example, while on campus, perhaps I see a person of typical student age dressed like a law student, and thus activate the “rich person” schema that is the basis for my everyday smooth interaction with law students, and which differs (despite overlaps) from my person schema for students in natural sciences. If we not only develop implicit practical knowledge regarding our use of the person impression (independent from its richness), but also develop explicit *knowledge* pertaining to the relevant person information, or at least develop easy explicit access to it, then we go beyond a person schema. We can characterize this new unified information as a person image.

5.3 Person images

In detail, then, what is a person image? A person image is a unity of relatively easily and explicitly available information about a person, including her mind-set. On the basis of typically implicit person schemata, young children learn to develop explicit *person images*. These are models of individual subjects or groups. In the

case of individual subjects, they may include names, descriptions, stories, whole biographies, and visual images highlighting both mental and physical dispositions as well as episodes. Person images are essentially developed not only by observation but also by telling, exchanging, and creating stories (or “narratives”).¹⁵ Person images presuppose the capacity to explicitly distinguish the representation of my own mental and physical phenomena from the representation of someone else’s mental and physical phenomena. This ability develops gradually, reaching a major and important stage when children acquire the so-called explicit theory-of-mind ability (operationalized by the false-belief task, see Wimmer & Perner 1983).¹⁶ Then they are able to construct explicit person images by characterizing a person such that they attribute a biography to an individual. There is strong folk-psychological evidence that we have explicit person models of the people we deal with extensively, e.g., family members, and people about whom we tend to have a lot of explicit knowledge. The same is true for relevant groups of persons we deal with often. Even in professional contexts this leads to judgments that can be inadequate: the apparent association between wearing revealing clothes and immodesty and promiscuity has been shown to cause not only laypeople but also police officers and judges to hold victims of rape to be responsible for their having been assaulted (Lennon et al. 1999). An essential part of becoming an adult is learning to interact socially with other humans, by developing sophisticated and explicit person images of the groups of professions we have to come to any sort of arrangement with. We often have explicit beliefs about medical doctors, managers, secretaries, craftspeople, etc., and we try to deploy these beliefs to deal with these people in a smooth and efficient way. When we

¹⁵ This is the aspect of the narrative approach to understanding other minds, mentioned above (e.g., Hutto 2008). But narratives are only one method of establishing a person model. Representatives of a pure narrative approach underestimate the importance of other sources, such as perceptions, feelings, interactions, etc., which often do not involve narratives.

¹⁶ There is a long and not fully understood process of development from implicit false belief sensitivity to explicit false belief understanding (de Bruin & Newen 2012a; 2012b). Person images actually presuppose an explicit representation of false beliefs.

have stored a person image in memory, and are placed in a new situation in which we see and recognize the person, there is evidence that we immediately activate the biographical knowledge we have available. For example, when test persons were asked to judge the traits of target individuals from photographs, the test persons' responses continue to be influenced by what they have explicitly learned about the people in question (Uleman et al. 2005). A recent neuroimaging study (Hassabis et al. 2013) indicated that when test persons were asked to predict the behaviour of persons, they essentially relied on prior knowledge of personality traits, which in this particular study were implemented in two ways, namely as agreeableness (the tendency toward altruism, cooperation, and the valuing of harmony in interpersonal relationships as opposed to antisocial and exploitative behaviours) and as extroversion (in contrast to introversion). The test person became acquainted with four types of personalities that had been constructed from combinations of high and low versions of agreeableness, on the one hand, and high and low versions of extroversion, on the other. In the test situation they had to predict the behaviour of four specific persons who were exemplars of the four personality types. The authors report that the predictions of behaviour were mainly based on personality traits and that the latter also had rather clear neural correlates: by using functional magnetic resonance imaging (fMRI) the authors showed that there is a neural correlate for recognizing (and imagining) high agreeableness (in contrast to low), namely in the left LTC (lateral temporal cortex) and dorsal mPFC (medial prefrontal cortex), as well as for recognizing (and imagining) high extroversion (in contrast to low), namely in the pCC (posterior cingulate cortex); in addition the recognition (and imagination) of one of the four personality types was correlated with four distinctive patterns in the anterior medial prefrontal cortex (mPFC). In line with my proposal, the authors of the fMRI study write: "Different patterns of activation in the anterior mPFC could reliably distinguish between the different people whose behavior was being imagined. It is hypothesized that this

region is responsible for assembling and updating personality models" (Hassabis et al. 2013). Since the study was based on explicit evaluation of personality features or types, I take this to support the existence of person images. Yet even if the reader accepts the idea of person models, she may be sceptical about whether we need to distinguish person *schemata* and person *images*.

5.4 Why should we distinguish person schemata and person images?

A very convincing case that forces us to make a distinction between person schemata and person images comes from taking a closer look at a typical patient suffering from Capgras syndrome, a misidentification syndrome. Sufferers have the delusional belief that one of their closest relatives, e.g., their wife, has been replaced by an impostor. Such a patient typically says things like "this person looks exactly like my wife, she even speaks and behaves like my wife and she expresses her typical desires but she is not my wife" (Davies et al. 2001); thus, one aspect of this mental disorder is the observation that all the features explicitly believed to be possessed by the wife are correctly attributed. We can account for this by asserting that the patient has an intact person image of his wife. Nevertheless, the usual person identification has gone wrong. According to a standard analysis, what is lacking in the case of the Capgras patient is a feeling of familiarity that normally comes with perceiving a well-known person. How can we account for this in the new framework? When perceiving his wife, the subject intuitively develops and activates a person schema. One aspect of the person schema is the person's identity.¹⁷ As the Capgras case nicely illustrates, the registration of a person's identity is a result of an integration process that relies not only on visual features but also on an implicit emotional evaluation, and that these together trigger an explicit judgment. While the

¹⁷ The involvement of identity already at the level of implicit schemata is supported by Haxby's model of face perception according to which we have to distinguish a core cognitive system involving the recognition of face identity and an extended cognitive system which is enabling the recognition of facial expression (Haxby et al. 2000).

visual recognition fits, here the emotional evaluation is inadequate and the feeling of familiarity is lacking; and in the case of this disorder, the Bayesian integration process for these features leads to an implausible result, since the emotional mistake overrides the visual adequateness. Thus, the Capgras patient has an adequate person image of his wife but an incorrect person schema, and the tension between the two is solved by developing the (implausible) hypothesis that she is an imposter. This analysis is in line with two-factor theories of the Capgras disorder, according to which two distinct factors cause the phenomenon¹⁸: first, the lack of familiarity, and, second, a local breakdown of rationality that enables the irrational belief-formation on the basis of a severely disturbed person schema (Davies et al. 2001).¹⁹ Several other cases seem to be accounted for if we accept the evidence for a two-factor theory of person modelling—namely a first level of intuitive and implicit person impression and a second level of explicit person evaluation, which are described respectively as intuitive person schemata and explicit person images.

A contrast case to Capgras syndrome is the Fregoli syndrome, wherein a patient has the delusional belief that one and the same person, usually a persecutor, is following her, who is able to radically change his outer appearance. The sufferer then connects people with rather different outer appearances and treats them as the same persecutor. One explanation, still in need of testing, is that this time the feeling of familiarity is developed too often, probably by top-down initiation due to the delusional belief

that the subject is being persecuted. The delusional belief, together with an inadequate feeling of familiarity, may explain the syndrome.²⁰ But again we need to distinguish the two factors: a level of implicit feeling or impression, and a level of explicit judgment. This time the delusion produces a breakdown of rational judgment formation, i.e., the person model of the other is strongly influenced by the delusion: the person schema formation may be largely intact but has a local defect due to being dominated by the delusional belief. In general, monothematic delusions (delusions about a single belief content) seem to rely on two factors (Coltheart et al. 2007): “[o]ne factor has to explain the strange experiences patients claim to have, while the other factor has to explain the misattribution of actions and thoughts” (Vosgerau & Newen 2007, p. 40).

Are there nonpathological everyday cases that support the distinction between person schema and person image? One illustration can be drawn from Mark Twain’s “Huckleberry Finn.” At first Huck helps the slave Jim to escape from slavery; but then he rethinks his support in the light of the law, and forms the judgment that he should turn him in to the slavehunters. But when he has the opportunity to do so, Huck actually ends up protecting Jim. Why does he do this? Huck has a person schema of Jim that is constituted by a person impression according to personal interactions that are dominated by empathy; thus he has a positive impression of Jim and there exists between them a growing friendship. On the other hand, he has a person image of Jim that is dominated by the fact that he is a slave, such that he has to accept his role in society, to do the hard work, to live without freedom, and thus that it is forbidden to aid his escape. Cases of tension between an intuitive person impression (being helpful, being peaceful) and a person image dominated by the knowledge that the same person is a pathological murderer are often reported by judges and policemen. A less dramatic tension seems to be part of our everyday experience of “false” friends (we may still think of someone as

¹⁸ In the literature there are discussed one-factor accounts to explain mental disorders, e.g., in the case of schizophrenia (Gallagher 2004): a top-down approach argues that disturbances of higher-order cognition is the only source for thought insertion (Stephens & Graham 2000) while a bottom-up approach argues that thought insertion is a product of disturbances of neural or basic cognitive processes (like perception). Most of the recent accounts are hybrid account which we call two-factor theories.

¹⁹ The fact that person identity as a component of person schema formation is not only based on visual but also on an emotional evaluation is supported by the case of prosopagnosia, i.e., the inability to recognize the face of the person one is seeing, even though one is able to see and perceive the rest of the person adequately. Despite the fact that a person suffering from prosopagnosia is not able to see the familiarity of the face, we can measure increased skin conductance for familiar but not unfamiliar faces, thereby demonstrating intact (albeit covert) emotional recognition of known others (de Haan et al. 1992; Tranel & Damasio 1985).

²⁰ For a discussion of delusional phenomena, see Coltheart et al. (2007) and Hirstein (2005).

a friend while implicitly already noticing signs of unfair treatment), though of course the tension can also exist the other way around. As illustrated above, the visual features of a person are often loaded with social information, and often involve the activation of negative prejudices which, after a more careful investigation of the person, can be opposed by a positive person image. The general functional role of person models is to simplify the structuring and evaluation of social situations, to enable a quick evaluation of the person in a given situation, and to initiate adequate behaviour. An additional special functional role of person models consists in stabilizing my self-estimation, since there is a strong tendency to have positive stereotypes of one's own in-group members and negative stereotypes of the out-groups' (see Volz 2008, p. 19). These examples illustrate not only that we need to distinguish the person schema and person image, but also that we have a tendency towards harmonizing both. Thus, if one of them is disturbed we tend to adjust the other, which may result not only in wrong judgments about persons, but in extreme cases may become an aspect of a mental disorder, as described above. Finally, to distinguish them is compatible with the claim that a person image may often gradually evolve on the basis of a person schema such that partially the same information about a person changes the status of accessibility from implicit to explicit. But we also have to distinguish both kinds of person models because often an implicit representation of a person as unfriendly exists simultaneously with an explicit evaluation of the same person as friendly.

5.5 Person model theory (PMT) and its relation to other main theories

The central claim of PMT is that we organize information about others by forming person models. We account for a multiplicity of epistemic access strategies, while direct perception and interaction are the main source for person schema formation. Person image formation is based on all the epistemic strategies we have examined, including theory-based inferences and (high-level) simulation strategies. Why, then, is

PMT not a version of TT? Person models are more general and allow for a unification of rather parsimonious information about a person, which does not warrant being called a theory since it does not form even a minimal package of systematically-interconnected beliefs. As we learn more and more about the same person, our person model may develop into a theory. Thus, this is not to deny that we often have rich person models that are theories; and thus I can account for the empirical evidence that supporters of TT tend to rely on. A further question concerns how PMT is related to ST. Simulation is one epistemic strategy in which person models are used to understand others: if I have evidence that another person is similar to me in relevant respects, then I may use my self-model, either the self-schema or the self-image, to produce an explanation or a prediction of the other's behaviour. But I also often have clear knowledge that the other is different from me in relevant respects, especially when there are great differences in the three main categories—sex, age, and race—or in cultural background. In such cases simulation is not used. Although simulation is a worthy epistemic strategy, it is only of limited and constrained use in everyday understanding. How is PMT related to interaction theory and direct perception theories? It explicitly accepts the important role of both as epistemic strategies, but insists that in addition to understanding others in situations of direct interaction there is also often an understanding of others just by observation. The use of these two strategies seems to depend heavily on the personality traits of the person who aims to understand another: while extroverts mainly rely on interaction, introverts (who avoid social contact) mainly rely on observation. Furthermore, these theories do not offer an answer to the main question addressed in this article, namely how we organize the information about other people that we already have. The narrative account offers one answer here, and again we can account for the role of narratives that in the case of rather rich person models may be sources for creating or enriching the models further, or they may also concern the way a person model is memorized. But the narrative account

person model theory

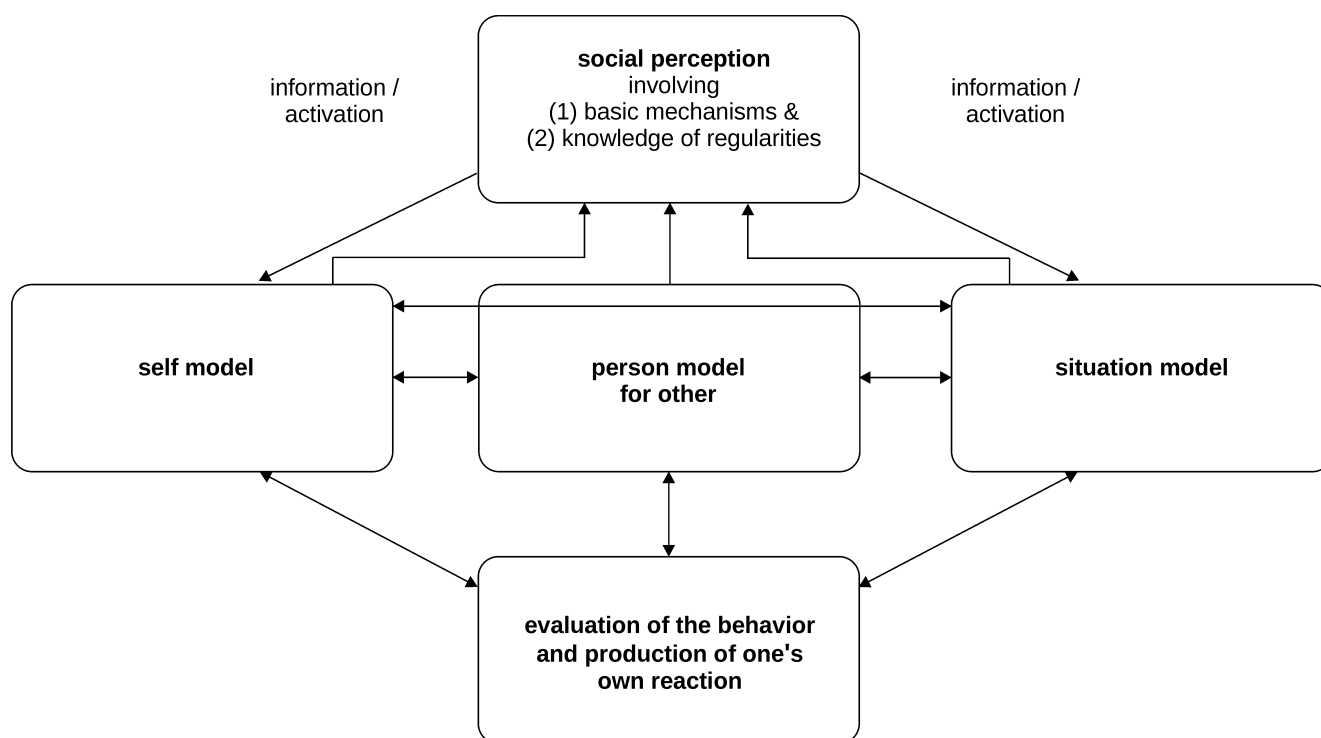

Figure 2: Interaction of person models with situation models in understanding others

alone ignores the strong relevance of our intuitive understanding of others as it is anchored in person schemata. This short overview, then, indicates that all of the evidence that representatives of other theories put forward can be integrated into this view, while there is further evidence for my theory, e.g., rich evidence that there is an integration of information into person models by person perception. Notably, PMT allows us to account for certain mental disorders, and I have cited evidence from a very recent fMRI study that is further supportive of the organization of information according to person models.

5.6 Widening PMT: Person models, situation models and culture

Does PMT give us the complete story about understanding others? What about my understanding of a person whom I only see from behind, when queuing at a self-service restaurant? Here it seems sufficient to predict her behaviour just by expecting her to act according to the so-

cial conventions of a self-service restaurant. Understanding the situation alone seems to be sufficient for an understanding of and interaction with the other.²¹ This is an important observation that suggests a widening of my theory: we do not only create person models, but also situation models, and our understanding of others uses both types of model as input and selects the most helpful model for evaluating the other person. If I have no person model of this individual, if seeing someone from the back gives me only very parsimonious information, and if I am only interested in getting my lunch, then the situation model may be dominant in dealing with persons in this context. As soon as minimal enrichment of person information is available we naturally tend to rely on person models. The fact that situation models are used at all is supported by successful artificial intelligence (AI) studies working with scripts and

²¹ These types of cases are considered in Gallagher & Hutto (2008), in the section “Pragmatic Intersubjectivity”. Their view is close to a multiplicity view. A minor criticism is that we have to account for such cases independently from being in interaction with someone. They may also involve only observing the other.

frames that can account for human behaviour (Schank & Abelson 1977). Furthermore, in Asian cultures the understanding of other people seems to rely much more on social conventions, since people are strongly expected to behave according to these conventions. In general, situation models are more important for understanding others in “collectivistic” cultures than in individualistic cultures where explanations and predictions of behaviour are usually more reliant on individual belief–desire explanations. Such observations as these require us to give an account of situation models. This can be easily done by widening the theory of understanding others such that it includes situation models, as well as the interdependence of personal models and situation models. It can also include a dynamic, involving bottom-up and top-down processes that lead to an activation or construction of the most plausible person model for interacting with, explaining, or predicting the behaviour of the other person.²² Here is a rough outline of the process leading to understanding others in the rich sense of interacting, such as in observing, explaining, or predicting (see Figure 2).

In general, we should note the important role of culture in shaping our way of modelling persons (Vogeley & Roepstorff 2009). As we have seen, culture modulates the relevance of person models in relation to situation models. But it also influences our formation of person models, for example by shaping our person perception. To illustrate: Japanese individuals are encouraged to be sociable and cooperative (Moskowitz et al. 1994), to be affiliative rather than competitive (Yamaguchi et al. 1995), and to show obligation to others (Oyserman et al. 1998). Concerning dominance and subordination, Japanese people learn to be rewarded for subordinate behaviour, while Americans learn to be rewarded for dominant behaviour. This

also shapes the perception of dominance and subordination in others. Typical neurological activations of the mesolimbic reward system can be shown to be shaped by the respective culture: Americans show a higher activation of this system when doing and seeing dominant behaviour (in contrast to subordinate behaviour) while with Japanese people we can observe the opposite: they show a higher activation of exactly the same system when doing and seeing subordinate behaviour (Freeman et al. 2009). Thus, the perception of dominant and subordinate behaviour is connected with opposite evaluations (Americans highly esteem dominance while Japanese people highly esteem subordinate behaviour) and a different set of personality traits. Cultural influences on the psychological and neural level are also reported for self-models: on the psychological level, the difference between an Asian interdependent self and a Western independent self was reported by Markus & Kitayama (1991), while a respective difference in neural correlates was also recently discovered (Sui & Han 2007).

6 Conclusion

Our understanding of other minds is based epistemically on a multiplicity of strategies, the core strategies being direct perception, interaction, simulation, and theory-based inferences (including learning from narratives). The most important aspect of understanding others is the activation of prior knowledge of individuals or groups of persons. This is organized into person models. The main claim of PMT is that we rely on *person models* to understand others. These person models form the basis for perceiving and evaluating persons, their social behaviour, and their mind-set. We develop person models for ourselves, for other individuals, and for groups of persons (group models). Furthermore, all types of person models can be realized on two levels: (implicit) person schemata and (explicit) person images. A *person schema* is a bundle of information including information about sensory-motor abilities, voice, face, basic mental dispositions, etc., and such schemata are intuitively used, implicitly developed, and not usually

²² There is already one dynamic model of person construal available in the literature that also supports my dynamic theory of understanding others with person models, i.e., the model of Freeman & Ambady (2011). Despite its merits in describing social perception in more detail as regards the interrelation of bottom-up and top-down processes, the authors neither account for the claim that our rich prior information is mainly organized on the level of persons (not faces or subpersonal features), nor do they account for the interaction between person models and situation models.

easily accessible for linguistic report. A *person image* is a unity of explicitly-registered mental and physical dispositions as well as situational features (like perceptions, emotions, attitudes, etc.) that is usually easily accessible for linguistic report (albeit sometimes with the help of gesture, drawings, etc.). The PMT has several advantages over existing accounts of social understanding (e.g., TT, ST, and interaction theory), since it can account for all of the following criteria:

1. It explains specific and more general social understanding of particular individuals in terms of individual person models and group person models. (Not accounted for in ST.)
2. It accounts for the difference, for which evidence is presented, between implicit, intuitive forms of social understanding and explicit deliberative ones by appealing to the role of person schemata and person images respectively. (Not accounted for in interaction theory.)
3. It does justice to folk-psychological evidence that we understand very familiar persons much better than unfamiliar ones: We have rich person images of individuals with whom we are very familiar. (Deficit of all former theories.)
4. It marks adequately in what ways our understanding of others and our self-understanding are interdependent, e.g., in special cases of simulation, understanding the other relies on self-models. (Generally not accounted for in TT.)
5. It offers an adequate framework that is in line with the best explanations of some mental diseases in understanding others, such as the Capgras and Fregoli syndromes. (Deficit of ST.)
6. It can account for cultural differences in social understanding: Future research will show how person models vary with culture, and we have already illustrated that it varies in the case of self-models between Asian and Western cultures. (Not accounted for in any former theory.)

Thus, PMT is at least a serious alternative account, and certainly a candidate for future investigation.

Multiplicity Needs Coherence – Towards a Unifying Framework for Social Understanding

A Commentary on Albert Newen

Lisa Quadt

In this commentary, I focus on Albert Newen’s multiplicity view (MV) and aim to provide an alternative framework in which it can be embedded. Newen claims that social understanding draws on at least four different epistemic mechanisms, thus rejecting the idea that there is a default mechanism for social cognition. I claim that MV runs the risk of combining elements that have been described in meta-physically incompatible theories. I will argue that multiplicity needs coherence, which can be achieved by applying the theoretical framework of first-, second-, and third-order embodiment (1-3E; [Metzinger 2014](#)) to the study of social cognition. The modified version of this theory, 1-3sE (first-, second-, and third-order *social* embodiment), can serve as a unifying framework for a pluralistic account of social understanding.

1 Introduction

The multiplicity view (MV) is part of Newen’s person model theory (PMT) and claims that individuals apply multiple epistemic strategies to make sense of other people, namely simulation, theoretical inference, direct perception (DP) and primary interaction.¹ He thus interestingly argues against the view that there is

something like a default strategy of social understanding. In the following, I will scrutinize MV and, in doing so, attempt to reach three goals: First, I reconstruct the main claims of MV and suggest that the development of such a pluralistic account of social cognition can be seen as contributing to the so-called “interactive turn” ([Overgaard & Michael 2013](#); section “The multiplicity view”). MV has the potential

¹ For a brief explanation of the terms, see [Newen this collection](#), pp. 1-2.

to integrate bodily and interactive contexts, while also paying more attention to the phenomenology of social encounters. Second, I argue that current pluralistic depictions of social cognition – of which MV is a clear example – run the risk of operating under (often implicit) contradictory background assumptions. In the section “Multiplicity needs coherence”, I first show how and why different social cognitive mechanisms have been described under different sets of metaphysical assumptions. Since these assumptions are often contradictory, a coherent version of MV cannot simply claim to combine them. I then go on to argue that the concept of DP as an epistemic mechanism is either metaphysically incompatible with simulation and theorizing, empirically implausible, or – if it is re-formulated so that it fits a representationalist description – does not meet the goal of integrating embodiment and phenomenology anymore. I will thus claim that DP should be used as a phenomenological rather than epistemological concept. My third goal is then to suggest novel ways of adopting a pluralistic perspective on social cognition, while remaining in metaphysically coherent territory. Metzinger’s theory of first-, second-, and third-order embodiment (1-3E) is a conceptual framework that combines representationalist and non-representationalist levels of analysis in order to show how a specific phenomenal quality (e.g., phenomenal selfhood) can arise within an embodied system (Metzinger 2014). Metzinger claims that phenomenal properties are computationally grounded in a representation of one’s body (the “body model”, *ibid.*, p. 273), which in turn is physically implemented by bodily and neural structures. I aim to apply this idea to the study of social understanding (section “1-3sE – Levels of social embodiment”). This application enables a more fine-grained depiction of different phenomenal qualities in social encounters and shows their putative relation to representational and physical counterparts. I ask which parts of the body model could potentially be shared and thus be exploited for a skillful navigation of an individual’s social environment. In a last step, I sketch the physical grounds of social cognition.

2 The multiplicity view

The multiplicity view (MV) is part of Albert Newen’s person model theory (PMT), which provides a rich and detailed account of social understanding. It attempts to answer two central questions in the research field of social cognition, which the author neatly differentiates and then again integrates into a comprehensive theory. The first question asks which epistemic strategy humans use to access the mental states of others and to gather information about them. Approaches advocating Simulation Theory (ST; e.g., Goldman 2006), as well as direct perception (DP; e.g., Gallagher 2008), have attempted to yield an answer to that question, while Theory Theory (TT; e.g., Gopnik & Meltzoff 1997) and Narrative Practice Hypothesis (NPH; e.g., Hutto 2008) focused on a second question: How is the information we obtain to understand others stored and organized? By sorting out these questions, Newen shows that different theories have tried to tackle different problems, which I believe to be a very useful and fruitful contribution to the research field. It reveals that the four main theories mentioned above are less competitive than originally thought, since, on closer examination, they actually aim to give answers to different questions. This viewpoint enables one of Newen’s main arguments, namely that each of these approaches can be merged into one unified account of social understanding. He takes three steps in arguing for his theory. In a first step, he differentiates between the two questions in the research field of social cognition mentioned above, thus setting up a dividing line between the vast manifold of different approaches and theories. Secondly, the author puts forth a pluralistic account of social cognition, the multiplicity view (MV). In doing so, he attempts to answer the first question discussed earlier. In a third step, Newen tackles the second question of how knowledge about other people is organized and stored. He claims that this happens through the formation of so-called *person models*, hence person model theory (PMT; see Newen this collection).

By laying out MV as a pluralistic account of social cognition, Newen aims to steer the discussion in the research field into a different direction, away from debating whether social understanding is a form of simulation, theoretical inference, DP or interaction. Instead, he argues that all four epistemic strategies are applied, depending on the social context (cf. [Newen this collection](#), p. 7). MV is of particular interest, because it reflects two growing convictions in the research field. First, by paying attention to DP and interaction, it does justice to demands that arose in the so-called “interactive turn” ([Gallotti & Frith 2013](#); [Overgaard & Michael 2013](#)) and can thus be seen as part of the movement itself. The interactive turn claims that researchers have not paid enough attention to the phenomenology of social encounters ([Gallagher 2001](#)), the interactive contexts in which most social situations are embedded ([De Jaegher & Paolo 2007](#)) and the role of the body and emotions in social cognition ([Schilbach et al. 2013](#)). This directly relates to MV, since it aims to include intuitive ways of social understanding that do not necessarily require simulation and theoretical inference and thus to widen the theoretical scope towards less “cognitivist” views. The second conviction is that there is more to social cognition than a single all-purpose mechanism ([Adolphs 2006](#), p. 30; [Fiebig & Coltheart in press](#)).² (Human) social cognition obviously is manifold; it has many aspects that are not only phenomenologically distinct (just think of the different experiences you have when trying to figure out your advisor’s somewhat cryptic Email, or when trying to make your 4 year-old eat her spinach), but also draws on several cognitive mechanisms that are differently implemented. It therefore makes sense that we can find something useful in each of the four theoretical approaches discussed so far; while ST and TT are plausible accounts to describe and explain “higher-level” social cognition that requires

quite sophisticated skills, other theories such as DP or interaction theory cover more intuitive ways of understanding others. Merging them into a comprehensive theory seems to be a natural next step.

[Newen](#) claims that

[t]here is no standard default strategy of understanding others, but in everyday cases of understanding others we rely on a multiplicity of strategies which we vary depending on the context and on our prior experiences (and eventually also triggered by explicit training). ([this collection](#), p. 7)

How does he arrive at this conclusion? Newen argues against the view that only *one* of the mechanisms that have been proposed to be important for social cognition (simulation, theorizing, DP and primary interaction) can plausibly be viewed as the default strategy by which humans understand each other. The main argument against such a single-mechanism view is that their activation seems to be highly context-dependent. Simulation, according to Newen, presupposes similarity between two interacting individuals. Theorizing only applies in complex social situations which need explicit and thoughtful disambiguation. Encountering someone of whom we already have rich prior information activates DP, while social situations that are easy to understand can be disambiguated by primary interaction. Thus, [Newen](#) concludes that “[o]nly the combination of all four strategies, in full sensitivity to the context and applied on the basis of our experience in successfully using the strategies, makes us experts in understanding others” (*ibid.*, p. 7).

3 Multiplicity needs coherence

While this surely is an attractive way to describe social understanding, and does justice to its oft-proclaimed manifoldness, these mechanisms have been described in several theoretical frameworks that operate under different (and partly contradictory) metaphysical

² Such a view can already be found in Goldman’s work. He endorses a hybrid account of mindreading, which describes “a number of ways to blend simulation and theorizing elements into a mosaic of mindreading possibilities” ([Goldman 2006](#), p. 43).

background assumptions.³ Thus, a simple combination of them does not come easily. Simulation and theory-based inference have been described within a computationalist, cognitivist framework which often assumes that the mind is mainly a representational and internal device (Bruin & Kästner 2012), i.e., a functional structure locally realized in the brains of individual organisms. Bodily and environmental structures play at most an enabling or causal role for a specific *internal* mechanism. In contrast, DP and primary interaction, both of which are concepts stemming from the phenomenological tradition, have their roots in an enactive account of cognition (cf. Gallagher 2008, p. 537), thus rejecting basic metaphysical assumptions of cognitivism (e.g., representationalism, reductionism, mechanistic explanations; Rowlands 2009).⁴ The theoretical background of DP and primary interaction views the mind as a non-representational, relational device which emerges within the skillful interaction between organism and environment:

The enactive interpretation is not simply a reinterpretation of what happens extraneurally, out in the intersubjective world of action where we anticipate and respond to social affordances. More than this, it suggests a different way of conceiving brain function, specifically in nonrepresentational, integrative and dynamical terms. (Gallagher et al. 2013, p. 422)

More specifically, enactive and phenomenological approaches to social cognition not only see the body as part of cognitive processing, they also assign a very important status to interaction. While enactive theories display interaction as (at least possibly) *constituting* social cogni-

ive processes (De Jaegher & Paolo 2007, p. 493), traditional mindreading theories have not even considered interaction to be an element which could influence social cognition (cf. Fuchs & Jaegher 2009, p. 466).

There are several reasons why ST and TT have been spelled out in a more cognitivist set of assumptions, while DP and primary interaction have been described in reference to an enactive framework. Although their roots in the history of ideas plays an important role, there are deeper systematic reasons why it makes sense to couch them in different sets of metaphysical assumptions. To see this, consider the relation between the external world and internal processing in either framework. A rather cognitivist view assumes that the task of the brain is to figure out the outside world and that this world is *internally represented*.⁵ Since other people belong to this world outside of one's own mind, it follows that the causes for their behavior need to be inferred by internal representation processing as well. Because it is assumed that the brain is the only mental organ (Hohwy [this collection](#)), the *location* of (social) cognitive processing thus can be said to be inside one individual's head. Simulation and theorizing fit neatly into this picture of the mind; they are inference processes which function to disambiguate social input and are implemented by specific neural mechanisms. By contrast, an enactive view of social cognition as has been described by De Jaegher and colleagues and advocated by Gallagher, presupposes two different assumptions. First, in order to assume that interaction dynamics carry as much of the "cognitive load" to understand other minds as is proposed, a relational view of the mind enters the picture. It is important to understand that an enactive view is not the same as an externalist view, which could be compatible with assumptions of

³ I am well aware of the fact that there are many shades of both cognitivist and enactive views. I will therefore focus on the views of the authors that have been cited by Newen in the target paper. For a general introduction, see for example Thompson (2010); Varela et al. (1993); Rowlands (2009).

⁴ The difference between enactive and phenomenological theories seems to boil down to the explanatory scope. While enactivism explicitly claims to offer a radically different alternative to cognitivism and thus builds a proper account of cognition (Varela et al. 1993) phenomenology is mostly seen as a description of experiential phenomena (Gallagher 2008).

⁵ Although this seems to be a rather "old" view, it is currently celebrating a comeback. Jakob Hohwy, for example, claims that the consequences of advocating predictive processing (2013; see also Clark 2013a) are to adopt a fully internalist picture of the mind. In his words, there is an "evidentiary boundary" (Hohwy 2014, p. 6) between what has to be inferred (viz., hidden causes in the external world) and the inference device (the brain). Accordingly, all the processing takes place within this boundary, which happens to be the skull (cf. *ibid.*, p. 8). Please note, though, that both Clark and Seth propose a more embodied perspective on prediction (Clark [this collection](#); Seth [this collection](#)).

the cognitivist camp (cf. Rowlands 2009, p. 54). The mind is, according to such an enactive perspective, neither internal nor external; it constitutes itself within the relation (hence *relational*) between an embodied agent and its environment (cf. Di Paolo & Thompson 2014, p. 68; Engel et al. 2013, p. 202). Such a view enables the claim that interactions are examples of this unfolding mental process and thus constitute social cognition. This claim is incompatible with an internalist perspective, which does not ascribe any constitutional power to mind-external properties.

Furthermore, if the external world and the minds of others could be *directly* perceived without further mental processing or inference, neither simulation nor theoretical inference would be needed. This is exactly the point of the non-cognitivist camp, as becomes obvious in this quote by Newen: “The mental states of others are not hidden, and need not to be inferred on the basis of perceiving the behavior; rather, behavior is an expression of the mental phenomena that, in seeing the behavior, is also directly seen” (this collection, p. 5). What does it mean that something can be *directly* seen? Gibson (1979) introduced DP in relation to his famous conception of “affordances”: “The affordances of things for an observer are specified in stimulus information. They seem to be perceived directly because they are perceived directly” (Gibson 1977, p. 79). Importantly, the direct perception of affordances is possible because, according to Gibson, affordances are physically *real* (i.e., they exist independent of the perceiving subject) and as such are perceivable properties of objects in the environment (cf. 1979, p. 129). Note how this is crucially different from a view which assumes that object properties need to be mentally represented, thus requiring an intermediary step.⁶ However, Gallagher makes explicit in a footnote (cf. 2008, p. 537) that his conception of DP is not to be *entirely* equated with a Gibsonian notion of the term. Gallagher emphasizes that he does not deny the underlying

complexity of perceptual processing, much rather he counts those processes as belonging to perception. He thus puts forth the conception of “smart perception”:

But this informing process is already built into the perceptual process so that as I consciously perceive, my perception is already informed by the relevant sub-personal processing. I don’t first perceive and then add memory in order to recognize my car. My perception, in this sense, is direct even if the sub-personal sensory processing that underpins it follows a complex and dynamic route. (*ibid.*, p. 537)

Even with that kind of definition, his view still presupposes that there are properties of external objects that can be “directly” picked up, that exist independently from the perceiving subject. As such, it is indeed *reminiscent* of a Gibsonian conception. The difference between cognitivist and non-cognitivist pictures of social cognition, in the cases that I just described, seems to boil down to the metaphysical assumption of whether or not there are hidden causes in the outside world that require an inference or representational mechanism in order to access and process them. While ST and TT clearly assume such a view, DP denies it. Therefore, I claim that MV cannot simply combine theoretical elements that draw on such considerable metaphysical differences.

Another important difference between these theoretical approaches is how each treats the issue of phenomenology. While the experiential nature of social encounters plays at most a minor role in mindreading theories, such as ST and TT, the phenomenal level is of paramount importance for the enactive camp, who advocate for DP. This becomes most obvious in the claim that the experienced smoothness and immediacy of social interactions tells us something about the epistemic access to other minds. However, “directness” as a concept in academic research is relative to a specific level of description. Let me explain this in more detail. Consider Gallagher’s argument that smart perception is a subpersonally informed mechanism (cf.

⁶ In the following, I will use the requirement of intermediary steps as the distinctive feature that differentiates directness and indirectness. In doing so, I follow De Vignemont: “There is a direct access if and only if the causal transmission of information is direct and does not involve intermediary steps” (2010, p. 291).

2008, p. 537) that directly enables an individual to perceive the minds of others without “additional mental effort.” It is based largely on the rapid activation of mirror neurons (30-100ms, *ibid.*, p. 541), such that he claims a distinction between a merely perceptual process and an additional mental process does not make sense. In his words:

A distinction at the neural level between activation of the visual cortex and activation of the pre-motor cortex does not mean that this constitutes a distinction between processes that are purely perceptual and processes that involve something more than perception. (*ibid.*, p. 541)

The question that follows is how one should individuate mental mechanisms, and I suggest that *functional properties* are much more substantial and conceptually relevant individuation criteria than temporal properties. It is, to me, highly questionable whether temporal correlation justifies assuming that there is mechanistic inseparability. The functional role of a mental mechanism seems a much less arbitrary criterion. Furthermore, it enables a more fine-grained view of the subpersonal processes that underlie social cognition. Instead of talking about perception—which could include all processes if only they are activated in a more or less specific amount of time—it is possible to take a closer look at which brain region correlates with which mechanism. If mechanisms are individuated by their *functional role* instead of the temporal properties of the physical realizers of this functional role, it makes sense to assume that the visual system and the mirror neuron system are distinct. If they are, however, it is unfeasible to speak of “smart perception”. This concept presupposes that perceptual and post-perceptual processes can coherently be described as *one* mechanism, which I reject. Additionally, the concept of “direct perception” does not apply anymore either, since mirror mechanisms should be seen as a functionally distinct and therefore intermediary step in the process of understanding others. I thus conclude that DP—as described by Gallagher—does not co-

herently apply to the subpersonal level of description.

This relates to my main point, namely that there are different levels of description at which a phenomenon can be scrutinized. At the phenomenological level, DP can be described as the experience of *directly* and *immediately* perceiving the other person’s mental states. I walk into my living room, I see my friend’s face and I experience myself as instantaneously knowing that she is really upset. However, this experiential quality of directness is brought forth by a subpersonal process, which is indirect, as I have argued above. At any other level of description, therefore, directness does not apply. In this view, DP is a phenomenal quality of some mental states and should thus not be confused with the epistemic mechanism *itself*. The simultaneity in our everyday experience does not justify anything on other levels of description. I therefore argue that DP should be treated as a phenomenal quality of *some* social encounters instead of assigning it the status of an epistemic strategy to access other minds.

Note that Newen does not explicitly support a phenomenological or enactive view of the mind, nor does he make any claims about the metaphysics of social cognition. What he does do, however, is emphasize Gallagher’s conception of DP and primary interaction as being the main sources for an epistemic access to other minds (cf. Newen *this collection*, p. 8). If Newen was to reject the strong claims of a non-representational view of (social) cognition, however, it is questionable how closely his notions of DP and primary interaction, as core concepts of his theory, actually relate to their original formulations. This leaves us with two options. The first is to assume that Newen fully endorses the views of his oft-cited colleague. In this case, the problem of compatibility becomes obvious. The second, and more likely possibility is that the author does not support DP and primary interaction with all their metaphysical implications. It indeed seems that he rather re-formulates both concepts so that they possibly fit into a representational framework. According to Newen (*this collection*, p.5), DP is realized by a process of pattern recognition and primary in-

teraction – although Newen explicitly cites [Gallagher & Hutto \(2008\)](#) – is characterized as follows: “[...] I notice a social act being directed towards me and so start to interact, such that a standard interaction is realized, which may be nonlinguistic but may also involve linguistic communication [...]” ([Newen this collection](#), p. 7). What is problematic here is that one of the most interesting and valuable features of MV gets lost, namely its potential to fulfill demands of the interactive turn. A true fulfillment would require widening the theoretical scope of social cognition by going beyond the study of individual brains and considering bodily, interactive and phenomenological processes more carefully.

What needs to be reconciled and made conceptually consistent is thus our choice of a specific, unified methodological framework—our overarching theoretical approach of simulation, theory-based inference, DP and primary interaction—since they all describe important aspects of social understanding. It should be a common aim to work with a coherent set of metaphysical assumptions, since whether or not one agrees on either set of background assumptions has important implications for both theoretical and empirical research. Not only does that decision influence our choice of the *unit of analysis*, i.e., how we frame the explanatory unit for empirical research. For a long time, this unit has been one individual observing another. It has been claimed, however, that this does not properly reflect the real nature of social cognition, and thus a shift is needed:

The explanatory unit of social interaction is not the brain, or even two (or more) brains, but a dynamic relation between organisms, which include brains, but also their own structural features that enable specific perception-action loops involving social and physical environments, which in turn affect statistical regularities that shape the structure of the nervous system [...]. ([Gallagher et al. 2013](#), p. 422)

When an enactive or phenomenological perspective is adopted and the status of interaction as constituting social cognition is accepted, this

adds an additional *level of analysis* (i.e., an “interactionist stance”; [De Jaegher et al. 2010](#)) while erasing one that is profound and fundamental for most researchers: representation. Furthermore, the shared goal to pay more attention to the body, interaction and phenomenology comes with many methodological challenges. For all these reasons it should be in the common interest of the research field to find a way to ease the tensions.

As I have shown, Newen tries to combine four elements that might not be entirely compatible. However, the core of his idea is highly valuable, and certainly should not be rejected. What his pluralistic account of social cognition claims is that there are low-level social mechanisms that mainly rely on interaction and do not need complex or explicit thought, while higher-level, sophisticated mechanisms play a just as important role for the phenomenon. While some social situations require processes that allow complex thinking, other contexts can be intuitively disambiguated. In what follows, I will sketch an alternative framework, based on Metzinger’s theory of three-level embodiment, which I claim is able to integrate the four elements while operating on coherent background assumptions. Additionally, it has the potential to fulfill the demands of the interactive turn by paying more attention to interactive contexts, the role of the body and the importance of phenomenology.

4 1-3E – First-order embodiment, second-order embodiment, third-order embodiment

Before I describe how the framework of 1-3E itself can be exploited for a pluralistic picture of social cognition, let me describe the framework in more detail. Metzinger’s goal is to provide a framework which shows how the experience of being a self is generated within an embodied system (cf. [Metzinger 2014](#), p. 272). The basic assumption is that experiential phenomena (such as phenomenal selfhood) can be described at several different levels: they have a specific phenomenal quality (i.e., phenomenological level of description), which is brought forth by under-

lying computations and representations (i.e., computational/representational level of description). These are implemented by their physical counterparts (i.e., implementational level of description). 1-3E is a theory about the grounding relations between them, that is, the grounding relations holding between phenomenal properties of representational states and their physical and computational resources. In a broader context, Metzinger claims that “the self” is not a thing or an entity (2004), but rather the phenomenal product of a complex computational process which happens to take place in embodied systems. If that is the case, however, the following question arises: How exactly is the experience of being a self generated within an embodied system? In other words, what are the grounding relations of phenomenal selfhood?⁷

Metzinger introduces three levels: first-order embodiment, second-order embodiment and third-order embodiment (Metzinger 2006, 2014). Importantly, these concepts not only describe different levels of embodiment and their relation *within* one system, they also refer to different *classes of systems* which possess different kinds of embodiment. To see this, think of the following three systems which all possess a body and some sort of skillful behavior: a worm, an advanced robot (e.g., the “starfish”, see Metzinger 2007), and a human in a waking state. As for the worm, it is safe to say that, in order to navigate its environment, it directly exploits its physical (i.e., bodily) resources. It is highly unlikely, however, that one would find any rule-based computation over an explicit symbol-like representational structure in the worm’s nervous system. In Metzinger’s terms, this kind of system possesses first-order embodiment (1E system). In contrast to this rather rudimentary kind of embodiment, 2E systems (i.e., systems which possess second-order embodiment) do unconsciously represent themselves *as* embodied. This means that they have some kind of body model that can be exploited by the system in

several ways (e.g., as a functional tool for motor control) and sustains skillful interaction with the environment. Importantly, 2E enables counterfactual representation, i.e., the ability to represent possible states without actual execution. The body model thus functionally underlies both physical and virtual behavior (see Cruse & Schilling this collection). What 2E systems are lacking, however, is a *phenomenal* representation of themselves *as* embodied systems. While a robot like the starfish can *use* its unconscious body representation to steer movements, it does not *experience* itself as doing so. Only systems that possess third-order embodiment (3E systems) experience this phenomenal quality of being an agent that owns a body. Humans in non-pathological waking states, for example, possess this kind of embodiment. Along with the ability to use their body model in the same way as 2E systems do, they have the additional sense of owning and controlling this model (cf. Metzinger 2014, pp. 274–275). Interestingly, it is also here that we once again find the phenomenology of “directness” and “immediacy”. It is important to note that 2E and 3E systems always possess lower levels of embodiment as well, since they build onto each other and higher levels presuppose the existence of lower levels. In this way, 1-3E can be seen as a grounding theory. To briefly summarize, systems that phenomenally represent themselves as embodied agents possess 3E. Phenomenal properties of states, described at this level, are computationally grounded by referring to a unified representation of the body – second-order embodiment. This unconscious body model, in turn, is grounded in physical and bodily resources, which are described at the lowest level of the hierarchy.⁸

Metzinger is clear about the relation between 2E and 3E; the representational content

⁷ “It is the problem of describing the abstract computational principles as well as the implementational mechanics by which a system’s phenomenal self-model (PSM; cf. Metzinger 2003, 2007) is anchored in low-level physical dynamics, in a maximally parsimonious way, and without assuming a single, central module for global self-representation.” (Metzinger 2014, p. 272)

⁸ I have argued before that a simple combination of cognitivist, representational, and enactive, non-representational perspectives results in a metaphysically incoherent view. One could ask why it should now be possible for 1-3E to put together non-representational and representational levels of description. As I have described earlier, most enactive theories reject representations entirely (e.g., Fuchs & Jaegher 2009, p. 466). That is one important reason why such a view is incompatible with representational theories. Grounding theories, however, take a different perspective on representations. They view them as *grounded* in bodily processes (cf. Pezzulo et al. 2013, pp. 6). As such, representations can be seen as a phenomenon that gradually emerges within an embodied system (cf. Metzinger 2014, p. 278).

of 2E is “elevated to the level of global availability and integrated with a single spatial situation model plus a virtual window of presence” (2014, p. 274). However, one thing that remains relatively vague in his theory is the relation between 1E and 2E. The problem I see here is that Metzinger does not explicitly describe what actually grounds 2E and which role bodily structures play besides that of yielding a grounding relation.⁹ A 1E system is defined as a “purely physical, reactive system”, which adapts to its environment by exploiting its physical resources. This is not, in my view, what is being represented by a 2E system, which represents itself “as an embodied agent” (*ibid.*, p. 273). What is needed is a more detailed and specific description of 1E and its relation to 2E. Therefore, the discussion of 1E in my own proposal is twofold. First, I analyze the low-level mechanisms that can be described at this level, claiming that they enable basic social skills (e.g., coupling). Second, I describe which neural, bodily and perhaps even extra-bodily structures most likely underlie social processes that are located at the level of 2sE.

There is one important aspect of 3E that I wish to describe in more detail as it will be crucial for my theory. Metzinger distinguishes two kinds of phenomenal properties instantiated by conscious representational states; they can be either *transparent* or *opaque*. Notice that he uses those terms in a rather counterintuitive way I will try to make sense of in the following.¹⁰ An analogy that might help to do so is to think of the difference between a freshly cleaned and a quite dirty window front. In the first case, when the glass is transparent, we can see everything behind it while not perceiving the glass *as* a medium we are looking through. However, if the glass is dirty and opaque, we will not only have trouble seeing the things behind it, we will also perceive the window *itself as* something we are looking through.¹¹ In analogy, consider mental states (and

their processing stages) as either transparent or opaque. A mental state is opaque when it is experienced *as* a representational state. A quite straightforward example is explicit thought where an individual is consciously aware of the fact that she is thinking. The process of representation *is represented as such* in this case, and is therefore opaque. In contrast, if a state is transparent, earlier processing stages are not phenomenally represented; they are not part of the experience of an individual. In the case of phenomenal selfhood, for example, all that is experienced is the sense of being a self in a world. The fact that this experience is a representational process is not part of its phenomenal content. Note that the distinction between phenomenal properties of epistemic mechanisms (such as computations and representations) and epistemic mechanisms themselves is central to the concept of transparency. If we do not experience that a specific phenomenal state is generated subpersonally, when the underlying processes are not elevated to the level of experience, all we experience is the subjective, phenomenological profile of that state. Such a claim is only valid, however, if we assume that these two levels are actually distinct, which seems to be denied by some philosophers in the phenomenological tradition.

In what follows, I will modify parts of the 1-3E framework in order to make it suitable for a pluralistic view of social understanding. The basic scaffold of the theory is retained, since its hierarchical structure is helpful for describing a multi-faceted phenomenon like social cognition. It also offers the possibility for future research to pair 1-3E and 1-3sE with other hierarchical theories of cognition, such as the predictive processing framework (PP; Clark 2013b; Hohwy 2013). PP has not only been described as a very promising theory to unify perception, action and cognition (Clark 2013b), it has also been fruitfully applied to social cognition (Kilner et al. 2007). 1-3sE has the potential to integrate this explanatorily powerful approach, the details of which can be spelled out in future research, but cannot be pursued in this commentary. I furthermore adopt the idea that different levels

don’t see the window, but only the bird flying by.” (2003, p. 358)

⁹ He gives, though, an example of phenomenal dream states, showing how (parts of) the body model is grounded in bodily structures and processes. Physical eye movements, in this case, most likely ground the phenomenal experience in lucid dreaming (cf. Metzinger 2014, p. 276).

¹⁰ For a more detailed description of former usage of the terms, see Metzinger 2003, pp. 345–358.

¹¹ Metzinger uses a similar example: “With regard to the phenomenology of visual experience transparency means that we are not able to see something, because it is transparent. We

of embodiment represent different levels of sophistication and complexity in a system. In order to strengthen this idea and to give an even more differentiated view of social understanding, I aim to make the difference between transparent and opaque social states more obvious. While the general distinction between transparency and opacity is retained, I will modify this aspect in order to make it fruitful for social understanding. To do so, I introduce the concept of “3sE+”, which describes experiences in social situations that need explicit and conscious thinking.

Transparency makes it furthermore possible, according to Metzinger, to distinguish one’s own body from that of others (cf. Metzinger 2014, p. 274). However, there is an objection I wish to make about this point. I claim that a self-other distinction that functionally serves to identify one’s own body in contrast to those of others is already present at the level of 2sE and thus can be achieved without *phenomenally* representing one’s body. I will argue for this claim in more detail in the next section.

Additionally, my proposal offers novel ways to enrich Metzinger’s original account. He claims that the functional structure of the body model opens a window into social cognition (cf. *ibid.*, p. 273). However, I suggest that this could be a bidirectional relation. There are hints in the literature that being immersed in a social environment is crucial and formative for more general cognitive skills and their development. For example, anecdotal evidence shows that emotional neglect of caregivers severely impairs the physical and mental development of children (Zimmer 1989). Empirical research furthermore shows that the presence, interaction, perception and emotional engagement of and with others shape self-related body representations (e.g., Furlanetto et al. 2013; Schilbach et al. 2013). Longo & Tsakiris (2013) thus conclude that this line of research suggests a strong connection between first-person and so-called second-person (Schilbach et al. 2013) processes, which needs to be considered by researchers of each camp: “Such findings support a model of first-person perspective according to which our sense of self is plastically affected by multisensory informa-

tion as it becomes available during self-other interactions” (Longo & Tsakiris 2013, p. 430). I thus conclude that it should not only be considered how the development of a self-model influences social cognition, but also which role social processes play in forming such a self-model. This opens interesting and new questions for research on both social cognition and the self. One could ask, for example, whether some social cognitive skills are necessary for the development of a stable self-model or whether there are “genuinely social” parts of the self-model.

5 1-3sE– Levels of social embodiment

In this section, I will introduce an alternative framework in which I describe different processing stages of social understanding as different levels of social embodiment. Before I go into detail about how to apply 1-3E to social understanding, let me motivate my strategy here. I have already pointed out why MV yields an attractive theoretical assumption for research on social cognition. It allows, to briefly repeat, the integration of different aspects of a manifold phenomenon and thus aims to give a comprehensive perspective that is able to encompass sub-areas of interest and research. The advantage of couching MV into 1-3E is that its hierarchical nature affords this integration at different levels of description, while operating on a set of coherent background assumptions. As a grounding theory, it suggests how different levels of analysis relate and at the least has the potential to assign an important role to aspects that lay outside an individual brain. As such it can also do justice to demands from the interactive turn, viz. the consideration of interaction dynamics and their possible role for social cognition as well as taking the phenomenology of social encounters seriously. However, MV suffers from the problem of metaphysical incompatibility. 1-3E, on the other hand, is a representational account that offers a metaphysically sound ground for a manifold phenomenon. My goal is to scaffold a framework for human social cognition, which, as I will argue, can be described as a case of 3E in non-pathological human individuals.

I will now briefly give a rough overview of my proposal of a three-level model of social understanding which I dub “1-3sE” (first-order social embodiment, second-order social embodiment, third-order social embodiment)¹², before I go into detail about what each level amounts to. As in the original version of the framework, levels of social embodiment represent both levels *within* a system and different *kinds* of systems. I thus assume that each social third-order system possesses first- and second-order social embodiment, too. In this commentary, I will focus on describing levels of embodiment within social systems, since this aspect of the framework is of greater importance for a pluralistic view of social cognition.

As previously mentioned, I take it that 1sE fulfills a twofold function: First, it serves as the implementational level of description, showing which physical parts ground higher-level, representational and phenomenal processes. Second, low-level sensorimotor mechanisms subserve basic social interactions (e.g., coupling or synchronization). 2sE involves the instantiation of a model which pre-reflexively represents features of the body. It is assumed that parts of this body model can be shared and thus functionally underlie social cognitive processes that may well operate at the unconscious level, such as imitation, joint attention and action understanding. Finally, 3sE describes cases of consciously experienced social understanding. I claim that there are various kinds of phenomenal experiences in social situations that can be differentiated by applying the concepts of transparency and opacity. Since I consider opaque social mental states to exhibit a very special kind of experience, which is not only rare, but might also entail an additional level of representation, I introduce an extra level: 3sE+. I will now describe the specific levels and their relation in more detail, before I show how my view overcomes the shortcomings of MV.

5.1 Third-order social embodiment (3sE)

Individuals that phenomenally represent themselves as social individuals can be described as

social 3E systems (3sE). There are certainly many different ways in which humans experience themselves as being social, but I will focus on those that are mentioned by Newen: DP, personal-level simulation, and explicit theoretical inference.

The concepts of transparency and opacity allow a more fine-grained distinction of different phenomenal experiences of social encounters, as they offer a way to emphasize the similarities and differences between various phenomenal qualities in social situations. DP describes the experience that I can, without being aware of any intermediary steps, understand another person. Importantly, as Zahavi points out, the perceived directness still holds in cases of “unsuccessful” social understanding, such as deception or misunderstandings (cf. 2011, pp. 548–549). Although I can get what you say completely wrong, for example, I would still *experience* myself as *immediately* understanding what you are saying.¹³ Since, as I have discussed earlier, the experiential nature of a mental state is not to be equated with its epistemic complexity, we can assume that DP operates on several subpersonal mechanisms. These are, however, not explicitly represented. Hence it makes sense to describe DP as resulting from *transparent* social cognitive states. By doing so, it is possible to keep its phenomenal status as immediate and direct, while not equating this quality with its epistemic status. In contrast, theorizing and personal-level simulation have a quite different phenomenal characteristic. In these cases, the process of *constructing* a specific insight about the other is part of the experience, may this be by explicitly simulating the person (e.g., “If I was her, what would make me excited about having a cat?”), or through theoretical inference (e.g., “People usually own cats to feel less alone, maybe she is excited to have a furry companion now”). They can thus be said to result from *opaque* social cognitive states. What distinguishes transparent from opaque states is the degree to which one’s own social cognitive processing, which is directed at the other person, is explicitly represented *as* a process.

¹² Note that Schilling and Cruse have already used the abbreviation “1-3sE” to describe levels of situated embodiment. I thus chose a lower case “s” to emphasize the difference (cf. Schilling & Cruse 2008, p. 72).

¹³ “There is, so to speak, nothing that gets in the way, and it is not as if I am first directed at an intermediary, something different from the state, and then only in a secondary step target it.” (Zahavi 2011, p. 548).

However, as already mentioned, I see the need to modify Metzinger's conception of 3E in order to reflect a proper distinction between transparent and opaque social states. I claim that opaque states exhibit an additional level of representation, since the representation process itself is part of the phenomenal experience. In order to emphasize that this is a special and probably rare phenomenon, I introduce the level of "3sE+". Both transparent and opaque social states are certainly to be located at the third level of embodiment, since they possess phenomenal properties. Metzinger suggests that the distinctive feature of 3E in contrast to lower levels is that it enables the system to identify itself with its body (cf. Metzinger 2014, p. 274). The resulting phenomenal properties of self-identification and selfhood stem from the experienced immediacy that comes with transparency (cf. *ibid.*, p. 273). If this is the case, it can be assumed that phenomenal states are not *either* transparent *or* opaque, but that transparency is part of *any* phenomenal state. The degree to which the representation process is explicitly represented varies, transparency and opacity are thus gradually arising properties (cf. Metzinger 2003, p. 358). Additionally, it could well be that there is a constant oscillation between transparency and opacity, depending – for example – on specific contexts and situations. However, opacity and the resulting experiences seem to be more high-level features that can only be found in a small subgroup of species. This is obvious in social understanding, since full-fledged theoretical inference and high-level simulation are not very likely to be found in most non-human animals and human infants. It seems that in the case of opaque states there is an additional level of representation that requires a higher level of sophistication, which should be made more explicit in the hierarchical framework. Transparent and opaque mental states – at least in this case for social understanding – reflect two different kinds of phenomenal experiences that might also have different underlying mechanisms. I thus introduce, in order to do justice to this difference, an additional level of 3sE, namely 3sE+. 3sE+ describes those phenomenal states during which one is aware of the con-

structing process and which occurs in situations that require this kind of reasoning in order to disambiguate the input. This additional distinction at the level of 3sE enables a more detailed view and underlines the difference between transparency and opacity.

One question that arises at this point is the following. We have assumed that opacity means to phenomenally represent (parts of) the actual process of representation. Does that mean that in the case of theorizing and simulation one would find their underlying representational processes to be subpersonal kinds of theoretical inference and simulation? There are two points that speak against this assumption. First, there are justified worries that the conception of implicit theorizing as an unconscious process stretches the concept of a theory too far (e.g., Blackburn 1992). These arguments against TT have been presented extensively in the literature and I will thus not repeat them here. In the case of simulation, secondly, it seems that subpersonal or low-level simulation does not necessarily generate the phenomenal experience of simulating. Consider the many studies that have been conducted to explore whether the activity of the mirror neuron system can be seen as a kind of implicit simulation that enables social understanding (for a review, see for example Cataneo & Rizzolatti 2009). In most of these experiments that found mirror neuron activity to be correlated with social understanding, it seems that the phenomenal experience has the character of DP rather than explicit simulation.¹⁴ Such a view, as I hope to have shown, has two advantages. It describes different kinds of phenomenal experiences in social encounters and distinguishes them by referring to the concepts of transparency and opacity.

5.2 Second-order social embodiment (2sE)

Assuming that there is something like a representational body model, we can now ask which

¹⁴ Note that this is a speculative claim, since almost none of the studies contain phenomenological reports. It could be fruitful, however, for future research to pay more attention to the experience that participants have in a specific experimental setting. This would help to understand which kind of epistemic mechanism generates which kind of experience.

parts of it can be exploited for social cognition. In order to do so, let me briefly recapitulate how to conceive of this body model. It has been described as a “grounded, predictive body model that continuously filters data in accordance with geometrical, kinematic and dynamic boundary conditions” (Metzinger 2014, p. 273). Furthermore, Metzinger predicts that parts of this model can be shared by individuals: “[...] on a certain level of functional granularity, this type of core representation [i.e., the body model] might also describe the generic, universal geometry which is shared by all members of a biological species” (*ibid.*, p. 273; see also Schilling & Cruse 2012). Together with Gallese he argues elsewhere that the mirror neuron system plays a crucial role in generating a basis for both an “internal model of reality” as well as a “shared action ontology” (Metzinger & Gallese 2003, p. 550). This means, as I take it, that the body model contains information that represents one’s own body, but is not completely self-specific. To see this, consider that in order to be shared, representations must not be too specific as to not generalize to the bodies of others. I will come back to this point soon. This consequence worried Newen, leading him to reject the view that mirror neurons form a basis for social cognition:

Why are mirror neurons not an essential part of understanding others? They represent a type of action or emotion that is independent from a first- or third-person perspective; but the distinction between self and other is an essential part of understanding others ([this collection](#), p. 4).

This raises the question of what exactly it is that can be shared by individuals. Since these considerations are central to the possibility of exploiting the body model for social understanding, I now aim to refute the worry and give a possible answer to the question.

Mirror neurons were discovered in the premotor cortex of macaque monkeys more than 20 years ago. They fire, as is famously known, both when an individual executes and observes an action (Gallese et al. 1996; Rizzolatti et al. 1996;

Rizzolatti & Craighero 2004). Although there is considerable controversy about their existence in humans (Hickok 2009), their actual function (Jacob 2008), and their explanatory power (Borg 2007), they are considered by many researchers to form one of the crucial systems for understanding others (e.g., Stanley & Adolphs 2013, p. 512). Mirror neurons are indeed neutral to the agent of an action – they fire whether an action is executed by oneself or another person. Insofar, critics are right to say that it is not obvious how they could provide the important distinction between self and other. However, it seems that there are two important facts left out in this line of thinking. Firstly, it has been suggested that there are inhibition mechanisms that “control” shared representations and provide the basis for a self-other distinction (for a more detailed discussion, see Brass et al. 2009). Secondly, mirror neurons have always been presented as being embedded in a *system* (hence mirror neuron system, e.g., Cattaneo & Rizzolatti 2009; Iacoboni & Dapretto 2006; Rizzolatti & Craighero 2004). This system consists of areas which contain mirror neurons, but also regions which contain neurons that do not have bimodal properties and encode only self-generated actions, as described by Jeannerod & Pacherie (cf. 2004, pp. 131–132).¹⁵ Thus, it is correct that mirror neurons *alone* do not distinguish between self and other. However, this is a rather impoverished view, since they should never be considered in isolation. A similar thought which helps to refute the worry is given by De Vignemont who adopts the view that mirroring can be seen as sharing body repres-

¹⁵ “The problem of agent-identification, however, is solved by the fact that other premotor neurons (the canonical neurons) and, presumably many other neuron populations as well, fire only when the monkey performs the action and not when it observes it performed by another agent. This is indeed another critical feature of the shared representations concept: they overlap only partially, and the non-overlapping part of a given representation can be the cue for attributing the action to the self or to the other. The same mechanism operates in humans. Neuroimaging experiments where brain activity was compared during different types of simulated actions (e.g., intending actions and preparing for execution, imagining actions, observing actions performed by other people) revealed, first, that there exists a cortical network common to all conditions, to which the inferior parietal lobule (areas 39 and 40), the ventral premotor area (ventral area 6), and part of SMA contribute; and second, that motor representations for each individual condition are clearly specified by the activation of cortical zones which do not overlap between conditions [...]” (Jeannerod & Pacherie 2004, pp. 131–132)

entations (2014a). She argues that shared body representations do not threaten a self-other distinction because they always contain information that is too self-specific to be shared. They are, in her words, “[...] Janus-faced. They face inward as representations of one’s body and they face outward as representations of other people’s bodies” (De Vignemont 2014b, p. 135).

A closer look at her conception also yields a possible answer to the question of what it is that can be shared with others. De Vignemont argues that it must be a rather coarse-grained representation of one’s body, since bodies differ considerably in many aspects like size, gender, posture etc. This representation, which De Vignemont dubs the “body map” (De Vignemont 2014a, p. 289, 2014b, p. 134), contains information about the basic configuration of body parts and thus serves as a functional tool to localize bodily experiences. Irrespective of individual differences of this map, some of its content is so coarse-grained that humans are still able to imitate others or experience vicarious bodily sensations, both of which have been claimed to draw on shared body representations. In other words, what can be shared is that part of the body map whose content is general enough to apply to all kinds of bodies, no matter their differences.

Although this is surely no exhaustive inquiry of the matter, these thoughts provide an idea of how to view 2sE as enabling social cognition: at the representational level, there are parts of the body model which can be shared with others.¹⁶ These parts, however, have to be embedded in a system that also contains self-specific information. Otherwise it would be impossible to attribute an action, an experience or observation to the agent concerned. It now becomes obvious why I claimed earlier that a self-other distinction does not need a *phenomenal* representation of one’s body. The unconscious body model and its shared parts seem well furnished to provide such a distinction and thus make unconscious social processes such as mimicry and involuntary imitation possible.

5.3 First-order social embodiment (1sE)

Although interaction is certainly a topic that has been the least explored by researchers of social cognition, it nevertheless should be considered carefully by any theory that aims to provide a comprehensive view on social understanding. Including interaction is particularly challenging, since most attempts to do so came from proponents of an enactive perspective on the mind. However, I have argued that a pluralistic model of social cognition cannot simply combine enactive claims with cognitive ones (see section 3 “Multiplicity needs coherence”). What is needed is an approach of social understanding that integrates interaction as a phenomenon that most probably does not need explicit, high-level representation. 1sE offers a way to describe such low-level social processes. Knoblich and Sebanz, for example, review several cases of “social coupling”. Individuals tend to synchronize their movements if they are sitting next to each other in a rocking chair (cf. Knoblich & Sebanz 2008, p. 2022), a process which can plausibly be described without representation. This sort of “entrainment” (*ibid.*, p. 2023) is a case of coupling during which individuals influence each other’s behavior without consciously intending to do so. There are also cases in the animal kingdom that can be described at the level of 1sE, such as the formation and synchronization of fireflies (Suda et al. 2006).

The next step is to depict the implementation of specifically “social parts” of the body model. What physically grounds them is described at the level of 1sE. One buzzword in the research field of social cognitive neuroscience is “the social brain” (e.g., Dunbar 1998; Gazzaniga 1985). This term refers to all the different areas in the brain that have been found to be correlated to cognitive processing in social situations, including, of course, the mirror neuron system. While the investigation of brain regions and their functions for social cognition is a well-established endeavor, it will be more interesting to look at other possibilities of implementing social cognition. The role of interaction for social cognition, for example, has been hotly disputed in the research field. As I have il-

¹⁶ Sharing means that representational content overlaps, at least partially. For a more detailed discussion on sharing, see De Vignemont 2014b; Jeannerod & Pacherie 2004.

lustrated earlier, some claim that interaction dynamics could *constitute* social cognitive mechanisms (De Jaegher et al. 2010). However, such a view is only sustainable in a radically enactive set of assumptions and as such is not an option for the framework I am suggesting here. What should be considered, though, is whether being in an interaction is *necessary* for some social cognitive states. It has been suggested by recent studies that activation patterns differ depending on the situational context and the degree of emotional engagement in a social situation (Schilbach et al. 2013). These results point to this possibility, but it still needs more careful investigation whether or not they justify the claim that interaction in any way *physically grounds or enables* social cognition.

Such basic and non-representational forms of social understanding have been neglected by the research field for a long time and are in need of more empirical and philosophical investigation. Especially research on joint action and coupled systems is therefore important to sort out 1sE.

6 Conclusion

My first goal in this commentary was to show that MV as a pluralistic view on social understanding is a valuable contribution to the interactive turn. It has the potential to integrate insights from different directions of empirical and theoretical research and thus to yield a comprehensive account on social cognition. However, I argued that such an approach needs careful consideration concerning its metaphysical background assumptions. I demonstrated that parts of MV as laid out by Newen are not fully compatible and that it thus needs a different kind of framework which allows a coherent picture.

I presented an alternative model by applying Metzinger's framework of 1-3E to social cognition, hence 1-3sE. Although the details are still to be spelled out in future research, 1-3sE has several advantages that enable a coherent and fruitful framing of MV. It integrates all four social mechanisms mentioned by Newen and thus can be seen as a pluralistic account of social cognition. What is different,

however, is that those four elements are described at different levels of description. As such they all play a specific role in the overall image of social understanding and merge into a manifold, but unified picture. Basic interaction, in this theory, can be accounted for without making radical claims in either direction; we do not need to assume that the mind is relational, as claimed by proponents of the enactive theory. However, we also do not have to ascribe a high level of sophistication to a system in order to be able to interact. In my proposal, interaction (or at least simple interactive mechanisms) can function without any complex representation. Interaction is thus located at the lowest level of the hierarchy, namely 1sE. The next level of social embodiment describes representational and computational processes that subserve social cognition. I showed in which ways a model of one's own body could enable social cognition and which parts of such a model could possibly be shared with others. 2sE encompasses these processes. I further argued that DP should be treated as a phenomenological rather than epistemological concept and should thus be described at the level of 3sE. By doing so, I aimed to avoid mixing up different levels of description and to yield a coherent usage of the term. High-level simulation and theoretical inference have been described at the level of 3sE+, the highest level of the hierarchy, thus doing justice to the fact that they are very special and probably rare cases of social cognition. The application of the notions of transparency and opacity offered a way to emphasize the phenomenological variety that comes with different social situations.

There are still many open questions and this is by no means an exhaustive description of how 1-3sE can be used to frame social understanding. My goal here was to highlight its potential to provide a framework which offers novel ways to (1) incorporate the phenomenal level of description with its representational counterparts, (2) to integrate the role of the body as shaping and grounding social cognitive processes and thus (3) to depict social cognition as a representational, but still embodied ability.

Acknowledgements

I would like to thank the Barbara-Wengeler-Stiftung for their financial support, Thomas Metzinger and Jennifer Windt for giving me the opportunity to be part of this project, two anonymous reviewers for their valuable feedback, and Luke Miller for helpful suggestions on form and content.

A Multiplicity View for Social Cognition: Defending a Coherent Framework

A Reply to Lisa Quadt

Albert Newen

Lisa Quadt's commentary focuses on my theory about the multiple epistemic strategies humans use to receive information about one other's mental phenomena. She develops a principle worry about the theory's underlying metaphysical foundations, arguing that I am committed to an incoherent metaphysical framework. In this reply, I show that I am not committed to the position she attributes to me and I outline an alternative framework that is my actual background view. I illustrate this framework by discussing emotions and argue that emotions are individuated as integrated patterns of characteristic features. This enables me to combine a representational account of emotions with a theory of direct perception of basic emotions as well as with an understanding of some emotions relying on theory-based inferences. Thus, I have a coherent metaphysics. Finally, I show that the alternative suggested by Quadt has its own problems.

1 Introduction

With my PMT (person model theory), I aim to answer two questions. While the first question asks which epistemic strategy humans use to access the mental states of others and to gather information about them, the second question asks how the information we obtain to understand others is stored and organized. The answer to the second question is the core of the PMT. It states that information about other in-

dividuals or types of persons is stored and organized in person models and that these are realized on two levels, i.e. the implicit level of person schemata and the explicit level of person images. It further argues that philosophical theories so far have predominately ignored the fact that we usually understand others relying on rich background information concerning them and their situation.

Lisa Quadt's commentary focuses on my theory concerning the epistemic strategies humans use to receive information about others' mental phenomena, and she develops a principle worry about the underlying metaphysical foundations. I am grateful for this challenge, which gives me the opportunity to clarify my background view. The MV (multiplicity view) outlined in the target paper claims that we do not rely on one epistemic strategy alone, as is suggested by most proposals in the literature, but that we rely on a multiplicity of strategies which, for the most part, are implicitly activated on the basis of contextual conditions. These strategies include simulation strategies, theory-based inferences, and direct perception as well as understanding by social interaction and by relying on narratives. Quadt's main worry is that MV may be based on an incoherent metaphysics and is thus unacceptable as it stands. In the first part of her reply she aims to defend the incoherence claim, while in the second part she offers an alternative metaphysical framework. My reply is structured as follows: In the next paragraph I briefly describe how Quadt defends her claim about the supposed incoherence of my metaphysical background and show that I am not committed to the incoherent framework she attributes to me. In the second section, I make explicit my actual background metaphysics (which was not the focus of my article) and argue that it is coherent, reinforcing that I am not committed to the metaphysics that Quadt attributes to my position. Finally, I argue that the alternative metaphysics suggested by Quadt relies on a distinction between transparency and opacity that cannot carry the weight it is supposed to carry.

2 Am I committed to an incoherent metaphysics?

Quadt describes correctly that the MV I advocate combines epistemic strategies that are described in several different positions, including ST (Simulation Theory) (Goldman 2006), TT (Theory-Theory) (e.g., Gopnik & Meltzoff 1997), and IT (Interaction Theory) (Gallagher 2001), as well as theory of direct perception

(Gallagher 2008). As a consequence, she presupposes that I am committed to the metaphysical foundations of each of these positions, while each position argues for a distinct epistemic strategy. If I were committed to accepting such metaphysical foundations, I would thereby offer an incoherent metaphysics. Quadt shows this by arguing that Simulation Theory and Theory-Theory, on the one hand, presuppose metaphysical claims that are not consistent with the presuppositions from Theories of DP (direct perception) and ITs, on the other hand (3). Quadt claims that ST and TT are *cognitivist theories* that presuppose internalism, mental representations, and the idea that mental phenomena are private hidden entities to which we have no direct access. To register mental phenomena we have to rely on perceiving the behaviour and expressions of other people and have to *infer* the existence of mental phenomena. Quite the opposite view is taken by the *non-cognitivist theories* of DP and IT. They allow for externalism of mental phenomena (as being realized by two people and their interaction), they deny the existence of mental representations, and they presuppose that mental phenomena are not hidden but directly perceivable. Thus they rely on non-inferential access to mental phenomena by direct perception. The following quote illustrates the main features of the contrast Quadt develops:

The difference between cognitivist and non-cognitivist pictures of social cognition, in the cases that I just described, seems to boil down to the metaphysical assumption of whether or not there are hidden cause in the outside world that require an inference or representational mechanism in order to access and process them. While ST and TT clearly assume such a view, DP denies it. Therefore, I claim that MV cannot simply combine theoretical elements that draw on such considerable metaphysical differences. (Quadt 2015, p. 5)

My first general reply to this worry is that I only take on the description of an *epistemic strategy* of acquiring and using information

about other people in order to understand them. An epistemic strategy like a simulation (to put oneself in the other person's shoes) or a theory-based inference is not automatically connected to a metaphysical commitment. De facto, the philosophers who are famous for holding ST or TT combine their view with a metaphysical background, but it does not follow that the epistemic strategy they describe *must be combined* with the metaphysical background they offer. We can easily see this for example in the case of two epistemic strategies like theory-based inferences and direct perception of mental phenomena. These can be easily combined in a way that allows that some mental phenomena with intense expressive components like basic emotions (Ekman et al. 1972) can be directly perceived (see below), while complex mental phenomena like propositional attitudes may be at least often inferred if the social understanding cannot rely on honest utterances but only on some ambiguous behavioural cues. Thus, the de facto incompatibility of the metaphysical presuppositions of the two main lines of theories of social understanding does not imply that I am committed to inheriting both presuppositions and that I thus run into an incoherent metaphysics. In fact, I do not presuppose two metaphysical principles for the same mental phenomenon; instead I only need to allow for the application of two epistemic strategies of understanding mental phenomena, which may be applied to different mental phenomena (or to the same type of mental phenomenon in different situations). In the next section I outline my alternative metaphysics and illustrate both that it is coherent and that it can allow for direct perception as one epistemic strategy for registering some mental phenomena.

3 Defending direct perception in an alternative metaphysical framework

In general, I prefer to think of mental phenomena as representational, but I do not see that this prevents me from integrating the epistemic strategy of direct perception. Furthermore, I characterize basic emotions as realized in one individual (individualism but not internalism).

At the same time, I remain neutral as to whether joint emotions (e.g. joint enthusiasm about a goal achieved by one's team) have to be analysed as extended emotions. Furthermore, I think that basic emotions are not hidden mental phenomena but can be directly perceived e.g. on the basis of face-based recognition of emotions. Thus, I think that some mental phenomena can be registered non-inferentially. But of course, direct perception of some mental phenomena is *only one* of at least four epistemic strategies that we can use, depending on the context.

To sketch my theory of direct perception I will focus on basic emotions like anger, fear, happiness, sadness, etc. (for a classification of emotions see Zinck & Newen 2008). My metaphysical view of emotional episodes is that they are integrated patterns of characteristic features (Welpinghus & Newen 2012; Newen et al. 2015). Let me use the example of fear as illustrated in Newen et al. (2015): an emotional episode of fear towards an aggressive dog is constituted by the integration of the following characteristic features: (1) a typical physiological arousal that is a consequence of bodily changes due to changes in the autonomic nervous system, including increased heart rate and flat breathing; (2) a typical behavior or behavioral disposition, including flight or freezing behavior; (3) a typical facial expression, gesture, or body posture, etc.; (4) a typical phenomenal experience of fear; (5) a typical (explicit) cognitive evaluation of the dog in front of me (e.g., "This is an aggressive pit bull"). Furthermore, every emotional episode has (6) an intentional object, i.e. the dog in front of me. Features 1–5 are integrated into an (often implicit) appraisal of the intentional object as dangerous. The emotional episode is constituted by the integration of all the characteristic features mentioned so far, including the appraisal. This view allows that in another implementation *some* features would be missing. For example, the explicit cognitive evaluation of the dog as an aggressive pit bull is not necessary to be in fear towards the dog in front of me. Or the facial expression may be inhibited, due to intense training to attain a poker face, yet I may still be in fear. As long as a minimum of features is realized, we still have

an episode of fear. The two main features that are necessary in all emotional episodes are a registration of minimal physiological arousal and an intentional object. The integration of both is needed to have an emotional episode (Barlassina & Newen 2013). But other features may be lacking while still remaining characteristic of most episodes of the relevant type of emotion. One might wonder why I do not include neural correlates. Since I argue from a position of antecedent naturalism, neural correlates are not an extra component in addition to the characteristic features already mentioned above. We might mention neural correlates as an informative aspect for the individuation of certain features of emotion, but we do not have to, since they concern the same features that have already been mentioned, with information accessed in a different manner.

If one accepts the ontology of emotions as individuated by an integrated pattern of characteristic features, it follows that the expression of an emotion by face, body posture, and gestures is a *constitutive* part of the emotional episode (and not a causal consequence). Thus, I do not hold internalism about mental phenomena. Given this theory of the individuation of emotions, I also argue for the thesis that one way of recognizing emotions is by perceiving the relevant pattern (Newen et al. 2015). A recognition of the other person's fear can be attained by directly perceiving the pattern of fear. How can we account for this, while at the same time accepting that the feeling of fear is a private subjective experience in so far as a person still may have the feeling even if she is able to keep a poker face? Perceiving fear is comparable to perceiving a house. Both are processes of pattern recognition on the basis of a minimal package of characteristic features: I can recognize a drawing as one of a house, even if one or two of the characteristic features of a house are missing. How is this possible? Perceiving an object is not a purely passive process, like taking a photograph; it is a constructive process.¹ One

important aspect of the constructive process is the enrichment of selected core sensory information. And one way of realizing this enrichment is by the activation of a rich memorized mental image that best suits the core sensory information. If we have learned the relevant pattern of what a house looks like from the outside, and memorized a respective mental image, then seeing a child's drawing initiates an interaction of bottom-up and top-down processes. These include the activation of this stored mental image, such that it enriches the core sensory information to form a perceptual experience of seeing a drawing of a house even if the front door is missing in the drawing.

The same process of pattern recognition takes place in the case of recognizing an emotion like fear. The relevant pattern of fear is formed either on the basis of having personally experienced a situation of fear or on the basis of having observed others in such situations. One thereby acquires a memorized pattern of fear with typical features. If one now observes a person with a typical facial expression in a situation where she is being attacked by a dog, one can see the fear of the person. The perception of fear is realized by seeing the freezing behaviour, the facial expression, and the intentional object (i.e. the aggressive dog), because these features activate as part of the process of perceptual processing the whole pattern of fear. Thus, I can *perceive* fear in the face of the person being attacked by the dog. The theory of perception is one according to which perceptual processing allows for a systematic enrichment of information and for influencing of perceptual processes by memorized images or background knowledge. These top-down influences are discussed under the label cognitive penetration. So I am committed to the view of perception as cognitively penetrated as it is defended in detail in Vetter & Newen (2014). But this does not involve any claims concerning the metaphysical commitments ascribed to me by Quadts in her commentary. Recognition of emotions is analysed in a framework that explicitly allows for mental representations but specifies them in a way that nevertheless allows for direct perception as one form of access to the recognition of

1 All modern theories of perception account for this constructive component, e.g. O'Regan's and Noë's theories of enacted perception (O'Regan & Noë 2001; Noë 2005), as do theories of cognitive penetration (Macpherson 2012; Siegel 2012) and theories of predictive coding (Hohwy 2013; see also Hohwy this collection; Clark this collection).

emotions. As has been spelled out in detail elsewhere (see [Newen et al. 2015](#)), in principle I allow for three types of recognizing of emotions: two types of direct perception are distinguished in terms of top-down processes of shaping perception involving background images or beliefs; and one is characterized by theory-based inferences. Thus, I distinguish “(1) (a basic form of) perceiving an emotion in the (near) absence of any top-down processes, and (2) perceiving an emotion in a way that significantly involves some top-down processes (a strongly concept-modified form of perception). Both types of perceiving emotions can be distinguished from (3) inference-based evaluation of an emotion pattern. The latter presupposes a stable evaluation of an emotion as being *F*, which then may be modified or reevaluated by reflecting on the information” ([Newen et al. 2015](#), p. 197). To sum up: Direct perception can be based on a metaphysical framework that regards emotions as integrated patterns of characteristic features and this allows me to combine it with presupposing mental representations of emotions (as memorized rich patterns), on the one hand, as well as with a non-inferential recognition of some emotional episodes on the other. The pattern theory of emotion is furthermore able to account for internalistic features of emotions like the feeling of fear, but also for individualistic yet expressive features like behavior and expression in face, gesture, and body posture. This metaphysics of emotions is coherent and is compatible with several epistemic strategies for recognizing them, e.g. direct perception as well as theory-based inferential understanding.

Let me make a further clarificatory remark about my reply to the coherence worry: I illustrated my metaphysics taking emotional episodes as a core example. This does not imply that I analyze *all* mental phenomena in this way. Although I think that some mental phenomena can also be individuated as integrated patterns of characteristic features like self-awareness/self-consciousness (see [Gallagher 2013](#)) or object perception, I remain neutral on the question of how far this analysis can be generalized and about the possibility that some mental phenomena need a different metaphysics

as basis. For this reply it is sufficient to have shown what a concrete paradigmatic example of a coherent metaphysics for emotional episodes looks like, in order to prevent the danger of running into an incoherent metaphysics as a unavoidable consequence of the multiplicity view concerning epistemic strategies of understanding others.²

4 Quadts proposal FOR an alternative metaphysical framework

Although I think I do not need an alternative metaphysics, since I have a coherent one already, I would like to briefly comment on Quadts account. She starts with a remark on embodiment. I do not really see any serious disagreement with my views here. For it is fine by me that phenomenal properties and mental representations in general are realized within the body —and sometimes not only in the brain but within our whole body (see the discussion of emotions). Furthermore, I said that in this reply I leave open whether we need an extended realization basis for some mental representations. Quadts alternative proposal, with which she aims to deliver a new framework for a multiplicity view, introduces different levels of embodiment. One way to read her distinction is that it offers a characterization of different types of representation that unfold during ontogeny. This basic idea is entirely consistent with my work. In other papers I discuss in detail the development of different types of representation in ontogeny ([Newen & Vogeley 2003](#); [Newen & Fiebach 2009](#); [de Bruin & Newen 2012](#)). There are of course differences in how one might form types of representation but discussion of these goes beyond the scope of this reply.

Let me now elaborate on an important point of disagreement. Quadts proposal is based, among other things, on the distinction between transparent and opaque ways of being involved in a mental state. She takes this distinction from [Metzinger \(2003, 2004\)](#). We can illustrate this dis-

² Let me highlight that the multiplicity view of understanding others is only one part of my person model theory and this epistemic aspect is in addition defended and further developed by my former PhD-student Anika Fiebach in the following paper which just appeared: [Fiebach & Coltheart 2015](#).

inction using the example of the mental event of perceiving an apple. This event is transparent if I am only consciously aware of the apple, while it is opaque if I am (also) aware of my mental state of seeing the apple: “[w]hat distinguishes transparent from opaque states is the degree to which one’s own social cognitive processing, which is directed at the other person, is explicitly represented as a process” (Quadt 2015, p. 12). The relevant move is Quadt’s claim that the epistemic access of direct perception in social cognition can be explained by transparency, while the epistemic access of simulation and theory-based inference can be explained by opacity.

Here I think she is on the wrong track. This distinction between transparency and opacity in the case of a mental state of attributing a belief leads to the idea that I am not only aware of the other person having a belief with content *p* but that I am also focussing on being consciously aware of the process of my attributing a belief to the other. The latter can of course happen in case of reflective processes of attributing beliefs; but normally we are in a mode of just using our ability to attribute beliefs automatically, focusing on the other’s belief and its content (not on our own process of attributing it). We normally deal with our mental state of attributing beliefs in a transparent way, contrary to the analysis offered by Quadt. Furthermore, direct perception can also be used opaquely in rare cases of being reflectively aware of guiding images: if I am an experienced chess player, I can perceive the chess board in a way that is best described by cognitive penetration, and in some cases I may be aware of the mental image which guides my perception, i.e. I see a position and know how to act because I consciously memorize the fact that I see exactly the same position I saw in a previously played game. Thus, the distinction between transparency and opacity is not helpful for characterizing the different strategies of epistemic access to another’s mental states.

5 Self-models and person models: how are they related?

Finally let me point out an important question raised by Quadt, namely how are person models

and self-models related to each other? A self-model is a special type of person model, the person model that someone develops of herself. This is also done at the two levels of an implicit self-schema and an explicit self-image. I intend to elaborate on the interaction between self-models and person model of others in future articles, but I completely agree with Quadt when she says that there is bi-directional informational exchange regarding both types of models in humans (which is also indicated in my paper in figure 2, p. 21): “I thus conclude that it should not only be considered how the development of a self-model influences social cognition, but also which role social processes play in forming such a self-model” (Quadt 2015, p. 10). The PMT has potential as a framework for a theory of human self-consciousness.

Concept Pluralism, Direct Perception, and the Fragility of Presence

Alva Noë

This paper has three main aims. First, I criticize intellectualism in the philosophy of mind and I outline an alternative to intellectualism that I call Concept Pluralism. Second, I seek to unify the sensorimotor or enactive approach to perception and perceptual consciousness developed in O'Regan & Noë (2001) and Noë (2004, 2012), with an account of understanding concepts. The proposal here—that concepts and sensorimotor skills are species of a common genus, that they are kinds of *skills of access*—is meant to offer an extension of the earlier account of perception. Finally, I describe a phenomenon—fragility—that has been poorly understood, but whose correct analysis is critical for progress in the theory of mind (both perception and cognition).

1 Introduction

The present study takes its starting point from the enactive or sensorimotor, or, as I now prefer to call it, the actionist approach to perception and perceptual consciousness (O'Regan & Noë 2001; Noë 2004, 2012). Actionism is the thesis that perception is the activity of exploring the environment making use of knowledge of sensorimotor contingencies. Sensorimotor contingencies are understood to be patterns of dependence of sensory change on movement. The proposal, then, is that we make use of this knowledge of the way our own movement gives rise to sensory change to explore the world. This knowledge-based or skilful activity *is* perceiving.

We characterized the relevant kind of knowledge as *knowledge* precisely in order to mark the continuity between perception and “higher”, more intellectual kinds of cognition such as thought and planning (O'Regan & Noë 2001). At the same time, we were quick to characterize the relevant forms of knowledge as practical, non-propositional, as implicit, or as “skill”, precisely in order to avoid over-intellectualizing perception.

In *Action in Perception* (Noë 2004, Ch. 6), I defended the view that perception requires the mastery and exercise of concepts. In doing so, I took myself to be lowering the bar on what it is to have a concept, rather than raising the bar on

what it is to be a perceiver. It was always my view that the resulting account was one in which understanding (mastery and use of concepts, including sensorimotor skills) and perception (exploration of the environment drawing on a variety of skills, including concepts, as conventionally understood, and also sensorimotor skills) worked together in human and animal mental life. As I put it later, “understanding” and “perception” arrive at the party together (Noë 2012).

Although actionism places great emphasis in the importance of movement, action, and the body for the theory of perception, on the claim that perceiving is an activity, and on the proposition that perception is not a representation-building activity, it was never the intention of the view to deny the critical role of understanding and knowledge. The point, rather, was to offer a unified account of perception, consciousness, thought, and action. But the details were not entirely worked out. Knowledge, skill, ability, and understanding were not carefully defined, and the precise relation between the account of perception and that of conceptual understanding was not spelled out in detail. I try to rectify that here.

My basic strategy in this paper is as follows. In part I, I offer an extended discussion of what I call intellectualism. I define the view, criticize it, and show how even critics of the view tend to share many of its presuppositions. In part II, I try to offer an alternative to intellectualism, namely concept pluralism, which builds upon the actionist conception of concepts as “skills of access”. Concepts, I propose, should be thought of as techniques for enabling access to what there is. In this way—the details will become clear later on—I offer a way of thinking about concepts that is unified with the basic elements of the earlier theory of perception.

One caveat: I don’t take up the issue of animal experience and cognition in this paper, even though it is directly relevant to the topic.

I

2 Modes of understanding

Kant (1791) said that concepts are predicates of possible judgement. That’s what concepts are.

They are creatures of judgement. He also believed that concepts play a basic role in cognition. They organize the data of sense. Without concepts, sensory experience would be empty sensation; without sensory influx, there’d be nothing for concepts to organize. For Kant, judgement gives the basic form of experience (*Erfahrung*).

Frege (1891) said that concepts are functions from objects to truth-values. In this he appeared to break with Kant. Concepts have nothing to do with judgement or with our cognitive organization. They are before all that. This is in tune with Frege’s well-known anti-psychologism, according to which grasping, understanding, judging, and communicating are of no relevance to logic or ontology.¹ But Frege doesn’t actually sever the link between concepts and judgement; he only frames it differently. Concepts figure in what is judged; they belong to *judgeable content*. So Frege preserves Kant’s link to judgement, but in a de-psychologized version.²

Frege’s anti-psychologism gets him into trouble.³ The fact that concepts are not themselves psychological, in the sense of being ideas or associations or feelings, doesn’t mean that they are not tied to understanding or judgement, for nothing forces us to think of understanding and judgement as psychological in that sense. At the same time, the claim that concepts are “third-realm” entities gives little substance to the idea that they are, in the relevant sense, objective. Finally, if concepts are some sort of occult abstracta, then it isn’t at all clear how we can grasp them. And surely, whatever concepts are, it is the case that we can grasp them.

I’ll return to this set of issues later. But for now let us agree that for both Kant and Frege, concepts are tied to judgement, where this means something like: they are tied to categorizing, to explicit reasoning, to subsuming objects under concepts. Each of these thinkers offers an account of concepts, or of the under-

1 See, for example, Frege’s “Thoughts”, (1918–1919).

2 Not that I mean to suggest that it is right to think of Kant as actually offering a psychological account. But it might look this way from Frege’s perspective.

3 As both Dummett (1973) and Baker & Hacker (1984) have noticed.

standing of concepts, in what I'll call the mode of judgement. According to Kant and Frege, grasp or understanding of concepts finds its natural, true expression in judgement.

This paper takes its start from the observation that there would appear to be other modes of conceptual activity, other ways for understanding (for concepts) to find expression in our lives. At least on the face it, judgement would not seem to be the only mode of conceptual understanding.

Take, for example, *perceptual understanding*, or what we might call *understanding concepts in the perceptual mode*. Consider reading. It is difficult to tell, looking at the entrance to the Taj Mahal, which bits of squiggle are mere ornament, and which are writing in Classical Arabic. You can have this experience, it is available to you, only if you are not fluent in Classical Arabic, or in this style of Arabic script. This marks the spot of the basic phenomenon: there would seem to be a mode of understanding that is perceptual in nature. It is impossible, as a psychological matter, to see meaningful text as a mere squiggle. For the one who knows, for the one who can, meaningful words just show up.

Compare this with the case of a scholar studying Renaissance paintings in which writing is shown embroidered into the robes of magi and other fabulous figures. Are these scripts in a familiar language, or could they be marks from a forgotten one? Or are they *pseudo*-scripts? How do you decide? A keen problem and one that affords opportunity, for it demands reasoning, explicit categorization, and judgement.⁴

But nothing like that seems to be going on when you are reading. And the point is general: it operates at the level of our everyday seeing. It is difficult, maybe even impossible—psychologically speaking—to see familiar kinds of things around us as mere things. We always see them as this or that.

I don't mean that when we see, we *represent* the things we really see around us as this or that, by bringing them under the relevant con-

cepts, by categorizing them, as it were, in judgement. The point rather is that the things we see, the things around us, are familiar, known, comprehended, understood, and recognized, from the very outset. Concepts are geared in before we are even in a position to ask what something is or to make a judgement about it.⁵

So we have here a distinct way in which concepts, or the understanding, can be put to use outside the setting of judgement. Specifically, as I've said, this is an example of the deployment of concepts in the perceptual mode or, more simply, perceptual understanding.

Note, in saying perception is a non-judgemental mode of understanding, I don't mean to deny that there might be an interdependence between the judgemental and the perceptual modes. Maybe only one who can judge can perceive and precisely because perception enables judgement. And maybe it is only of one who can have perceptual experience that we could ever say that he or she is in a position to judge about anything.⁶ My point is that, on the face of it, judging is one thing, and perceiving another, and yet they are both ways of exercising the understanding.

There are other modes, as well.

Concepts also get deployed in what I call the *active mode*; understanding, that is, can find expression, immediately, in what we do. There is such a thing as *practical* understanding. And what makes the relevant understanding practical is not that it is an exercise in judgement on, as it happens, practical matters. What makes it practical, in my view, is that it is the gearing in or putting to work of one's understanding in the absence of any call for, or even space for, reflection or judgement.

The dog walker's knowledge of dogs, for example, is put to work in the way he or she adopts a gait that suits the dog and encourages or permits it to accomplish its sniffy, doggy business; and so also in the way the owner spontaneously shortens the leash as another dog approaches; it is exhibited, even, we might say, in

⁵ As Heidegger (1927) would have put it, the things we encounter are *always already* familiar.

⁶ I return to this issue of the unity of concepts in section 6 below.

⁴ For a discussion of this fascinating topic, see A. Nagel (2011).

the cool she keeps when the two dogs begin barking and straining at their leashes. Without a word, in the absence of deliberation, or explicit thought, the owner knowingly engages the nature of dogs.⁷

And there may be still other kinds of understanding, other *styles* of conceptuality. For example, there is also perhaps what we could call the emotional mode, or maybe it would be better to say the personal, or even *interpersonal* mode. Tears, feeling, injury, but also posture, standing distance to others, navigating in a social environment, can all show a highly refined attunement to situation, relationship, status, goals, tasks, and so on. It takes understanding to do all this, even though we rarely try to make this understanding explicit and even though, very probably, we cannot do this, even in ideal circumstances. Let us say that in this kind of responsive engagement with our social worlds we display understanding.⁸

To summarize: there is a case to be made for the existence of at least three, maybe four, distinct modes of understanding. There is the judgemental mode, the perceptual mode, and the active mode, and perhaps also the personal mode.

3 Intellectualism vs. the intellectualist insight

I have proposed that there are at least three or four distinct modes of understanding. I now turn to the familiar thought that among these varieties of expression of conceptual understanding, only one—the judgemental mode—is genuine. The other modes, according to this idea—that is, the perceptual, the active, the personal

—are expressive of understanding only derivatively, thanks to the fact that they are guided or controlled, from outside as it were, by true understanding in the judgemental mode.

I will call this view intellectualism. Intellectualism, as I am defining it, is the view that one modality of conceptual expression is basic, namely, the judgemental, and that the others are domains where understanding finds expression only derivatively.⁹

Plato and Descartes seemed to have believed something like this. For them, a mere sensation rises to the level of perception, and a mere movement to the level of action, only if it is subject to guidance by reason. The soul is divided against itself and it achieves integration only when it is controlled in the right way from above.

Intellectualism is probably the establishment view in cognitive science. When you see the Pole Star, for example, as [Fodor & Pylyshyn \(1981\)](#) insist, you represent whatever it is that you really see—a pattern of irradiation of the retina, perhaps—as the Pole Star. To suppose otherwise is to suppose that vision could be, as [Gibson \(1986\)](#) had claimed, a *direct pick up* of what there is around us. But Pole Starhood, like the third dimension, is not something that gets projected onto the retina. The whatness of things, their nature, no less than the third-dimension itself, are not, strictly speaking, visible. We need judgement, the application of concepts (in this case perhaps automatic and implicit) in the building-up of mental representations, to get something like the world into our experience.¹⁰

Jason Stanley, in a series of writings ([Stanley & Williamson 2001](#); [Stanley 2011](#); [Stanley & Krakauer 2013](#)), defends what I am calling intellectualism. You perform a skilful ac-

⁷ This example is from [Stephen Mulhall \(1986\)](#).

⁸ With this last example we move beyond description to the suggestion of an argument. The thought is that the relevant forms of understanding couldn't be underwritten by judgement, since we are not able, as a general rule, to frame the needed judgements. Indeed, something like this line of thought is already suggested in the way I've sketched the perceptual and active modes above. Recall the celebrated case of [Oliver Sacks \(1970\)](#): a man can't recognize the item before him as a glove; his powers of judgement are fine—he describes what he sees as a self-enclosed piece of fabric with five outpouchings—and he knows what a glove is. The case is illustrative because it brings out that it is less the fact that he can't recognize the glove, and more the very fact that he needs to think about it all, that brings home the thought that in our normal life there is no room for that sort of deliberation.

⁹ Intellectualism can be defined differently. For a variety of approaches to problems in this vicinity, see [Bengson & Moffett \(2011\)](#).

¹⁰ This was [David Marr's \(1982\)](#) view. The content of visual experience is given in a 2.5D sketch, that is, in a depiction of what is given in the projection of the world onto the retina. It is only in so far as vision yields *knowledge* that it goes beyond what is given in this intermediate-level representation and gives rise to a fully conceptual 3D model. But for Marr, and for his recent advocates ([Prinz 2013](#)), although we live in the world of the 3D sketch, our experience is confined to the intermediate-level representation. And crucially, for these thinkers, you don't need concepts or understanding at the intermediate level. You just need optics.

tion, according to Stanley (2011), only when your action flows from your knowledge of true propositions. He elaborates:

[t]here are all sorts of automatic mechanisms that operate in a genuine sense sub-personally. The human (and animal) capacity for skilled action is based upon these mechanisms. What makes an action an exercise of skill, rather than mere reflex, is the fact that it is guided by the intellectual apprehension of truths. (Stanley 2011, p. 174)

Is intellectualism right? Should we be intellectualists?

It is important that we notice, right away, that intellectualism is right about something. It does justice to the fact that there is understanding, and there is conceptuality, at work wherever we think and perceive and act and talk, as we have been considering. Conceptuality, understanding, and knowledge pervade not only the mental, but our lives and our being. Certainly, it is in evidence wherever we can speak of agency. Stanley insists (in the quotation above) that we can only speak of *skilful* action where there is understanding at work. He perhaps ought to have said that we can only speak of action at all, as opposed to mere reflex, or mere movement, where there is also understanding.

The question I would like us to consider is this: do we need intellectualism to secure this undoubted intellectualist insight, as I will dub the recognition of the pervasiveness of understanding in our perceptual, active, as well as emotional lives? It's crucial that we notice the distance between the insight and the thesis. It's one thing to say that there is understanding at work in perception and action, and another to think that what makes this true is that perception and action are grounded on acts of judgement. Do we need to think that what guarantees and secures the involvement of understanding is the fact that our seeings, doings, and feelings are guided by judgements?

There are, right off the bat, two obvious grounds for suspicion regarding the intellectual-

ist thesis. For one thing, intellectualism at least threatens to obscure the differences to which I have been directing our attention among what at least appear to be authentically distinct ways of exercising one's knowledge and understanding. And so, it seems, it gets things wrong. Seeing and acting and dynamically reacting, most of the time at least, don't look or feel anything like bringing objects under concepts in judgement.

For another, intellectualism smacks of the arbitrary. Couldn't we maintain that perception is the basic form of understanding and that judgement, even in cases of pure reasoning and mathematics, rests on a kind of perceptual insight? Or that it is understanding in the active mode that is truly basic? Judgement itself depends on the mastery and exercise of conceptual capacities which are in the first instance practical. You need to know how to use concepts, after all, in order to use them in judgement.

In any case, let us ask again: are there reasons to endorse intellectualism? Why think that judgement is the primary and singular authentic modality of real understanding? Why be an intellectualist?

4 Troubles with intellectualism

Stanley's writings (Stanley & Williamson 2001; Stanley 2011; Stanley & Krakauer 2013) on the topic are suggestive. However, he seems to mistake evidence in favour of the insight (that understanding is present in perception and action, as well as in the setting of explicit deliberative thought) with support for intellectualism itself (for the view that judgement governs action and perception). And, on top of that, he may commit the fallacy of conceiving the whole genus on the model of one of its species; like thinking that every dog is a cat because, well, they are mammals, or that seeing is a way of touching because, after all, they are both forms of perception. In this case it is the fallacy of thinking that *knowing how* must be a form of *knowing that* because, after all, it is form of knowledge.

Let's turn to this last point first, briefly. Stanley (2011) notices that we use "to know" both for propositional knowledge and also for

practical knowledge (know-how). Contrary to what he suggests, however, there are cognate languages where this is not the case. For example, we don't express knowing how in German using the same verb that we use to express propositional knowledge (Stanley 2011, pp. 36-37). We use *können*, which means *can*; we don't use *wissen* (as in *wissen wie*).

But in any case, the more important point is, *so what?* How dispositive are facts like this supposed to be? It is common ground, I would say, that know-how is a form of knowledge, an achievement of understanding. The question is whether it is a form of knowledge of the same type as propositional knowledge, the sort of knowledge that gets expressed in judgement. Crucially, all the evidence in the world that it is a form of knowledge doesn't add up to evidence that it is propositional knowledge.

Now, as a matter of fact, we know that knowing how to do something is *not* merely knowing that a proposition is true, for any proposition you might care to think up. For knowing how to do something implies that you have the ability to do it (and vice versa), whereas the corresponding propositional knowledge has no such practical entailments.

Stanley would deny this (Stanley & Williamson 2001; Stanley 2011). You can know how to perform a stunt but be unable to perform it (because you've been injured, say); so, he claims, possession of know-how cannot be equivalent to possession of an actual ability. But this is unpersuasive. Of course it is true that you can know how to do something even though you are unable to do it. But this is because your being unable to do it is not, in the relevant sense, evidence that you can't do it! Consider: you can't swim if there's no water, even though you can swim. You can swim but you can't swim. Far from showing that know-how and ability part ways, this sort of consideration reminds us that they move along the same rails.

So knowing how to do something isn't possession of propositional knowledge: it doesn't consist in being in a position to make certain judgements. This is a point that Stanley and Williamson accept, if only implicitly, for they provide a different analysis of the cases precisely

to account for the critical link to action in the case of know-how. Knowing how to do something, on their view, consists in grasping a true proposition, yes, but it consists in grasping it in a distinctively and irreducibly practical way (making use of practical modes of presentation).¹¹

Again, it is worth noticing that to deny, as I do, that knowing how to do something consists in knowing the truth of a proposition, is not to deny that, as a matter of fact, knowing how to do something may put you in a position to make certain judgements, or may require you to appreciate the truth of certain propositions.

This brings us to the first point above: the confusion of evidence for the insight with evidence for the thesis. I am assuming that know-how, like propositional knowledge, is a form of knowledge. This common ground is already secured by the insight: our understanding, our knowledge of concepts, is put to use in both cases. So we can readily agree with Snowdon (2004), cited approvingly by Stanley (Stanley & Williamson 2001), that knowing how and knowing that go together—that where you have one, you have the other. In general, as Snowdon observes, if you know how to do something—say, how to get home from here—then you'll know that all sorts of things are true, such as, for example, *that* you need to turn left here, that you aren't already home, etc. And vice versa. Knowing how and knowing that, in this sense, commingle and cooperate. These considerations are adduced by Stanley, and by Snowdon, I think, to suggest that Ryle was mistaken in believing that the propositional and the practical are disjoint and disconnected (1949); in fact they operate together and in support of each other. This is an important point and one I endorse. And this is exactly what one should expect given the intellectualist insight. After all, understanding operates in both spheres: the practical and the judgemental or propositional. Crucially, however, the fact that the practical and the propos-

¹¹ Stanley (2011) offers a different account from that developed in Stanley & Williamson (2001). The former is framed in terms of modal parameters governing the interpretation of the relevant sentences. Although he insists that know-how does not entail ability, he admits that attributions of know-how exhibit more or less the same sort of modality as ascriptions of dispositions and abilities.

itional mutually entail each other in this sort of way lends no support to the intellectualist idea that one of these, the propositional, is foundational in respect of the other; indeed, it weighs against that very idea. Why press on and insist on this thesis when, it would seem, the insight on its own is enough to capture the phenomenon at hand?

Stanley's motivations seem fairly clear. He wants to break with the idea that propositional knowledge is detached and, as he puts it, behaviourally inert. He wants to insist that it's wrongheaded to think that athletes and clowns and craftspeople are skilful zombies, whereas philosophers and mathematicians and physicists are *intellectual* workers whose actions exhibit authentic brain-power. It may be, even, that he thinks this is a point of political significance.

Intellectualism isn't necessary to secure any of this, however. The insight has already done that.

In fact, intellectualism, as Stanley develops it, threatens to distort the nature of the cognitive achievements that are put to work in our practical, perceptual, and personal engagements. This comes out in the discussion of skill. Stanley & Krakauer (2013) defend Aristotle's claim (from *Metaphysics* 1046b) that we can only speak of *skilful action*, as opposed to mere habit, or brute capacities, where we can speak of *rational control* of action, and also where we can speak of teaching, learning, practicing, getting better, or achieving expertise. They defend Aristotle's claim that it is a mark of skilfulness, that you can voluntarily choose to perform what you can do skilfully *badly*.

This last point seems unlikely. I can't choose not to understand what you say, or to see writing as mere squiggles, or words as composed of bits I need painstakingly to sound or spell out. A guitarist cannot choose to experience the instrument in his hands as strange or unfamiliar. At best, maybe, I can pretend I am unable to do these things.

Is this because talking and reading and playing guitar are not really skilful at all, that they are mere habits outside the range of rational control? Hardly! They're expressions of skilful competence, rational understanding and

knowledge if anything is. The mistake is to think that a performance is only rational if control is exerted in the mode of judgement, as if from outside. The understanding that is put to work in our talk and play, as in our thought, is native to these various styles of engagements themselves.

Stanley and Krakauer make a lot of the demand that skill depends on knowledge of facts. It's worth noticing, yet again, that insisting, as I do, that skilfulness does not consist in the *exercise of concepts in the judgemental mode* does not entail that there can be skilfulness in the absence of the ability to exercise them in that mode. It may be, as a matter of fact—this is related to the Snowdon point above—that only someone who is sensitive to all sorts of facts, for example, about how something is done, will in fact know how to do it. This doesn't show that knowing how is a kind of knowledge of the facts. It shows rather that our distinct conceptual capacities may be interdependent.

Stanley and Krakauer try to draw a line between true skills, which are, in their sense, governed by rationality, and others—for example perceptual and linguistic skills—that are too basic, or too simple to qualify as skills in the fuller rational sense.¹²

One problem with this suggestion is that it is not so easy to draw a sharp line between skills and supposedly brute abilities. Take colour vision, for example, which is innate in humans. Despite this, it turns out that children find it very difficult to recognize and discriminate colours long after they've mastered the names of familiar objects, people, games, etc. As Akins (unpublished manuscript) has argued, this is probably because colours are not simple, as our phenomenology, or rather, our conventional wisdom about our phenomenology, leads us erroneously to believe. *Getting* blue or yellow or red is to develop a sensitivity to suites of constancies and variations—to ecological variation in what I have called *colour-critical condi-*

¹² Stanley & Krakauer (2013, p. 5) write: "[b]ut at some point, all such knowledge will rest on knowledge of basic actions, such as grasping an object or lifting one's arm. These activities are not skills; they are not acquired by or improved upon by training in adult life. Their manifestation is nevertheless under our voluntary control."

tions—that takes time and learning, and allows for criticism and reflection. Is colour vision basic? Or is it skilful? It may be both.

This is not a special case. Because seeing is saturated with understanding, it is very hard to find features of our ability that are not modulated by knowledge and context. Granted, the ability to discriminate line-gratings of different densities is fixed, at its limit, by the resolving powers of the eyes; yet our discriminations are likely to be sensitive to task and motivation, to attention and distraction—that is, very broadly, to our engagement with the meaningful world. So where does skill stop and brute ability begin? I am skeptical that learnability, teachability, or rational control provide an interesting or valuable demarcation. The most basic reason for this is that perceiving is never merely registration. It is a matter of knowledgable access (Noë 2004, 2012).

There is a second important issue as well. Consider language. Linguistic misunderstanding doesn't stop language in its tracks, ejecting you and sending you back to the grammar, written, as it were in advance, by those responsible for setting up the language. Rather, coping with misunderstanding—dealing with not getting how someone is using words, or how we should use them, or with not knowing how to use them—is one of language's familiar settings. We adjudicate and teach and learn and improve and criticize and define and formalize and evaluate *within* language, not from outside it. Language, contrary to the claims of Chomskyan linguistics, is not a rule-governed activity. It is a rule-using activity. And we make up the rules as we need them and for our own purposes. This may be controversial. But here's why I insist on it: according to the logician's or the linguist's picture of language, first you assign values to primitives, then you set up rules governing the construction of well-formed formulas. If you think of language this way, then it looks like you need judgement—the application of rules to cases—to secure the meaningfulness of what would otherwise be mere marks and noises. But we don't need judgement—we don't need understanding in the judgemental mode—to secure meaning. We don't need guidance from the outside.

The opposition between habit and skill is a false one; and it is a mistake to think that what marks the opposition is that habit is below or before understanding whereas skill is the deliberate exercise of understanding.

5 Troubles with anti-intellectualism

Some critics of intellectualism argue that perception cannot be conceptual, because if perception were conceptual, then perception would be a form of judgement. But the idea that perception is judgement over-intellectualizes perception.¹³

This is how I understand Gareth Evan's (1982) argument in connection with the Müller-Lyer illusion. You can experience the two lines in the Müller-Lyer illusion as different in length, even when you know, and so have not the even the weakest inclination to deny, that the lines are the same in length. The visual experience is one thing, and judgement another; hence experience is not conceptual.

Now, this is an example of an apparent disagreement between what you know to be the case (judgement) and how things look (experience). Things look precisely the way you know they are not. Experience and the judgement are in conflict. This shows, I would have thought, that experience, and the corresponding content, share the same kind of content. The fact that they are in apparent conflict shows that they are not somehow incommensurable. So if the one is conceptual, then so is the other.

But more important, for our discussion here, is that Evans seems to assume that concepts can only be in play if they are applied in judgement. Since experience is not judgement, there is no way for concepts to gear in. But that's to accept the basic claim of the intellectualist—judgement is the only way for concepts to get into the act—not to challenge it.

So Evans' argument against the idea that perceptual experience is conceptual—what we can think of as Evans's anti-intellectualism—actually takes what I am calling intellectualism

¹³ See Noë (2004, Ch. 6) for detailed engagement with the issue of the conceptuality of perception and the relation between my own position and that of John McDowell.

for granted. It takes for granted that there is only one genuine and legitimate mode of exercise of conceptual understanding, namely the judgemental.

Hubert Dreyfus (e.g., 2013) is responsible for a widely-influential criticism of intellectualism that is *crypto-intellectualist* in just this way.

Reasons, principles, and explicit knowledge guide perception and activity, according to Dreyfus, but only in the case of the novice. The expert, in contrast, is one who is engaged, in the flow. The expert, having mastered the rules and the concepts, has no further use for them. The expert is able to respond to the solicitations of situation and environment with no need for conscious thought or deliberate judgement.

A favourite example is that of the lightning chess player. There is literally no time, claims Dreyfus, for the chess player to analyse the situation and decide how to move. Moves are made in a flash. To suppose that the move is guided by reasons or judgement is to fall prey to a *myth of the mental*, according to which a mind-faculty, a faculty of judgement, say, accompanies our doings and is responsible for them being expressive of competence, intelligence, and understanding. For Dreyfus this idea is a dead giveaway of a distinct type of intellectualist psychologism. Yes, Dreyfus grants, if you ask the expert afterwards, why he or she made this move and not that one, he can give you a reason. But we have no more ground to suppose the reason was in operation before the player switched into the intellectual mode in response to the question than we do to suppose that the refrigerator light is always on because it is on whenever you open the fridge to look.

According to Dreyfus, understanding or reason operate only if there are explicit acts of rule-following, or judgement, that accompany, or even precede, every act. But why believe that? The baseball player doesn't need to be thinking about the rules for it to be the case that what he does is subject to them and is carried out, so to speak, in their light. The rules are there—in the form of umpires and rule books, and also dictionaries and courts of law, and earnest disagreement among participants—and we have access to them as need arises. The

fact that we can use them, and that we care about their correct use, is all that is needed for it to be the case that we act under their influence. The influence is not causal. It is normative.

Dreyfus goes further and insists that whether or not it is always legitimate to demand that *the phronesis*, as he calls the expert, invoking Aristotle, justifies his or her actions, it will not in general be possible for him or her to do so. You can't make explicit the myriad rules governing how we stand or react or explore or decide because, as a matter of fact, there are no such general rules. There is nothing to be made explicit. At best the chess master is likely to point to the situation on the board and exclaim, *look! This situation requires this move!*

But why is not this exactly the kind of reply that is required? Recall Wittgenstein's (1953, §88) example of "Stand over there!" This can be a perfectly precise command, as exact as rationality can require, even when it is not the case that one can specify, to the millimetre, say, where it is one is supposed to stand. For certain purposes, in certain contexts, one may need more precision. But in other contexts the demand for precision on the order of millimetres would be unreasonable. And so my thought here is that it is to set too high a standard on what it would be to have a reason for acting to demand that one can frame it independently of the situation one is in. It is precisely an over-intellectualized conception of what it would be to have a reason, or to make use of a rule, to suppose that rules and reasons need to be context-free and situation-independent, known in advance and applied, as it were, from outside one's engaged play¹⁴—just as it would be to over-intellectualize the intellect in general to suppose that concepts only gear in in the setting of judgement.

Here's the point: the use of rules themselves—which for Dreyfus is the hallmark of the detached attitude of the intellect—is itself an activity that admits of mastery and expertise and so also flow. And so we cannot insist that rule-use marks the boundary between engagement and detachment.

¹⁴ See McDowell (1994). His discussion of demonstrative senses and demonstrative concepts aims at just this point.

But once we allow that rules are used, and reasons proffered, from the standpoint of our engagement—from the inside—, then we need not fear that we have committed ourselves to an over-intellectualized conception of what it is to be engaged, just because we allow that we understand and can reflect on what we are doing.

Notice again that Dreyfus's picture—a picture he may take over from Heidegger (1927) and Merleau-Ponty (1945)—only counts as evidence against the idea that concepts and reasons and rules gear into perception and skilled action if we suppose that the intellectualist is right, that there is only one way for understanding to get into the act—namely, in the form of explicit deliberate judgement.

And notice that this way of rejecting intellectualism—on the part of Dreyfus, and other existential phenomenologists, and perhaps also Evans—pays a high price. For it must reject the idea that understanding and reason have any place at all outside the range of explicit deliberative reason, and so it has to give up the intellectualist's insight, namely that in our engaged, perceptual, and active lives, even when we are experts, even when we are skilled, our performance gives expression to knowledge, intelligence, and understanding. By accepting the intellectualist thesis that judgement alone is the only true way for concepts to gear in, Dreyfus and co. feel they are compelled to reject the idea that our lives as a whole, beyond the confines of deliberate exercise of reason and understanding, can be, or are, at one with our intellects.

What existential phenomenology may find difficult to appreciate—at least in Dreyfus's version of the position—is that conflict, disagreement, and disturbance of flow are themselves business-as-usual; they are normal moments in the way that even the expert carries on. We saw this in the language case. Expertise is not immunity; if anything, it is an evolved opportunity for new forms of vulnerability. Engagement is, as I shall put it, always manifestly *fragile*. That is, the liability to slip up, to get things wrong, is a built into the nature of the undertaking—of *any* undertaking. To go wrong is not, as a general rule, to stop playing the game—it is not the game's abeyance—it is rather a moment in

the development of play. But let's go back to language. We don't stop communicating when we fail to understand each other. At least that is not usually the case. Misunderstanding is an opportunity for more communication. Clarifying, reformulating, trying again, like criticism, are things we use language to do. The fragility is intrinsic and manifest. It doesn't mark out the game's limits. It marks one of its modalities.

I stated earlier that understanding in the active and perceptual modes leaves no room for the application of understanding in the judgemental mode. I suggested this was a reason for thinking that judgement can't be operating behind the scenes when we perceive and act. But we can amend this now in light of our consideration of fragility. It is internal to the very character of our perceptual and active involvements that they are liable, not so much to breakdown, in Dreyfus's sense, as to error, confusion, and other stutter-steps that require precisely that one now *think* about what one is seeing and what one is doing. Judgement and thought can, in this sense, live cheek-by-jowl with perception and action without, therefore, getting in their way.

In any case, Dreyfus's criticism of intellectualism fails. But it does so precisely because he fails to break with the over-intellectualized conception of the intellect at the heart of intellectualism. Dreyfus's anti-intellectualism fails because intellectualism fails. It is, in reality, a species of intellectualism. Neither Dreyfus, nor his would-be opponent, can do justice to the ways in which understanding operates outside the narrow domain of explicit reasoning. Both sides fail to accommodate the phenomenon of fragility.

II

6 Concept pluralism: A genuine alternative to intellectualism

So let us now turn our attention to the prospects for framing a true alternative to intellectualism. What would such an alternative look like?

A genuine alternative to intellectualism will be pluralist in that it will reckon that there

are different legitimate and non-derivative modes of understanding, and so it will hold fast to the intellectualist's insight that understanding is in play everywhere in our lives even as it rejects the intellectualist thesis.

One resource for such a pluralism is [Wittgenstein \(1953\)](#). Wittgenstein proposed that a concept is a technique, and that understanding, therefore, is a form of mastery, akin to an ability. An important fact about abilities is that they can be exercised in a multiplicity of ways. I can exercise my understanding of what a house is by building one, looking at one, painting one, living in one, talking about one, or buying one. So, from this standpoint, there is nothing more surprising about the fact that my knowledge can find expression in what I do, as well as in my knowledge of a proposition, than there is in the fact that my ability to read gets exercised both when I read a novel and also when I blush at the words on the bathroom wall.

This idea also helps us explain the unity of understanding. If concepts can be applied in walking the dog as well as in writing a treatise about dogs, what is the connection between these two self-standing and non-derivative modes of exercise of something that, surely, is a single conceptual capacity: an understanding of the concept *dog*? What gives unity to this understanding?

The idea that understanding a concept is mastery of a technique, a mastery that has multiple, distinct, context-sensitive ways of finding expression, helps here. One way to express understanding of *dog* is to talk and write about dogs. Another way is to be able to spot dogs on the basis of their appearance. Still another is to work or play comfortably with dogs. And the list goes on and on. We put our singular understanding of what dogs are to work in these different ways, and the understanding consists in the ability to do (more or less) all of that.

We are now in a position to appreciate that the claim that perception and action are, with judgement, non-derivative, original modes of understanding does not entail that these modes are independent of each other. The idea that the unity of a concept is a matter of unity-in-ability helps bring this out. The fact that

perception isn't beholden to judgement for its conceptuality doesn't mean that there could be perception in the absence of capacities for judgement. After all, typically, you can't be said to know a concept if you can't apply it in normal perceptual settings. Can you know what a tomato is if you are incapable of any active or perceptual engagement with tomatoes?

But we should also be careful. In so far as our concepts have unproblematic unity, then, on this Wittgensteinian view, this is because they are exercises of common abilities—abilities which are, of their nature, such as to admit a genuine multiplicity of expressions. But the unity of our concepts is not something that we can always take for granted.

Is there *one* concept of dog, or several, brought to life in different situations and sub-cultures at different times, for different purposes? Is there unity or just fragmentation? Is this a shared understanding? These are important questions, not for philosophy, particularly, but for culture. Look at the changes that have taken place in our thinking about *matter* over the last few hundred years. Or, to give a different kind of example, about *gender*. We have no choice but to work it out as we go along.

And crucially, there is no standpoint outside our thinking, talking, writing, persuading, imposing, regulating, prescribing and also describing, from which these questions can be adjudicated. This doesn't make the existence of dogs a matter of social construction. (Of course, dogs are, literally, bred and so constructed by us.) No, surely dogs have a mind-independent nature. But it does mean that it is hard and creative and unending work to bring that reality into focus in our shared thought, talk, perception, and activity.

There is no standpoint outside our thoughtful practices from which to ask after our own concepts. For our concepts are our own tools and techniques. This is where Frege went wrong. He seems to have thought that the only way to achieve *objectivity*—that is, sharability, articulability, and lawfulness—was by supposing concepts were out there, indifferent to how we grasp or understand them. In fact, they supervene on our grasping, negotiating, communicat-

ive activity. Frege made no allowance for fragility.

7 Concepts are skills of access

But can we say more than just that concepts are abilities? Abilities to do what? Well, we've already said: to talk and see and use and judge, and so on.

But I think we can do better. To do so, I draw on the actionist approach to perception developed in earlier work (Noë 2004, 2012). To begin to organise an answer, consider two familiar facts about visual perception. The first is that, as Euclid noticed, when a solid opaque object is seen, it is never seen in its entirety at once. Things always have hidden parts. The second is that the visible world is cluttered with all manner of stuff. Things get in the way, the view is interrupted, occlusion is the norm.

And yet, despite these striking limitations, we don't experience the world as cut off from us, inaccessible to vision, blocked from perception. The partial, fragmentary, and perspective-bound character of our visual access to the world is not a limit on what we see, a marking off of our liability to blindness; it is, rather, the very manner of our seeing. This is fragility again.

Not seeing through the solid and opaque, as if it were transparent, is not a perceptual failing but rather an accomplishment. And relatedly: we belong to the cluttered environment ourselves. We are not confined to what is projected to a point. We explore. And it is that exploring, that doing, that is the seeing. The seeing is not the occurrence of a picture or representation in the head; it is, rather, the securing of comprehending access, thanks to our possession of a specific repertoire of skills, to what there is. The generic modality of the way the world shows up in perception is not *as represented*, but rather *as accessible* (as I argue in Noë 2012). This is why our inability to see things from all sides at once, or to experience a thing's colour in all possible lighting conditions at once, is no obstacle to the presence of whole objects and colours in our experience.

The immediate environment is present in visual perception, not because it projects to the eyes, but because the person, by means of the use of his or her eyes as well as other forms of movement and negotiation, has access to that environment. Presence is availability, and its modalities—visual as opposed to tactual, for example—are fixed by the things we need to do, the negotiations, to bring and keep what is there in reach. Wittgenstein, in the *Tractatus* (1921), said that the eye is a limit of the visual field. But this is wrong: the adjustments of the eye, the need to adjust the eye, difficulties in adjusting the eye, are given in the way we see. Wittgenstein's point, I suppose, was that the eye doesn't see itself seeing (unless you look in a mirror). But here's a different model: seeing is like what an outfielder does. To say that the eye is not *in* the visual field is a bit like saying that the body of the outfielder is not in the field of play. But in fact the eye and the head and the hand and the arm and the glove are all in the field of play. And what we call *fielding the play* is precisely a temporally extended transaction in that whole environment. And the basis of the environment's availability to this or that modality of exploration, beyond the fact that it is there, is our possession of the skills, abilities, and capacities to secure our access to it. The occluded portions of the things we see are there for us, present to us, thanks to our skilful ability to move and bring them into view. Perception is fragile.

John Campbell, writing in a related context (2002), has said that we shouldn't think of the brain as representing the world; we should think of it as making the adjustments that, as he puts it, keep the pane of glass between you and the world clean and clear, as if it were continuously vulnerable to becoming opaque.

My thought is that *we* (not our brains) need continuously to make adjustments to keep the world in view, and to maintain our access to the world around us.

But I add: the character of the world's presence itself is precisely a function not only of what there is, but of what we know how to do, and what we do, and what we must always of necessity stand ready to do, just in case, to pre-

serve our access. You need to squint and peer and adjust to see things far away; and this makes a difference to how those things show up.

This is one reason why it is a mistake to suppose that we think of the adjustments that belong to the ways we bring the world into focus as the brain's work. No, it is our work, even if most of it is low-level, unattended, and done automatically. For it is this work that gives experience the quality that it has.

The scene is present for us in the manner of a field of play. This is a fragile presence. Its presence is not given to us alone thanks to what might happen in our brains, thanks to neural events triggered by optical events. Its presence is achieved thanks to what we know how to do. The basis of our skilful access to the world is, precisely, our possession of *skills of access*.

And this, finally, is what I propose concepts are. They are skills of access, or rather, a species of such. They are not so much devices by which we make the world intelligible, as much as they are the techniques by which we secure our contact with the world, in whatever modality. From this point of view, concepts like *dog* and *matter* are of a piece with other skills of access such as the not-quite-articulable sensorimotor skills we skilfully deploy as we navigate the scene with our thinking bodies.

From this standpoint, it is worth emphasizing that there is no theoretically interesting cleavage between seeing and thinking (as already argued in Noë 2012). Seeing is thoughtful and thought is perceptual at least in so far as it is, like seeing, a skilful negotiation with what there is, as just another modality of our environment-involving transactions. Presence, after all, is always in a modality—that is, it is always dependant on our repertoire of skills. And it is always a matter of degree. The hidden portions of the things we see *show up for us*, as does the space behind our head, and even spaces further afield. We have access—skill-based, partial, perspective-bound, and fragmentary—to it all.

Perception and thought, from the actionist perspective, differ as sight and touch differ. They are different *styles* of access to the world around us.

8 We use concepts to take hold of things, not to represent them

Let us come back to the more particular line of investigation that has been our concern.

The intellectualist is quite right that in so far as seeing is expressive of understanding, this is because we bring concepts to bear in our seeing. But the intellectualist is mistaken in holding that this is because we categorize what we see, in the mode of judgement, by applying concepts. It is rather that we see *with* concepts. Concepts are techniques by which we take hold and secure access. Their job is not to represent what is there; their job is to enable what is there to be present to us. You can't see the laser-projector if you don't know what a laser-projector is. Your possession of the concept is a condition on the laser-projector's showing up for you. It is the ability that lets you encounter what is in fact there.

Back to the example of text: your grasp of the relevant concepts enables you to read (to see what is there). Not because it gives you the resources to interpret or decode (although it does give you that). But because knowledge lets what might otherwise be unseen come into view. Knowledge can also, correspondingly, disable us. Your reading knowledge, for example, can make it difficult or even impossible to see the squiggles, the “mere marks”, which are also always there whenever you read.

And so across the board: we don't apply concepts in judgement to what we see in order to represent things; our possession of the concepts is what enables us to make contact with them themselves. We see *with* our concepts. They are themselves techniques or means for handling what there is. Think of the concept in perception not as a category, or a representation, but a way of *directly picking up* what is there (to re-use and rehabilitate Gibson's 1986 idea).

And so also for the active modality. My understanding gets expressed in what I *do* and it gets expressed directly—for example, I exercise my knowledge of teacups in the *way* I handle this cup; I grasp the cup with my hands, and also with my understanding. My under-

standing gets put to work in the fact that I am able to do this, in the fact that I know how to do it.

Understanding, I would urge, is put to work, in these doings, *directly*. We don't need to suppose an action is skilful or knowledgeable or expressive of understanding only when it is guided, as it were from without, by propositional knowledge—as if the understanding couldn't inform our practical knowledge and our action directly.

And we are now finally in a position to understand why this is the case: for then we would be owed an account of how understanding is put to work in judgement. And here, we are just thrown back on what we can do to bring what is there for us into focus, to achieve its presence.

9 Conclusion: The significance of fragility

The world shows up for us in perception and thought, but it has a fragile presence. It shows up in very much in the same way that what a person means shows up for us when we are in conversation, to return to the language example. Misunderstanding, outright failure to understand, are always manifestly live possibilities. It isn't only solid opaque objects that fail to reveal themselves in their totality to the single glance. What we are given, always, is an opportunity or affordance for further effort, engagement, negotiation, and skilful transaction. The world is present to thought and perception not as a represented totality—an idea in our minds, a representation in our brains—but as the place in which we find ourselves, where we live, where we work. The world is a big place, and so there is a lot for us to do if we are to secure our footing on its slippery grounds. But a slippery ground is still a ground, and we need to secure our footing.

Presence—in thought and experience—is fragile, in other words. Philosophy has been strangely resistant to fragility. Fragility is not fallibility. The point about fragility is that it is manifest. An object's colour shows up for us as something with hidden aspects; it presents itself

to us as something that is always on the cusp of variation, always ready to change with the least alteration in our perspective or in the conditions of viewing. A colour, no less than a solid object, has hidden aspects. We don't experience these aspects as isolated atoms—as if we were confined to what the camera sees. What we see, what we experience, outstrips anything that can be understood in optical terms alone. For we see, we experience, and we also think about, a world that manifestly goes beyond what can be taken in a glance. Our skills—our understanding, to use the term that has organised so much of this discussion—gives us access to what there is.

That access is achieved, but not once and for all. It is not as though we consume the world in encountering it so that now we can make do with what is inside us. Access is a work in process. Presence is fragile, manifestly so; but it is robust.

Acknowledgements

I have presented this paper at Georg-August-Universität Göttingen, Ruprecht-Karls-Universität Heidelberg, the University of Iowa, the University of Pittsburgh, Yale University, and also in Riga at the Riga-Symposium on Cognition, Communication and Logic in May 2013, as well as at the 2014 Wittgenstein Symposium in Kirchberg am Wechsel. I am grateful to these audiences for their helpful comments and questions. For comments on the talk, or on the written paper itself, I would particularly like to thank Michael Beaton, Andy Clark, James Conant, Caitlin Dolan, Hubert Dreyfus, Sean Kelly, John W. Krakauer, Zachary C. Irving, Edouard Machery, Thomas Ricketts, Jason Stanley, David Suarez, and Martin Weichold.

The Fragile Nature of the Social Mind

A Commentary on Alva Noë

Miriam Kyselo

In this paper I argue that while Noë's actionist approach offers an excellent elaboration of classical approaches to conceptual understanding, it risks underestimating the role of social interactions and relations. Noë's approach entails a form of body-based individualism according to which understanding is something the mind does all by itself. I propose that we adopt a stronger perspective on the role of sociality and consider the human mind in terms of socially enacted autonomy. On this view, the mind depends constitutively on engaging with and relating to others. As a consequence, conceptual understanding must be seen as a co-achievement. It is a fragile endeavour precisely because it depends not only on the individual but also on the continuous contribution of other subjects.

Keywords

Body-social problem | Enactive self | Fragility | Socially enacted autonomy | Socially extended mind

1 Introduction

In the paper "Concept Pluralism, Direct Perception, and the Fragility of Presence" Alva Noë offers an exciting and dense insight into his philosophical thinking. Combining his classical work on the active nature of perception (Noë 2004) with his more recent inquiries into philosophical method, presence, the arts, and human nature in general, Noë now aims at a more thorough account of conceptual understanding (2012).

Noë's proposal must be seen in light of the paradigm shift in the philosophy of mind and cognition, from a cognitivist and representationalist view to a distributed or embodied per-

spective on the mind. It is one of the so-called "E-approaches" to the mind (enactive, extended, embodied and embedded) that transcend the classical view of the mind as being an isolated entity located in the brain that passively represents an outside and independently-given world (e.g., Shapiro 2011; Clark & Chalmers 1998; Noë 2004; Varela et al. 1993; Thompson 2007; Kyselo 2013). There are significant differences between these views (and they will be of relevance below), but generally speaking they all rest on the assumption that cognition is not in the head and instead requires bodily action and the environment. Noë uses these insights

from the E-approaches to expand on the disembodied and representationalist view underlying the intellectualist approach to concepts, and in this way, he provides a timely and innovative elaboration of conceptual understanding that is more encompassing than previous approaches.

I am sympathetic to Noë's approach. Methodologically speaking, he illustrates what he promotes as the right style of philosophical analysis, an inquiry into the so-called "third-realm" that remains "in-between—neither entirely objective nor merely subjective" (Noë 2012, p. 136) but open for "conversation or dialogue" (Noë 2012, p. 138). My comment should be considered an elaboration in the same vein.

I agree with Noë with regards to the more general project of questioning traditional conceptions in philosophy of mind by adopting an embodied and distributed perspective. That said, however, I think that there is a problem with his proposal. Even though it provides a great number of important insights, I think, third-realm fashion, Noë's proposal fails as a general theory of understanding. The reason for this is that in a crucial way his own epistemological pre-conception of mind is not yet fully separated from the paradigm that it seeks to overcome: while Noë acknowledges the role of the bodily and active individual, he accepts a dichotomy that is prevalent in the traditional paradigm, namely the split between the individual and the world of others. His approach inherits what I have called the *body-social* problem (Kyselo & Di Paolo 2013; Kyselo 2014). The body-social problem is the third in a series of dichotomies in the philosophy of mind and the successor to the classical mind-body problem and the more recent body-body problem (Thompson 2007). The body-body problem is the question of how the bodily subject can be at once subjectively lived and an organismic body that is embedded in the world. The body-social problem elaborates on this and is concerned with the question of how bodily and social aspects figure in the individuation of the human individual mind. Philosophers of cognition systematically assume that the mind is essentially embodied, while the social world remains the context in which the embodied mind

is embedded. On this view, the social arguably shapes the mind, but it does not figure in the constitution of the mind itself.

In what follows, I first show that Noë's proposal entails the same presupposition and thus invites a new form of methodological individualism that risks limiting conceptual understanding to the endeavour of an isolated individual subject. I then introduce and discuss an alternative proposal for a model of the individual mind as a *socially enacted self*. I argue that since the world of humans is a world of others and our social relations are what matters most to us, the social must also figure in the constitutive structure of human cognitive individuation.¹ The human mind or self is not only embodied but also genuinely social. From an enactive viewpoint the self can be considered as a self-other generated autonomous system, whose network identity is brought forth through individual's engagement in bodily-mediated social interaction processes of *distinction and participation*. Distinction and participation refer to the two intrinsic goals that the individual follows and needs to balance. Distinction means to be able to exist as individual in one's own right. Participation refers to an openness to others and a readiness to be affected by them. It refers to the sense of self as connected and participating. Both goals are achieved through engaging and relating to others. The processes that constitute the identity of the human mind are therefore not defined in terms of bodily but rather interpersonal relations and interactions. On this enactive approach to the self, the body is not equated with the self but instead seen as that which grounds a double sense of self as a separated identity and as participating. The body mediates the individual's interactions with others (Kyselo 2014).

I outline how the model of the socially enacted self can combine with and elaborate Noë's actionist account of concepts so as to arrive at an even more encompassing view of human un-

1 By saying that sociality matters *constitutively* for the human self, I mean that without continuously relating and engaging in interactions with others, there would be no human self as a whole. The social is not only causally relevant for enacting selfhood, but it is also an essential component of its minimal organisational structure.

derstanding as well as a deeper appreciation of its fragile nature.

2 The risk of crypto-individualism

Noë observes a dichotomy between what he calls the *intellectualist* approach to concepts, the view that concepts are judgments, which is endorsed by Kant and Frege, and the *existential phenomenological* approach, such as that endorsed by Dreyfus, which argues that concepts are usually only used by the novice, and that understanding is otherwise already given through context and situation.² Noë disagrees with both positions. He rejects the idea that concepts are only judgments, fixed and just “out there”, to help us represent the world; yet contrary to the *anti-intellectualists*, Noë also emphasizes that conceptual understanding is not limited to the novice, but “at work wherever we think and perceive and act and talk”. What the existential phenomenologist thereby misses, according to Noë, is that skillful mastery involves learning and development. Noë assumes that, like intellectualism, anti-intellectualism makes the presupposition that concepts are equal to judgments and thus implicitly reduces the mind to a “realm of detached contemplation” (2012, p. 25). For that reason, Noë calls anti-intellectualism *crypto-intellectualist*.

Noë seeks to find an alternative to the two positions by questioning their very fundamentals. Rather than assuming that the world is just given and that everything is already present to us, Noë emphasizes the active contribution of the individual organism (2004, 2009). He proposes that we should adopt a pluralistic approach to concepts, according to which conceptual understanding is basically having the skills required for accessing the world. There are different types or modes of access to the world, including the modes of perception and action, the (inter)personal, and the emotional mode. On this *pluralistic* account, thinking and perceiving

are not very different from one another. Both are “a skillful negotiation with what there is, just another modality of our environment-involving transactions” (Noë [this collection](#), p. 16). From this perspective, judgements belong to a particular mode of access and form part of a broader set of skills of conceptual understanding. Noë then specifies the nature of our access to the world. The world is not just out there ready to be understood. Rather, it always has to be made available and actively brought into view or into “presence”, as Noë puts it. Concepts are the means by which we can achieve this. They are the techniques “by which we secure our contact” with the world ([ibid.](#)). But bringing the world into presence is not a fixed, one-time or uni-directional endeavour. Conceptual understanding involves continuous engagement with the world; it can change and also fail. Noë proposes the notion of *fragility* as a key for understanding conceptual activity as an open and necessarily vulnerable phenomenon, instead of a perfect application of definite representations of the world. In this way, he overcomes the limited view of both the intellectualist and anti-intellectualist perspectives according to which concepts are judgments about an independent world.

One of Noë’s crucial insights is that the traditional dichotomy between an objectively given world and subjectively experienced, internally-processed data about worldly objects can be overcome by grounding all conceptual activity in a broader “common genus”, i.e., skilful engagement with the world. But what is even more important, and in this I think Noë does not actually diverge far from Dreyfus and other existential phenomenologists, is that the established unity of different modes of understanding is not merely a unity in terms of styles of access to the world, but also a unity grounded in the *individual* mind as a whole. But what is that individual mind as whole?

Noë quite clearly presupposes that *we* are not our brains. We understand the world through navigating it with our thinking, skilful sensorimotor body (Noë [this collection](#), 2004). This view breaks with the cognitivist paradigm with regard to the constitutive elements of the

² The existential phenomenological approach refers to phenomenologists such as Heidegger and Merleau-Ponty who investigate the basic structures of human existence. One of their assumptions is that prior to any reflexive understanding, we are already attuned to the world simply through our bodily being in it. Dreyfus calls this pre-reflexive attunement to the world “absorbed coping” (2013, p. 21).

system that does the understanding, and it also breaks with it with regard to the relation of the understanding system to the environment: the system is not passive, but rather active and dynamical. What this elaboration implies, yet does not make explicit, is the fact that conceptual activity is done by a bodily *agent* who understands or has access to the world. After all, conceptual understanding is not just understanding *about* something but always also understanding *for* someone and *by* someone. To argue that thought and perception are unified as modes of access thus presupposes an individual who employs these different modes of access, someone for whom the world can show up. Without an agent that does the understanding, postulating a unification of modes of understanding would not make any sense, as any understanding would remain an action that has neither origin nor actor.

This is a point that [Evan Thompson](#), who is also a proponent of embodied cognition, has already made on some of Noë's earlier work on enactive perception (2007). According to Thompson, while emphasising the role of experiences of *objects*, Noë underestimates the role of subjectivity as such: the "sensorimotor approach needs a notion of selfhood or agency, because to explain perceptual experience it appeals to sensorimotor knowledge. Knowledge implies a knower or agent or self that embodies this knowledge" (Thompson 2007, p. 260). This is where I think Noë's underlying epistemology requires elaboration. Who or what is the individual subject that engages in this fragile endeavour of securing access to the world?

[Thompson](#) provides an insight that can be seen as a major step into the right direction: he proposes addressing the *body-body problem*, i.e., the question of how the agent can be at once subjectively lived and an organismic or sensorimotor body that is embedded in the world (2007, pp. 235–237), by proposing an enactive notion of selfhood. According to this notion, individual agency is defined in terms of *autonomy*. It is seen as a self-organised network of interconnected processes that produce and sustain themselves as a systemic whole—a bounded identity within a particular domain

(Varela 1997; Maturana & Varela 1987). According to [Thompson](#), it is this autonomous self that gives unity to the sensorimotor skills in terms of self-organisation and operational closure (2005, 2007). Operational closure means that some process relations of the autonomous network remain constant despite structural dependence on the environment, i.e., each process within the network is not only enabling but also enabled by some other process. With the production of such a self-organised autonomous identity the individual also acquires a basic subjective perspective, from which interactions with the world are evaluated respectively. This subjective perspective is what [Thompson](#) calls a pre-reflective bodily self-consciousness (2007, p. 261).

On Thompson's enactive account, the individual is now not only active and embodied but also an autonomous subjective agent. Importantly however, Thompson shares with Noë a dubious fundamental pre-supposition, namely the idea that the individual mind or subject can be equated with the individual sensorimotor body or organism. The autonomous agent is a self-organised "sensorimotor selfhood" ([Thompson 2005](#), p. 10). As a consequence, in both Thompson and Noë's views, the mind is empowered and freed, as it is no longer restricted to the passive, information-consuming existence that is distant to the world and confined to the narrow shells of our heads. Nevertheless, it still remains a mind of a body in isolation: in isolation from the world of others.³ This risk of an individualist account of the agent is the first horn of a dilemma underlying Noë's proposal. The second horn has to do with the fact that for Noë understanding is actually *not* an isolated endeavour. The social world is mentioned

3 [Thompson](#) clearly recognises the importance of intersubjectivity for the process of understanding, arguing that "human subjectivity is from the outset intersubjectivity, and no mind is an island" (2007, p. 383). He proposes (in line with Husserl) that humans are from the beginning intersubjectively open. However, it seems that Thompson's emphasis on sociality is either developmentally motivated and concerned with the intersubjectively-open intentionality in object perception or a question of our (rather sophisticated ability) to understand others and to make the distinction between self and other. But the subject herself, despite being intersubjectively open, is still a "bodily subject" ([Thompson 2007](#), p. 382). In other words, the structures of subjectivity itself, the very network processes that bring about the individual as an autonomous system, are determined bodily, not intersubjectively.

throughout the paper in the form of other subjects that seem to enable the individual's understanding in various ways. Some of the skills of access are interpersonal and also, as Noë emphasizes, have to be learned.

The question is, how do we learn skills? We usually learn through a teacher, and thus through the help of another being. Similarly, how do we discover a piece of art? By discussing it with a friend, who helps to bring about a new perspective on it. The person whom we misunderstand and try again to understand is another subject. Understanding is a highly intersubjective endeavour, not only developmentally—in the sense that we need others at some point in life to learn a particular skill—but also in a continuously on-going sense, for much of the very process of human understanding happens through and with others contemporaneously. Strikingly, however, though Noë admits this in acknowledging that understanding happens through communication and thus through the contribution of other subjects, the social does not seem to matter *constitutively* in his general theory of conceptual understanding. The mechanism and structures of the process of understanding are defined in terms of sensorimotor processes, not in terms of interactions with others, and the unity that grounds conceptual understanding is constitutively the sensorimotor body in object-oriented action; it is not, more dynamically put, the individual in its relation to other subjects. The worry is that in Noë's approach, the social part of the world would therefore only play the *weak role* of an outside and divided context. In contrast, on a *strong* reading of the relation between understanding and sociality, engagements and relations with others would have a more than developmental or contextual relevance. Instead, they would also be considered part and parcel of the very structure of the process of understanding, and they would (as I argue below) figure in the minimal constitution of autonomous selfhood.

Noë characterises Dreyfus's anti-intellectualist stance as "crypto-intellectualist" because Dreyfus allegedly accepts the premises of the intellectualist's view that understanding is rule-based judgement. Yet one might say that in his

attempt to overcome the dichotomy between existential phenomenology and classical conceptualism, Noë inherits a very similar problem. Noë's actionist approach opens the individual up to the world; but, perhaps because he is trying to avoid an implication of Dreyfus' existential phenomenology, namely the risk of losing the individual (as already immersed) in the world, Noë also risks over-emphasizing the status of the embodied individual, thereby missing the deeper relation between the individual and the social world. The undesirable implication is that conceptual activity is essentially an isolated undertaking (since according to standard approaches to embodiment there is nothing social about the individual body or organism *per se*). It is the lonesome individual by herself who navigates through the world, equipped with a great set of skills that enable her to act and to secure the access to the world.⁴ Because Noë seems to implicitly accept the individualistic premise of the traditional cognitivist view, one might say that that his proposal is *crypto-individualist*.

Noë is not alone in making the crypto-individualist presupposition. According to Post-Cartesian and non-cognitivist philosophy of cognition, the mind supposedly involves an active and dynamical engagement with the social and material environment, and also has an experiential dimension (Shapiro 2011; Clark & Chalmers 1998; Varela et al. 1993; Thompson 2007). But the integration of these aspects, and in particular that of the social and bodily dimension with regards to the individual that has or is the mind still remains a fundamental question. This is what I have called the *body-social problem*: how can the mind be at once a distinct bodily individual but at the same time remain open and connected to the social world? At the moment there is a dichotomy between views that posit that the mind is embodied and views that emphasize the relevance of situatedness and embeddedness. On the former view, the mind is active but confined to being an isolated indi-

4 Note that it does not actually matter whether one posits that the mind is in the head or in the body, both claims are compatible with the weak reading of the interrelation of individual and social world, according to which the social remains separated from the individual.

vidual. On the latter, the mind is primordially immersed in the (social) world. The first view risks a new form of methodological individualism where the individual mind, while no longer restricted to the brain, is now confined to the body. Here the social world becomes the external, independently given world into which these newly embodied and active, yet essentially isolated individuals parachute (Kyselo 2014).⁵ The second view focuses too much on the interaction dynamics and risks losing the immersed individual mind in the world (and social interactions), thereby blurring the very epistemological target of our philosophical inquiry (Kyselo 2013, 2014).

The body–social problem reveals a deeper linkage between Noë and the stance of the existential phenomenologist that he actually seeks to debunk. Both positions disagree with the traditional Cartesian picture of the mind; both hold that embodiment matters vitally for the mind. But notice that they also focus on different aspects of what a true alternative to the classical view might look like. The overall alternative basically involves a fundamental shift in thinking about the relation between an individual and the world. In this vein, Noë is right to emphasise the individual's power, giving it more responsibility in the very construction of its own mind and of the world it experiences, but so are the existential phenomenologists when they focus on worldly embeddedness and the fact that a great deal of our being in the world relies on pre-given structures that can surpass the individual's capacities. An emphasis on individual action and responsibility cannot mean that the individual is all alone. We would not have made enough progress if the main difference between Noë's proposal and the representationalist division between individual and world was that now, while being able to move towards the world, the world does not also move toward us but remains separate with regard to other subjects. Other people are active, too, and they shape not merely the world for us but also

who we are as subjects. But, speaking to the potential worry of losing the individual in worldly engagements, the solution is of course neither to negate any need for differentiation nor the necessity of the individual to have its own share in the very mechanism of understanding the world. Where I think both positions go wrong is in extrapolating from a part of adult human phenomenology (even when it is paired, as in Noë's case, with an objective account of the constitutive mechanism of experience) to a general theory of understanding. In crypto-individualism the individual mind carries a heavy burden. It is free from passivity and yet enormously restrained by the responsibility of achieving the access to the world (and the social world) and itself, all by itself. Existential phenomenologists, in emphasising the importance of the social world and its pre-given structures in bringing about understanding then ease the burden and free the individual from some of the responsibility in achieving this; and yet at the same time they also risk depriving the individual of its power and right to have a say in that endeavour.⁶

It should be clear that neither position on its own will suffice to overcome the dichotomy inherent in the intellectualist view on concepts. The individual cannot understand the world simply by being an individual body, but neither is the world already understood just by simply being immersed in it.

3 Deep dynamics and the enactive self

There exists a middle ground from which the dilemma of having to choose between too much or too little individualism can be avoided and a more complete epistemological basis for conceptual understanding achieved. Finding this middle ground basically consists in re-thinking the nature of the mind and of human understanding while doing more justice to the deep interrelation between individual and social world. To this end I have recently proposed the

⁵ This image is adapted from Varela et al. (1993), who criticise the traditional view as implying that the environment is a "landing pad for organisms that somehow drop or parachute into the world" (p. 198); instead, they argue that the relation between world and individual mind is co-determining.

⁶ This commentary is not the place to discuss this issue in detail, but it should be noted that such a view can be expanded to political philosophy and the philosophy of law, where it might have far reaching consequences for questions concerning the nature of individual rights and approaches to legal responsibility.

concept of the *socially enacted self* (Kyselo 2014, 2013; Kyselo & Tschacher 2014). On this approach, the individual is not sufficiently determined in terms of active embodiment; instead it is thought to incorporate social and relational processes into the structure that makes up its identity as an individual. This suggests that without a “social loop” we cannot speak about the human self as a centre of individuation in any interesting sense. After all, humans do not merely distinguish themselves against a background of material objects, but, crucially, against the world of other humans. They become someone, an identifiable individual against a world of other individuals and social groups.

This idea should become clearer by reconsidering, or making more explicit, a number of insights already implied in diverse approaches in embodied cognitive science.

First, Noë’s crypto-individualism captures something essential about the ways humans access the world: we often experience the process of understanding as something we do by ourselves—the concepts we acquire and employ are ours and to a large extent we appear to be in control in our attempts to secure the world. Noë’s other important insight is that conceptual understanding is an achievement. It is a far-from-perfect endeavour, involving experiences of vulnerability, openness, of not always being able to own and to access the world.

The second insight is appreciated in the debate on extended cognition. Clark & Chalmers in their now classical paper “The Extended Mind” propose that a tool, such as a notebook or a computer, can count as part of the individual mind (1998). This essentially functionalist position goes against Noë and “beyond the sensorimotor frontier” (Clark 2008, p. 195)—the mind is not restricted to the body but spreads across neuronal, bodily, and environmental features. The extended cognition approach to embodiment has been criticised for being too liberal, since it lacks both a principled definition of “body” and of “cognition”. It remains unclear how an environmental prop or technology could be integrated into the cognitive architecture of an individual mind (Kyselo & Di Paolo 2013, see also Menary this collec-

tion). Yet, despite these shortcomings I believe there are two important insights in this extended functionalist account: first, that the individual should not be restricted to the biological realm (be it the brain *or* the body) but incorporates tools and technologies, and second, that the mind transcends the individual physiological body and that the world matters constitutively for determining the boundaries of the mind.

The third insight comes from the enactive approach to cognition, which proposes that the mind is basically an autonomous system that self-organizes its identity based on operational closure. The enactive approach thereby shares with extended cognition the idea that the individual is not clearly separable from the environment. On the enactive view, the individual’s mind is “defined by its endogenous, self-organizing and self-controlling dynamics, does not have inputs and outputs in the usual sense, and determines the cognitive domain in which it operates” (Thompson 2007, p. 43). Identity is therefore not a given thing or a property, but *relational*: brought forth through the individual’s on-going and dynamical interaction with the world. This approach adds an insight derived from philosophy of biology, namely that like living beings, cognitive beings create an identity that they strive to maintain, and that understanding the world depends on the purposes and concerns of that identity (Weber & Varela 2002; Thompson 2007) in that they guide and structure our understanding.⁷

The three variants of embodied cognitive science therefore all reject the mind–body dichotomy and emphasise a dynamical interrelation between embodied individual and world. All of them however, either miss or do not fully acknowledge that the world is social and that the individual is also a psychological and social being whose concerns are more than object-oriented. This is where the enactive approach to the social self comes into play. It basically elaborates on and integrates the above insights, i.e., action (sensorimotor cognition), co-constitution

⁷ Interestingly, this is also an insight Dreyfus pointed out much earlier when he argued that the “human world, then is prestructured in terms of human purposes and concerns in such a way that what counts as an object or is significant about an object already is a function of, or embodies, that concern” (1972, p. 173).

(extended cognition), and grounding in selfhood (enactive cognition), by adopting a much more radical perspective on the dynamical interrelation between the individual and the world—let us call this perspective *deep dynamics*. Deep dynamics means that the nature of the relation between individual and world is one of strong co-constitution: not only does the individual actively shape and structure the world, the world, too, affects the individual in its basic organisational structure. If identity and domain depend on each other in a strong and mutual sense, as the enactive approach to cognition has it, then even more advanced non-organismic or virtual notions of the body do not change the fact that the organismic bodily domain is an individualist domain (Kyselo & Di Paolo 2013). In other words, the organismic body cannot be related to the social at the same level of organisational closure. The enactive approach to the self would suggest instead that the level at which human selves can be usefully operationalised as autonomous identities is social, not merely embodied. Admittedly, by emphasising how conceptual understanding is shaped through social engagements with others, Noë's approach obviously also implies a bi-directional relation between individual and world. Similarly, as we have seen above, Thompson's sensorimotor subject is also clearly involved in intersubjective interactions (2005, p. 408). However, the bi-directional impact in these accounts is more *shallow* than in the present proposal, as they consider the (social) world to play a contextual or developmental role, or to matter with regards to shaping object-recognition. In deep dynamics, in contrast, we expand on the insight of extended cognition that the mind transcends brain and body by acknowledging that this not only the case through interactions with tools but also through our social interactions and relations with other subjects. The idea then is that *qua* being embedded in a social world, the self, and by that I mean the individual as a whole, constitutively relies on its interactions and relations to other subjects. According to this elaboration on the enactive account of selfhood, the self can be defined as a socially enacted autonomous system. It is:

a self-other generated network of precariously organized interpersonal processes whose systemic identity emerges as a result of a continuous engagement in social interactions and relations that can be qualified as moving in two opposed directions, toward emancipation from others (distinction) and toward openness to them (participation). (Kyselo 2014)

In line with the concept of operational closure, both types of processes, distinction and participation, are required to bring about the individual self. Without distinction, the individual would risk immersion or becoming heteronomously determined and forced to rely on the next best or a limited set of social interactions. But without participation and an act of openness towards others, the individual eschews structural renewal, thus risking isolation and rigidity (Kyselo 2014). The point, however, is that this form of operational closure contains social interactions. In enactive terms, this is to say that the individual is at the same time self-and-other-organized. As a consequence, the self is not a given nor an individual bodily achievement but also and necessarily co-constructed with others. Both the individual and the world (that is, other subjects) have a say in the constitutive mechanism of someone's mind. In contrast to Noë's presupposition, the mind cannot be equated with the active body. Rather, the sensorimotor body becomes the ever-evolving interface that in being with others co-generates the very boundaries of what we call the self (Kyselo 2014).

At this point, proponents of embodiment might still want to insist that there is something about the body's role in grounding the sense of self that non-negotiably remains entirely independent from social interactions. I agree, if by "sense of self" one refers to the self as mere biological identity. However, if by "self" we mean the human self in distinction from other humans, then the proposed view challenges this intuition. It does this, however, without giving up the insight that the self has to do with individuation. The enactive notion of autonomy and self-organization saves the indi-

vidual from immersion in the social world by appreciating that the distinction between individual and world is an organisational, not ontological distinction. Our sense of being a distinct someone is something that is achieved together with others, not just qua being a biological body.

The basic idea of the socially enacted self is therefore not to overcome the tension entailed in the body-social dichotomy but rather to welcome and recognise it as a necessary property of mind itself and to thus integrate this tension into a general theory of understanding. On this view, the individual mind has to continuously negotiate its identity as an individual agent and its understanding in dependence on other subjects. As a consequence, uncertainty, conflict, and a permanent need for negotiation and co-negotiation are part and parcel of being an essentially social human mind. This is why it might be useful to distinguish several senses of fragility. Fragile understanding is one of them. But on the enactive account of selfhood, mind itself is fragile.

4 Varieties of co-presence

Let us now explore a couple of implications that a deep dynamics view has for conceptual understanding. By basing conceptual understanding on an understanding of the individual as a socially enacted autonomous system, we can do justice to existential phenomenologists who emphasize the importance of situatedness and flow and also to Noë's rightful actionist call for emancipation of the passive individual mind. For Noë, the unity of conceptual modes is derived from positing an active, thinking, sensorimotor body. The present proposal suggests that the unity is grounded in a socially co-organized individual. Noë's idea of thinking of experiencing and understanding the world as a "relation between a skillful person and really existing thing" (2012, p. 42), could thus be elaborated by saying that the intentional relation is also a relation to other subjects, so that intentionality is actually co-generated. Yet this co-generated intentionality is not merely about sharing a perspective on the world; it is a co-generated rela-

tion that feeds into the very organisational structure of mind itself. The person involved in the intentional relation is a social subject. In accordance with the two-fold structure of socially enacted autonomy, this would also mean that self-reflexivity has a social structure, entailing a sense of being a self as separate individual and a sense of being open and connected to the world.

Here lies the deeper reason for why the process of understanding is fragile. The fragility of understanding consists precisely in the fact that the unity of mind is never a given, but is itself an on-going achievement. Since, as I suggest, this is an achievement with others, presence does not merely depend on what we do, but also on what others do, and especially on what we do with them. In other words, presence is actually *co-presence*. It is clearly outside the scope of this commentary to explicate this in more detail, but generally speaking it means that understanding simply never really is the endeavour of an individual mind. This complements Noë's perspective and invites future explorations in at least two fundamental senses.

First, with regards to the role of others in empowering the individual by enabling access to the world: our conceptual skills are acquired and the acquisition of these skills usually happens in interaction and by learning together with others. But our ways of understanding are also *continuously* shaped and mediated by being with others, be it through cultural norms, biases, advice, or advertisement. Apart from the obvious fact that much of instantaneous understanding happens together with others, even in the absence of others, in the process of understanding, we often presuppose another subject or at least some implicit act of relationality. Noë says that "there is no such thing as a perceptual encounter with the object that is not also an encounter with it from one or another point of view" (2012, p. 138). I could not agree more, and yet I suggest we also embrace the idea that these other viewpoints are not merely defined in terms of changes in head or body-movement but also in terms of loops to and from different subjective and intersubjective view points.

If conceptual understanding has the purpose of bringing us into contact with the world, as Noë claims, then we should not underestimate the role of others and of our being open to them in making this contact possible. To consider human understanding as fragile is also to admit a limitation of the individual's capacities and to allow others and our dialogues with them to play a fundamental role. In this sense fragility can be a source of power. Our minds are open, not only to the world, but also to contributions from others.

But that said, and this is the second and final implication of the enactive self for the basic nature of human understanding, the social nature and fragility of mind also restricts the individual's capacities. When the social plays a marginal and contextual role, the individual's responsibility in understanding the world is immense and the optimism in the individual's capacities can become a heavy burden. The other side of fragility is that the presence of the world is not only "not for free", as Noë puts it, but it is actually sometimes not available at all. It is not available because other subjects have a say in the construction of our understanding, and given that they have perspectives and interests of their own, their contribution may sometimes be out of reach, run contrary to what we need, or even confuse us deeply. The fragile nature of our social mind can therefore also deny us access to the world.

5 Conclusion

In his book *Varieties of Presence*, Noë refers to Kafka's *The Metamorphosis* (1915), the story of Gregor Samsa, who wakes up as an insect, lying on his back, unable to move. Noë uses the story to illustrate the upshot of his philosophy of understanding. "We are not only animals", he says, but we "achieve the world by enacting ourselves. Insofar as we achieve access to the world, we also achieve *ourselves*" (Noë 2012, p. 28).

On the presented alternative, the actionist nature of self-achieved understanding is only half of the story. I have suggested that our minds and selves are genuinely social and thus transcend the limits of our bodily existence. The human self vitally depends on others and is

achieved together with them, through negotiating a permanent tension of maintaining a sense of individuality while not losing the connection to others (distinction and participation).

From this perspective, the point of Kafka's story is therefore not so much to deny that we are animals, but rather to claim that we are *social* animals that achieve ourselves *together* with others. Reflecting the basic insight of this paper, the story thus illustrates the fragility and social nature of human existence. It is an expression of desperation and of the suffering that can come when others refuse or are unable to comply with our basic needs: being recognised as individual and as someone who belongs to others. Having lost contact with himself as a human subject in the bureaucratic machinery of his professional life, Samsa awakes as an insect, his new embodiment an imprint of alienation and loss of recognition. But the loss cuts even deeper. With his alien embodiment Samsa the insect is rejected by his family, so that he finds no salvation in his private life. Samsa dies from social isolation. From an enactive view of the self as a joint achievement, Kafka's *The Metamorphosis* captures (like much of his other work) the consequences of our deep vulnerability and limited freedom and the drama of the loss from which we can suffer precisely because we are social beings.

The social structures that we depend upon empower our ways of understanding; yet for the same reason they can also enslave us, and seriously limit our mental capacities. This, I suggest, is not merely the case for institutions and their bureaucratic apparatus but also applies to our direct intersubjective relations, be they with lovers, friends, family, or co-workers.

Presence is therefore not simply availability—since this would suggest the subject's unwarranted access to the world. Presence is rather a joint achievement, and the nature of doing things together is that there will always be leaps and limitations. In this way, failure and limited control over the ways we understand the world are not entirely the responsibility of the individual and its techniques and skills, but also a deeper expression of the genuinely social and co-constructed nature of understanding.

Beyond Agency

A Reply to Miriam Kyselo

Alva Noë

In this paper I respond to [Kyselo's \(this collection\)](#) claim that actionism, and other versions of the enactive embodied approach to mind, fail to accord social relations a constitutive role in making up the human mind. I argue that actionism can meet this challenge—the view makes relations to others central to an account of human experience—but I also question whether the challenge is clear enough. I ask: what exactly does it mean to say that social relations play this sort of constitutive role?

1 Introduction

In my contribution to this volume ([Noë this collection](#)), I seek to bring out the truth in intellectualism. The intellectualist is right, I concede, that understanding is at work throughout the domain of agency—wherever we can talk of perception, or thinking, or action. Understanding is pervasive. The trouble with intellectualism, I argue, is that it cleaves to an unrealistic conception of what is demanded for understanding to come into play. In particular, it adheres to an over-intellectualized conception of understanding, according to which an action, or a perception, can be conceptual only if it is guided, as it were from above, by explicit acts

of judgment. In my target paper I also criticize *anti*-intellectualist views, such as that of Dreyfus, for failing to break with intellectualism; such views reject the pervasiveness of the understanding because they accept the intellectualist's hyper-intellectualized conception of what understanding is and because they find it implausible that our experiential or cognitive lives are intellectual in this way. In this brief reply to Kyselo's excellent commentary, I would like to say something about what the anti-intellectualism of the sort I criticize in the paper *gets right*. I now want to try to bring out the insight in anti-intellectualism.

2 The truth in anti-intellectualism

If the intellectualist is right that understanding saturates the space of agency, the anti-intellectualist is right that there is also understanding *beyond* the limits of our agency. Stanley (2011, cited in Noë [this collection](#)) relied on the opposition between the personal and the subpersonal; he supposed that what makes a mere reflex, which is subpersonal, an action, which is personal, is that it is guided by knowledge or reason. But the opposition between reflex and action is not exhaustive, and the crucial dimension is not that of the contrast between the personal and the subpersonal. Consider conversation, as an example. We can characterize conversation as a personal-level action. But there is a way of describing the phenomenon that defies such characterization. When two people talk they adopt similar postures, they pause at coordinated intervals, they adjust their volumes to match each other, they move their eyes and modify their dialects, all in ways that are governed by their interaction (see Shockley et al. 2009 for a review of this literature). Talking is what I elsewhere call an “organized activity” (Noë [in press](#)). One remarkable feature of organized activities, in this sense, is that they are not guided by the participants or authored by them. Another is that they are carried on spontaneously and without deliberate control. And yet another is that they are clearly domains in which highly sophisticated cognitive capacities—looking, listening, paying attention, moving, undergoing—are put to work.

Notice: I said above that talking, in the sense I have in mind, is not a personal-level activity. What I mean by this is that the sort of tight coupling and temporal dynamics, the sort of organization we see at work when people talk, is not best characterized at the level of minutes, hours, choices, etc. that normally characterize the personal level. But nor is this a phenomenon of the subpersonal level. For one thing, we aren’t interested in something happening in the nervous system of *one* individual. We are interested in something encompassing two (or more) people. For another, we aren’t interested in processes unfolding at time-scales of

milliseconds. No. We *are* interested in what people do, but in a manner that is truly *beyond* agency. We are interested, here, in a phenomenon of the *embodiment level* (as distinct from the subpersonal or the personal level).

And yet we remain, when thinking about conversation—or any other organized activity—very much in a domain where we can and must speak of cognitive achievement, understanding, skill, and so on.

One upshot of these considerations, then, is that while understanding, as I argued above, is a necessary condition of agency, it is also present beyond its limits. Another is that understanding beyond the limits of agency cannot be understood individualistically. This is obvious in the case of intrinsically social activities, like conversation, but it is also true for organized activities that can be carried out by solitary individuals (such as *seeing*, for example).

The thing that anti-intellectualism gets right, as I see it, is the appreciation that a great deal of what we *do*, isn’t really done *by us*: activity happens to us; we find ourselves organized. We are made what we are in the setting of organized activities.

From the standpoint of the theory of organized activities—presented in more detail in Noë ([in press](#))—we are creatures who are from the very beginning caught up in world and other-involving organized activities; these activities form the lived substrate of our biographical lives as persons. Actionism, in these ways, is committed to a radical form of anti-individualism.

3 The challenge of crypto-individualism

Now, Kyselo has criticized actionism not for ignoring the social, but for failing to treat the social as constitutive of human cognitive organization. Kyselo’s point is that for actionism, other people and our relations to them “shape” the mind, but they do so in the same the way that any environmental conditions cause, constrain, or enable human experience; the view makes no allowance for the stronger possibility that other people and our social relations with them are actually *constitutive* of what it is to be a human

being. So she writes, with actionism as one of her targets in mind:

Philosophers of cognition systematically assume that the mind is essentially embodied, while the social world remains the context in which the embodied mind is embedded. On this view, the social arguably shapes the mind, but it does not figure in the constitution of the mind itself. (Kyselo [this collection](#), p. 2)

And she goes on to explain:

I argue that since the world of humans is a social world of others and our social relations is what matters most to us, the social must also figure in the constitutive structure of human cognitive individuation. The human mind or self is not only embodied but also genuinely social. (*ibid.*, p. 2)

In a footnote, she then elaborates:

By saying that sociality matters constitutively for the human self, I mean that without continuously relating and engaging in interaction with others, there would be no human self as a whole. The social is not only causally relevant for enacting self-hood, but it is also an essential component of its minimal organizational structure. (*ibid.*, p. 2)

Now, I admit that the language of earlier work (Noë 2004, 2012) can be taken to suggest something like crypto-individualism. In so far as I talk about presence as something that thinkers and perceivers “achieve,” and in so far as I insist that, in achieving the world’s presence in thought and experience, we also achieve ourselves, it can perhaps sound like I am describing the enactive feats of a heroic solitary agency.

I admit that’s how it sounds. But I was careful to warn against being misled in this way. So, for example, in a passage immediately following one that Kyselo cites, I write:

But we are not only animals. I am also a father, and a teacher, and a philosopher, and a writer. These modalities of my being were no more given to me than my ability to read and write. I achieve myself. Not on my own, to be sure! And not in a heroic way. Maybe it would better to say that my parents and my friends and family and children and colleagues have achieved me for me. The point is that we are cultivated ourselves—learning to talk and read and dance and dress and play guitar and do mathematics and physics and philosophy—and in this cultivation worlds open up that would otherwise be closed off. In this way we achieve for ourselves new ways of being present.

Here I explicitly repudiate heroic individualism; we achieve ourselves with and through others; we are cultivated by a world full of others and that’s the setting in which we bring the world into focus for consciousness.

Perhaps another feature that feeds the appearance of crypto-individualism is the availability of an idealist or anti-realist reading of enacting or achieving presence. It is not in fact my view—Kyselo herself is clear about this—that we make the world, or construct it. The world shows up for us, in perception, and in thought, and for action. But it doesn’t show up for free. Just as you can’t encounter what a text means if you don’t know how to read, so you can’t see what is there to be seen without the battery of understandings necessary for reaching out and picking it up.

We don’t make the world, just as we don’t make other people. In fact, the world, and others, are necessary for us to achieve contact with it *in three distinct ways*. First, our experience of others and the world depends on their existence. If they weren’t there, we couldn’t achieve access to them. Second, our possession and exercise of the relevant skills may require the presence and participation of others. Think of the turn-taking dance that is conversation; you can’t do that without the other. Third, our possession of perceptual and cognitive skills of access de-

depends on our development in the setting of personal relationships.

Does the commitment of actionism to these three kinds of dependence of our experience on our engagement with others meet the standard of offering an account of other people as not merely shaping but as constituting our mental lives? If not, I hope to be told why.

Let me offer a final example to try to clarify what is at stake. Take a baseball team. There will be nine players on the field at a given time during a game: a pitcher and catcher, three basemen, a shortstop, and the three outfielders. Notice that there are two different ways in which we can individuate these players. We can pick them out by the role that they play—by their position, in baseball parlance—or we can pick them out by *the player*, that is, by the particular person who is playing the role. Take the shortstop, for example. The shortstop is the near outfielder, or the far infielder; he is positioned between 2nd and 3rd bases. His job is to field balls hit to him and to deliver the balls to teammates in ways that work to his team's advantage. For our purposes it is important to notice that a shortstop is a social creature in the sense that a) to be a shortstop is to play a role that can only be specified by naming other positions and shared goals and needs, and b) that there is no such thing as a shortstop outside of the context of convention, practice, and history—for that is what baseball is: a structure in a temporally extended space of convention and practice. A shortstop, we might say, is a thoroughly social kind of thing. It is constituted by social relations.

Notice that this way of thinking about what it is to be a shortstop takes nothing away from the fact that shortstops are embodied and that they are in continuous dynamic exchange with their physical environment. The quality of a shortstop is usually framed in terms of the range of ground he can cover, the softness of his hands, the strength of his arm, the delicacy and control of his footwork, and finally, his understanding of what to do in the split-second heat of play. Physical and intellectual skill are all properties of this essentially social being, the

shortstop. And this is so for all the other players.

Now, the fact that being a shortstop is something “whose identity is brought forth through body-mediated social interaction”, as we could say, borrowing Kyselo's words ([this collection](#), p. 2), doesn't entail that the flesh-and-blood human being who is playing shortstop is also in the same way identity-dependent on his or her social relations. The individual existence of the man, after all, the actual guy, the living human organism, is presupposed by his entering into the kinds of relationships that can make it the case that he is also a shortstop.

This sort of consideration can be generalized: just as we can distinguish the player from the position he plays, so we can distinguish the *human being* from the *person* he or she also is. Personhood is enacted, achieved, or performed in ways not so different from the way being a baseball-player is undertaken. A person is defined by nesting and overlapping roles—daughter, employer, citizen, rebel, lover, failure, and so on. And these roles are genuinely constitutive of who or what a person is, of his or her identity. Truly these constitutive features that make a person the person she is are robustly and thoroughly social, in all the ways being a shortstop is social. You can't be a person on your own, any more than you can be a shortstop on your own. Persons are creatures of normative, evaluative spaces. Persons are performers. They perform their personhood. And they bear the ever-present burden of being evaluated. That, finally, is the difference between mere action and performance. Performance, as distinct from mere action, happens against the background of the possibility of being judged (good dancer, good father, good lover, good student, etc.).

Personhood is enacted. But what about being human? Is that enacted as well? Is one's status as a human being, like one's status as a person, or a shortstop, something that is accomplished through one's body-mediated social interactions?

This much is clear. Being a distinct human being is antecedent to entering into the kinds of

relationships that constitute one's being a person, or a shortstop. So it can't be that it is the same kinds of relations with others that constitute one's personal identity (in my sense) that constitute one's organismic identity as a human being. My question for Kyselo, then, would be: why should we say that human beings, above and beyond the persons they enact, are, in the relevant sense, constitutively social? Or better still, the question is: what is the relevant sense of "constitutively social"?

Let me be clear that I think it would be a mistake to hold that personhood, bound up with practice, convention, and history, though it is, is *merely* cultural, and that this cultural structure is stamped or imposed onto a pre-given biological substrate (the human being). No, each of us is both a human being and a person and any comprehension of our nature needs to do justice to both of these. A biological theory of *us* will be a theory of creatures who are both persons as well as organisms and will take seriously the way these loop back and down and the way they interact.

4 Conclusion

There is much in Kyselo's excellent response to which I have said nothing in reply. I am struck, in particular, by her powerful handling of the concept of fragility. I have tried, in this reply, to show that actionism, despite appearances of heroic individualism to the contrary, recognizes that people spend their lives in worlds that are always ineliminably social.

How Does Mind Matter?

Solving the Content Causation Problem

Gerard O'Brien

The primary purpose of this paper is to develop a solution to one version of the problem of mental causation. The version under examination is the content causation problem: that of explaining how the specifically representational properties of mental phenomena can be causally efficacious of behaviour. I contend that the apparent insolubility of the content causation problem is a legacy of the dyadic conception of representation, which has conditioned philosophical intuitions, but provides little guidance about the relational character of mental content. I argue that a triadic conception of representation yields a more illuminating account of mental content and, in so doing, reveals a candidate solution to the content causation problem. This solution requires the rehabilitation of an approach to mental content determination that is unpopular in contemporary philosophy. But this approach, I conclude, seems mandatory if we are to explain why mental content matters.

1 Introduction: The content causation problem

Philosophy delights in those aspects of the world that initially seem obvious and natural, but which on reflection turn out to be deeply mysterious. The mental causation of behaviour is one such phenomenon. Nothing could be more obvious than that our minds matter—that our beliefs and desires, and our perceptions and thoughts ultimately have a causal impact on our behaviour. And yet it has proved notoriously difficult to explain just how this could be the case.

The problem of mental causation has morphed and fragmented over the years. In its

original guise, it was the problem of how a non-physical mental substance or property could causally interact with the physical brain. The obvious solution to this version of the problem was to adopt a thorough-going materialism of some kind, with the consequence that mental phenomena are identified with properties of the brain from which they inherit their causal efficacy.

With the advent of functionalism in the later years of the last century, this “obvious” solution ran into difficulties. If mental phenomena are multiply-realizable, as the orthodox

construal of this metaphysical position seems to imply, then mental properties can't be identified with properties of the brain after all; and since the latter do all the causal work insofar as behaviour is concerned, the problem of mental causation re-asserts itself in a different form (Kim 1992; Crane 1995). This version of the problem of mental causation, which seems to generalise beyond the realm of the mental to all multiply-realizable phenomena, is still keenly debated in philosophy (Kim 2000, 2005; Hohwy 2008).

There is yet another rendering of the problem, however, that revolves around the causal efficacy of the specifically *representational* properties of mental phenomena. This third version typically arises in the philosophy of mind from the conjunction of three widely accepted theses about mental phenomena and their physical realization in the brain:

The content causation problem

1. Mental phenomena are causally efficacious of behaviour in virtue of their representational contents.
2. The representational contents of mental phenomena are not determined by the intrinsic properties of the brain.
3. The brain is causally efficacious of behaviour in virtue of its intrinsic properties.

The first of these theses is a fundamental tenet of both folk psychology and the computational theory of mind that has been constructed on its foundations. It is simply common sense that our perceptions and thoughts are about various aspects of the world in which we are embedded. It is also commonsense that mental phenomena causally interact with other mental phenomena and bodily behaviour in a fashion determined by their *content*—i.e., how they represent the world as being. Fodor refers to this as the “parallelism between content and causal relations” (1987).

The second thesis is widely accepted because most contemporary philosophers think that the representational properties of mental phenomena are determined at least in part by

factors beyond the brain. This is the conclusion drawn from a number of famous thought experiments implicating twin-earth, arthritis, and various species of tree (Putnam 1975; Burge 1979, 1986). But, even more importantly, the second thesis seems to be an entailment of the most popular approach among philosophers for explaining how the representational properties of mental phenomena are determined. This is the conjecture that mental phenomena are contentful in virtue of their causal relations with those aspects of the world they are about (Adams & Aizawa 2010).

The final thesis is consistent with all we know about the brain basis of behavioural causation. While the brain enters into complex causal relations with aspects of the environment via multifarious sensory channels, our best neuroscience informs us that the changes to musculature that constitute our behavioural responses are wholly determined by the intrinsic properties of the brain to which they are causally connected.

In conjunction, these three widely accepted theses form an inconsistent triad. This generates a distinct and narrower version of the problem of mental causation: How can mental phenomena be causally efficacious of behaviour in virtue of their representational contents if these contents are not determined by intrinsic properties of the brain? In what follows, I shall refer to this as the *content causation problem*. This is the version of the problem of mental causation with which I shall be concerned in this paper (see e.g., Kim 2006, pp. 200–202).

There are some philosophers who seek to resolve the content causation problem by rejecting either the first¹ or the third² of the theses composing the inconsistent triad. However, the most popular response has been to reject or at

1 This, for example, is one way of construing Dennett's instrumentalism (1978, 1987).

2 There has been a some discussion in the literature about whether the *relational* properties of brain states are implicated in the causation of behaviour. The standard way of defending this claim is by individuating behaviour *broadly*, so as to incorporate factors beyond bodily movements (Burge 1986; Wilson 1994). But many philosophers think this form of individuation does great violence to scientific practice in general and to neuroscience in particular, and hence this way of resolving the problem of content causation is thought to seem very unpromising (Fodor 1987).

least modify the second thesis. This leads to the the *narrow content program*:

The project of developing an account of mental phenomena according to which (at least the causally relevant component of) their representational properties are determined by intrinsic properties of the brain.

There are a number of different proposals about narrow content in the literature. Two of these have been particularly prominent. One is Fodor's suggestion that narrow contents can be unpacked as "functions from contexts to truth conditions" (1987, Ch. 2). The other is that narrow content is determined by "short-armed functional roles" (Block 1986; Loar 1981, 1982). But these (and other) proposals have been roundly criticised for failing to capture the *relational* character of mental content:

The main charge has been that narrow content, as construed in these accounts, is not real content. When one thinks of an apple, what one thinks about is not a role or a function, but a fruit. Real content must put the subject in cognitive contact with the external world. [...] A water concept, for example, must involve a relation between the thought wherein the concept is deployed and some worldly property or kind, presumably having to do with water. The problem with narrow content, construed as short-armed functional role or as a function from contexts to wide contents, is that it is not clear how it could involve any such relation. (Kriegel 2008, p. 308)

At this point, however, we seem to butt up against a classic paradox. On the one hand, those theories that appear to capture the relational character of mental content (i.e., causal theories) hold that content is not wholly determined by the intrinsic properties of the brain and, hence, imply that it isn't causally efficacious of behaviour. On the other hand, theories with the potential to account for the causal ef-

ficacy of mental content (i.e., narrow content theories), fail to capture its relational character. A solution to the content causation problem thus requires something that *prima facie* appears impossible: an explanation of the *relational* character of mental content that invokes only the *intrinsic* properties of the brain. Little wonder then that many philosophers despair of ever finding a solution to this puzzle.³

It is reasonable to hazard, however, that one of the main barriers standing in the way of a more productive treatment of the content causation problem is the radically underdeveloped understanding of mental content with which contemporary philosophy operates. In the foregoing quotation, for example, Kriegel characterises the relational character of content in terms of a subject's "cognitive contact" with the external world; yet he readily admits elsewhere that this notion is "not altogether transparent" (Kriegel 2008, p. 305). This is typical of the literature on this topic, which has become accustomed to describing content using the notoriously vague language of *aboutness*. While this language might capture our commonsense intuitions about mental phenomena, its imprecision may prevent us from discerning the lineaments of candidate solutions to the content causation problem.

This last point, at least, gives us the motivation for intruding yet another discussion into this already crowded philosophical space. The foundational conjecture upon which this paper is based is that the apparent insolubility of the content causation problem issues from an impoverished and unenlightening account of the relational character of mental content. Furthermore, this impoverishment is largely a con-

³ Perhaps the best we can do, according to some of these, is to accept that the representational properties of mental phenomena are causally inert, but to argue that there is enough room between explanation and causation for representational properties to be *explanatorily relevant*—despite their inertness (Baker 1993; Block 1989; Fodor 1986, 1989; Heil & Mele 1991; Jackson & Pettit 1990a, 1990b; LePore & Loewer 1989). A more radical response is to opt out of representation-based explanation altogether, as advocated originally by eliminativists (Churchland 1981; Stich 1983), and more recently by anti-representationalists (Brooks 1991). Finally, note that another radical position currently fashionable in philosophy—the extended-mind hypothesis (Menary 2010)—doesn't represent a solution to the content causation problem, since it signally fails to align mental phenomena with the brain-based causation of behaviour.

sequence of the *dyadic* conception of mental representation that has hitherto conditioned most philosophical thinking in this area. By contrast, a minority of philosophers has argued that mental representation is more properly analysed as a *triadic* relation. Triadicity, I will argue, yields a richer and ultimately more illuminating account of the relational character of mental content. Armed with this alternative treatment, we are in a position to assess the content causation problem anew. On the one hand, this novel viewpoint confirms the worry philosophers have expressed that causal theories of mental content are impossible to reconcile with the brain-based causation of behaviour. On the other hand, and much more positively, the triadic conception reveals a path that, from the perspective of content causation at least, looks more promising. The proposal that we travel down this path will undoubtedly face resistance, since it requires us to rehabilitate an approach to mental content that is unpopular in contemporary philosophy. But this approach, I shall conclude, seems unavoidable if we are to explain how mind matters.

2 The triadicity of representation

The bulk of philosophical writing on representation in general and mental representation in particular assumes, either explicitly or implicitly, that representation is a dyadic relation between something that does the *representing* and something that is *represented*. The task for a theory of representation, from this perspective, is to explain the necessary and sufficient conditions under which this dyadic relation obtains (see e.g., Stich 1992). But such a dyadic conception provides very little guidance about the relational character of representational content. All we have to work with is a mysterious action-at-a-distance phenomenon, whereby one part of the world, in virtue of the obtaining of a certain relation, is about another part.

To fill this gap, philosophers have almost invariably modelled their understanding of content on the semantic properties of the elements that compose our natural languages. Given the towering influence of Tarskian truth-conditional

semantics in this field, it is inevitable that the relational character of representational content is usually characterised in terms of *reference* (Kriegel 2008, p. 305). But such an approach, while perhaps appropriate for linguaform representation, sits awkwardly with all manner of the non-linguistic forms of representation with which we are familiar (Haugeland 1991; Fodor 2007; Cummins & Roth 2012). Moreover, it is not obvious we are more enlightened by replacing talk of aboutness with that of reference.

In this context, it is worth observing that over the years a minority of philosophers has expressed dissatisfaction with the dyadic conception of representation. The most salient complaint is that such an approach fails to take into consideration the role that “users” of representation play. The general thought here is that some parts of the world don’t represent other parts solely in virtue of some relationship between them; that the former represent the latter only when they are employed by some system to perform this representational function. According to Dennett, for example, physical entities “are by themselves quite inert as information bearers. [...] They become information-bearers only when given roles in larger systems” (1982, p. 217). Likewise, Millikan has long observed that a biological approach to representation forces one to consider not just the “production” of representations, but also their “consumption” (1984). And, in a similar vein, Bechtel argues that that since whether something acts as a representation is ultimately determined by its function for some user, it follows that there are “three interrelated components in a representation story: what is represented, the representation, and the user of the representation” (1998, p. 299).

This *triadic* conception of representation is not new, of course, since it forms the basis of Charles Sanders Peirce’s theory of semiotics, which was developed in the latter part of the 19th century (Hardwick 1977). Indeed, Peirce’s (sometimes obscure) writings embody one of the most comprehensive analyses of representation in all of philosophical literature. Peirce approached this issue principally by investigating those public forms of representation with which

we are all familiar—words, sentences, paintings, photographs, sculptures, maps, and so forth—but he also sought to apply his triadic analysis to the special case of mental representation. This suggests that Peirce’s writings might be an appropriate point of departure for exploring what the triadic conception entails about the relational character of representational content.

This strategy is very effectively adopted by von Eckardt when, following Peirce’s lead, she analyses representation as a triadic relation involving a “representing vehicle, a represented object, and an interpretation” (von Eckardt 1993, pp. 145-149).⁴ As with dyadic stories, the representing vehicle is the physical object (e.g., a spoken or written word, painting, map, sculpture, etc.) that is about something, and the represented object is the object, property, event, relation, or state of affairs that the vehicle is about. It is the addition of the interpretative relatum that sets the triadic account apart:

A sign [i.e., a representing vehicle] [...] is something which stands to somebody for something in some respect or capacity. It addresses somebody, that is, creates in the mind of that person an equivalent sign, or perhaps a more developed sign. That sign which is created I call the *interpretant* of the first sign. (von Eckardt 1993, p. 145)

Interpretation is thus understood as a cognitive effect in the subject for whom the vehicle operates as a representation. But as von Eckardt observes, not any kind of effect will do. This cognitive effect, presumably implicating the production of *mental* representing vehicles, must bring the subject into some appropriate relationship to the original vehicle’s represented object (von Eckardt 1993, p. 157). Given this constraint, it is natural to interpret this third relatum in terms of the subject’s *thinking* about the object in question. So (non-mental) representation, on the triadic story, is a *functional* kind: it is a process whereby a representing

vehicle triggers a thought (or thoughts) in a subject about a represented object.

There are a couple of significant consequences of the triadicity of representation. The first is that, contrary to a dyadic story, representing vehicles aren’t about anything independent of interpretations. Words, sentences, paintings, photographs, sculptures, maps, and so forth, considered in isolation from the cognitive impact they have on us, don’t represent. This, of course, does some violence to the way that we talk about public representing vehicles—but it is far from catastrophic. The relevant revision is to think of these physical entities as possessing the *capacity* to trigger the necessary cognitive effects in us. The second (and, for our purposes, more important) consequence is that, unlike dyadic accounts in which content is unpacked solely in terms of relations between vehicles and represented objects, the triadic story entails that content is also conditioned by the interpretative relatum. This imposes an additional explanatory requirement on theories of content determination. It is not enough to merely explain how relations between vehicles and objects make it the case that the former are about the latter. These theories must also explain how it is in virtue of these relations that representing vehicles are capable of triggering thoughts in subjects about represented objects.

Once it has been suitably modified for the special, and presumably foundational, case of *mental* representation, the additional explanatory requirement that triadicity imposes on theories of content determination can form the basis of a richer account of the relational character of mental content. Such modification is necessary, of course, because treating the interpretation of mental vehicles solely in terms of a subject thinking about a represented object violates the *naturalism constraint*. This is the requirement that we explain mental representation without recourse to the antecedently representational (see e.g., Cummins 1989, pp. 127–129; Cummins 1996, pp. 3–4; Dretske 1981, p. xi; Fodor 1987, pp. 97–98; Millikan 1984, p. 87; von Eckardt 1993, pp. 234–239).

The relevant modification is fairly obvious, however, and represents a well-trodden path in

⁴ Von Eckardt actually uses the terms “representation bearer”, “representational object”, and “interpretant” to describe the three relata implicated in representation. I prefer the terminology I have used here because it is more consistent with the philosophical literature on mental representation.

philosophy. From the perspective of Peirce's triadic analysis, the role of interpretation is to forge a psychologically efficacious connection between the user of a representing vehicle and the vehicle's object. With public forms of representation it is perfectly acceptable to unpack this in terms of the (non-mental) vehicle activating thoughts directed at the object. But if we allow this story to run a little further it will point us in the right direction for the interpretation of mental vehicles too. Thoughts directed at objects modify our behavioural dispositions towards these same objects. This is why public forms of representation are so useful—they enable us to regulate our behaviour towards selective aspects of the world. But this story can be transported into the brain in order to account for the interpretation of mental representing vehicles. Instead of external vehicles triggering thoughts, and these in turn modifying behavioural dispositions, we simply suppose that mental vehicles have the same cognitive and ultimately behavioural effects. This acts to block the threatened regress since, presumably, it is possible to unpack behavioural dispositions without invoking further mental representation.

We are now in a position to deliver on one of the aims enumerated in the introductory section: that of fashioning a more illuminating account of the relational character of mental content. We saw earlier that Kriegel describes this character in terms of the “cognitive contact” between mental phenomena and the worldly aspects they represent, but admits that this notion isn't particularly transparent. Happily, the triadic analysis of mental representation affords a means of explicating what this cognitive contact consists in. Rather than simply employing the vague language of aboutness, the triadic analysis encourages us to understand the relational character of mental content in terms of the capacity of mental phenomena to regulate the behaviour of subjects towards specific aspects of the world. Cognitive contact is thus a relatively straightforward causal capacity. It is the capacity of cognitive creatures, bestowed by their internal states, to respond selectively to elements of the environment in which they are embedded.

This is where things currently stand. A solution to the content causation problem requires something that *prima facie* appears impossible—namely, an explanation of the relational character of mental content that invokes only the intrinsic properties of the brain. But the paradoxical appearance of content causation, I have suggested, might be a legacy of the dyadic conception of representation that has conditioned philosophical intuitions about content determination, but which provides little guidance about the relational character of mental content. The triadic analysis of representation, I have argued, generates a more enlightening account of this relational character—one pitched in terms of the causal capacities of cognitive creatures to regulate their behaviour towards specific aspects of their environments. From the perspective of this analysis, therefore, a solution to the content causation problem requires a theory of content determination to explain how relations between mental vehicles and their represented objects can endow subjects with the capacity to respond selectively to those very features of the world.

Philosophers seeking to fashion theories of mental content determination over the centuries have famously focused on just two kinds of relations between mental vehicles and their represented objects: “causal” relations and “resemblance” relations (Fodor 1984, pp. 232–233). In the following section I shall engage in an all-too-brief appraisal of the prospects of these two world-mind relations to deliver a solution to the content causation problem.

3 World-mind relations and the content causation problem

Causal theories of mental content determination have dominated philosophy for nearly half a century. They hold that representing vehicles are contentful in virtue of being (actually, nomologically, or historically) caused by their represented objects (Devitt & Sterelny 1987; Fodor 1984, 1987, 1990; Stampe 1977, 1986). Perhaps the most well-known causal theory in all of the literature has been developed, through a number of iterations, by Dretske (1981, 1988, 1995).

What makes Dretske's account particularly apposite in the current context is that it has been fashioned, at least in its later iterations, to address explicitly the account of content intruded by the triadic analysis of mental representation (though Dretske doesn't use this terminology). At one point in his discussion, for example, Dretske states that he approves of Armstrong's (1973) description of beliefs as "maps by which we steer", and goes on to observe that "beliefs are representational structures that acquire their meaning, their maplike quality, by actually *using* the information it is their function to carry in steering the system of which they are part" (Dretske 1988, p. 81). This, for Dretske, motivates the very desideratum we extracted from the triadic analysis in the last section:

It will not be enough merely to have a C [inner state of some cognitive system] that indicates F [i.e., causally covaries with some external condition] cause M [some observable behaviour]. What needs to be done [...] is to show how the existence of one relationship, the relationship underlying C's semantic character, can explain the existence of another relationship, the causal relationship (between C and M) comprising the behaviour in question. (1988, p. 84)

Dretske's response to this problem, famously, is to appeal to teleology. It is only when an inner state, which causally covaries with some bit of the external environment, is "recruited" by the cognitive system (either by an evolutionary design process or through individual development) to cause appropriate behaviour, that the state acquires the *function* of indicating that part of the environment, and thereby comes to *represent* it (Dretske 1988, pp. 84–89).

On the face of it, Dretske's theory seems to represent a promising solution to the content causation problem. From the perspective of the triadic analysis, a solution to this problem requires an explanation of how certain relations between mental vehicles and their objects can dispose cognitive subjects to behave selectively towards those represented objects. Dretske's el-

egant proposal is that reliable causal relations between inner states and environmental conditions (i.e., when the latter reliably cause the former to be tokened) can endow cognitive systems with these dispositions when the former states are conscripted by design processes to cause behaviour that is in some way relevant to the latter conditions. When this happens, the inner states are elevated to the status of representing vehicles, and their subsequent activity in bringing about behaviour directed towards their represented objects are examples of content causation.

Unfortunately, a closer inspection of Dretske's suggestion reveals a fundamental flaw. Contrary to what he contends, the relations at the core of his proposal are powerless to explain the required behavioural dispositions. Rather than describing this problem in the abstract, let me illustrate it using one of Dretske's favourite examples of a very simple representation-using system:

A drop in room temperature causes a bi-metallic strip in [a thermostat] to bend. Depending on the position of an adjustable contact, the bending strip eventually closes an electrical circuit. Current flows to the furnace and ignition occurs. The thermostat's behaviour, its turning the furnace on, is the bringing about of furnace ignition by events occurring in the thermostat—in this case [...] the closure of a switch by the movement of a temperature-sensitive strip [...].

The bi-metallic string is given a job to do, made part of an electrical switch for the furnace, because of what it indicates about room temperature. Since this is so, it thereby acquires the function of indicating what the temperature is [...]. We can speak of [...] representation here. (Dretske 1988, pp. 86–87)

There is a subtle sleight of hand at work here, however. It is Dretske's contention that the bi-metallic strip is recruited (by the manufacturer) to play a causal role in the thermostat because

of what it indicates about ambient temperature. But that's not the full story. Bi-metallic strips have an *additional* property that appeals to the manufacturers of thermostats: their degree of curvature corresponds in an orderly fashion with ambient air temperature, such that it can be configured to complete a circuit when the temperature drops to a pre-set level.

In Dretske's thermostat example, therefore, there are two distinct relations between representing vehicles and represented objects: a systematic correspondence relation (wherein variations in ambient air temperature are mirrored by orderly variations in the bi-metallic strip's shape) and an indication relation (wherein variations in ambient air temperature *cause* variations in the bi-metallic strip).⁵ These two relations are not independent of one another, of course, as the former is mediated by the latter. But we can still consider which of these relations is doing the work, insofar as the capacity for the thermostat to control the behaviour of the furnace is concerned. And here the answer is clear: it is the fact that the curvature of the bi-metallic strip systematically mirrors the temperature, and not the causal covariation per se, that explains its capacity to operate the furnace in an appropriate manner. Consider the counterfactuals: curvature correspondence without causal covariation (e.g., where a mere correlation exists) would still generate the appropriate behaviour, but causal covariation without curvature correspondence (e.g., where the bi-metallic strip heats up but maintains its shape) wouldn't. The important point is that while the causal relation plays an important role in mediating the correspondence relation, it is the latter, not the former, that explains

the thermostat's capacity to bring about the desired behaviour.⁶

So Dretske's own example fails to satisfy the desideratum that he set for himself: the obtaining of a reliable causal connection between ambient air temperature and the bi-metallic strip doesn't explain the thermostat's capacity to control the behaviour of the furnace. Moreover, this example illustrates a fundamental problem with *all* causal theories of mental content determination: there is a fatal disconnect between world-mind causal relations, on the one hand, and the mind's behavioural dispositions on the other. This disconnect exists because any (actual, nomological, or historical) causal relations that might exist between external conditions and inner vehicles do not explain, in their own right, how a cognitive system inherits the capacity of behaving sensitively to the former. Whether cognitive systems have this capacity is determined by the properties of their inner vehicles in concert with their organizational, architectural, and motoric properties. And while external conditions can cause tokenings of and alterations to inner vehicles, the mere obtaining of such causal relations can't explain how the tokened or altered vehicles are capable of interacting with these multifarious systemic properties such that they bestow the appropriate behavioural dispositions.⁷ This is why manufacturers are very choosy about the materials from which they construct thermo-

⁵ Dretske scholars will cry foul at this point, of course. This is because Dretske claims that while indication is mostly founded on causal relations, it need not be. Indeed, he goes as far as to suggest that indication obtains whenever there is a non-coincidental covariation between vehicle and object (Dretske 1988, pp. 56–57). But this characterisation of indication transforms Dretske's proposal into something close to a resemblance theory (the approach to be examined in the next section), since it privileges systematic correspondence relations over causal relations. Consequently, insofar as Dretske's position is to be understood as a causal theory of content determination (as is widely assumed in the literature), it is essential that indication is interpreted as a relation of causal covariation. I adopt this interpretation in what follows.

⁶ One would expect to find causal relations mediating systematic correspondence relations between the representing vehicles of biological systems and aspects of the world. But, as Dretske is well aware, this is not always the case. Nature will make do with what works, and some kind of systematic correspondence in the absence of causal commerce will do just as well. This can be illustrated by another of Dretske's favourite examples: the evolutionary recruitment of magnetosomes in anaerobic bacteria to steer them towards deoxygenated water (1986). According to Dretske, evolutionary forces operating on these bacteria have selected magnetosomes because they are indicators of anaerobic water capable of influencing the direction in which the bacteria swim. But as Millikan has pointed out, the connection between the orientation of magnetosomes and anaerobic water is merely correlational, not causal (2004, Ch. 3). Magnetosomes indicate and steer northern hemisphere anaerobic bacteria in the direction of magnetic north, which results in these bacteria swimming into deeper (and hence deoxygenated) water. But there is no causal connection between magnetic north and deoxygenated water. In this case, therefore, magnetosomes have been selected because their alignment systematically corresponds with the direction of anaerobic water, not in virtue of any causal covariation between them.

⁷ Cummins reaches a similar conclusion, though via a somewhat different route (1996, p. 74).

stats. Engineering a causal covariation relation between ambient air temperature and the innards of a thermostat is easy; engineering these innards such that they possess the requisite causal capacities is a great deal harder.

Ultimately, therefore, Dretske's ingenious attempt to solve the content causation problem doesn't succeed. Dretske holds that the internal states of cognitive systems are elevated to representing roles when they are recruited by design processes to regulate behaviour towards the external conditions they indicate. He takes this to be a case of genuine content causation because he thinks that the causal relations between represented objects and representing vehicles can explain the causal activity in which the vehicles subsequently engage. But Dretske has over-estimated the explanatory power of world–mind causal relations. And he has done so because he has illicitly smuggled into his story a quite distinct form of content determination—one that exploits systematic correspondence relations between representing vehicles and their represented objects. Such systematic correspondences are, of course, a species of resemblance relation. The failure of Dretske's proposal is thus instructive, since it suggests that this alternative world–mind relation offers some prospect of a solution to the content causation problem.

Resemblance theories of content determination hold that representing vehicles are contentful in virtue of resembling their represented objects. The most obvious and straightforward application of this idea can be found in many public forms of representation, from photographs and paintings to sculptures and maps. But what is most significant about this approach for our purposes is that when vehicles resemble their objects, the former actually *replicate* the latter in some way, either by reproducing their properties or their relational organisation (more about which in the next section). And this affords a relatively straightforward way of explaining how a physical device, in virtue of incorporating vehicles that bear resemblance relations to the world, acquires a capacity to behave selectively towards particular elements of the environment. The thermostat's bi-

metallic strip reproduces—in the variations in its degree of curvature—the diachronic pattern of magnitude relations between ambient air temperature. Once this bi-metallic strip is incorporated into the thermostat, therefore, this device has a set of internal vehicles that dynamically replicates the external temperature. It is then simply a matter of rigging the innards of the thermostat so that its operation of the furnace is regulated by these internalised surrogates (Swoyer 1991).

Dretske is correct to judge this an example of content causation. It is a case in which the exploitation of a relation between environmental conditions and inner vehicles explains how the latter are capable of modifying a device's behavioural dispositions towards particular aspects of the world. But what is seldom acknowledged about this much-used example is that it demonstrates the causal efficacy of content fixed by resemblance. Despite this virtue, resemblance theories of mental content determination are unfashionable in contemporary philosophy, largely because they are widely thought to suffer from a number of fatal flaws. Before we end, therefore, it would be wise to engage in a degree of resemblance rehabilitation. This turns out to be easier than one might expect, however, once we adopt the perspective of the triadic conception of representation.

4 Rehabilitating resemblance

Despite the widespread assumption that they are fatally flawed, it's hard to find a sustained discussion of the problems associated with resemblance theories of content determination. Instead, one finds scattered somewhat haphazardly across the literature brief allusions to the same five objections. The canonical rendering of three of these can be found in the opening paragraphs of Nelson Goodman's *Languages of Art*:

The most naive view of representation might perhaps be put somewhat like this: "A represents B if and only if A appreciably resembles B", or "A represents B to the extent that A resembles B". Vestiges of this view, with assorted refinements, per-

sist in most writing on representation. Yet more error could hardly be compressed into so short a formula.

Some of the faults are obvious enough. An object resembles itself to the maximum degree but rarely represents itself; resemblance, unlike representation, is reflexive. Again, unlike representation, resemblance is symmetric: B is as much like A as A is like B, but while a painting may represent the Duke of Wellington, the Duke doesn't represent the painting. Furthermore, in many cases neither one of a pair of very like objects represents the other; none of the automobiles off an assembly line is a picture of any of the rest; and a man is not normally a representation of another man, even his twin brother. Plainly, resemblance in any degree is no sufficient condition for representation. (1969, pp. 3–4)

In short, representation can't be based on resemblance, since the latter is *reflexive* (where the former isn't), *symmetric* (where the former isn't), and *insufficient* (all manner of objects resemble others without representing them). But however influential these three objections might be when applied to a dyadic analysis of representation, they lose all force in the context of a triadic conception. This conception agrees with Goodman that relations between vehicles and their represented objects are insufficient to confer representational status. A representing vehicle must also undergo interpretation, either by triggering thoughts in a cognitive subject or by modifying the subject's behavioural dispositions. And it is this process of interpretation, according to a resemblance theory, that also enforces the non-reflexivity and asymmetry of representation.

A fourth objection is that resemblance theories of mental content are incompatible with our commitment to physicalism:

If mental representations are physical things, and if representation is grounded in [resemblance], then there must be phys-

ical things in the brain that are similar to (i.e., share properties with) the things they represent. This problem could be kept at bay only so long as mind-stuff was conceived as nonphysical. The idea that we could get redness and sphericity in the mind loses its plausibility if this means we have to get it in the brain. (Cummins 1989, p. 31)

But this objection is easily deflected once a proper understanding of the different forms of resemblance is in place. The most straightforward kind of resemblance—the kind that Cummins in the above quotation has in mind, for example—involves the sharing of one or more properties. This relationship can be termed *first-order resemblance*.⁸ It is this kind of resemblance that grounds the content of many public forms of representation, such as paintings, sculptures, and scale models. As Cummins points out, however, first-order resemblance is clearly unsuitable as a ground of mental content, since it is incompatible with what we know about the brain.

There is, nonetheless, a more abstract species of resemblance available. The requirement that representing vehicles share properties with their represented objects can be relaxed in favour of one in which the *relations* among a system of vehicles mirror the *relations* among their objects. This relation-preserving mapping between two systems can be called *second-order resemblance*.⁹ And while it is extremely unlikely

⁸ I am here adapting terminology used by Shepard & Chipman (1970).

⁹ To be more precise, suppose $S_V = (V, \nu)$ is a system comprising a set V of objects, and a set ν of relations defined on the members of V . The objects in V may be conceptual or concrete; the relations in ν may be spatial, causal, structural, or inferential, and so on. For example, V might be a set of features on a map, with various geometric and part-whole relations defined on them. Or V might be set of well formed formulae in first-order logic falling under relations such as identity and consistency. There is a *second-order resemblance* between two systems $S_V = (V, \nu)$ and $S_O = (O, o)$ if, for at least *some* objects in V and *some* relations in ν , there is a one-to-one mapping from V to O and a one-to-one mapping from ν to o such that when a relation in ν holds of objects in V , the corresponding relation in o holds of the corresponding objects in O . In other words, the two systems resemble each other with regard to their abstract relational organisation. As already stressed, resemblance of this kind is independent of first-order resemblance, in the sense that two systems can resemble each other at second-order without sharing properties. Second-order resemblance comes in weaker and stronger forms. As defined it is relatively weak, but if we insist on a mapping that takes

that first-order resemblance is the general ground of mental content (given what we know about the brain), the same does not apply to second-order resemblance. Two systems can share a pattern of relations *without* sharing the physical properties upon which those relations depend. Second-order resemblance is actually a very abstract relationship: essentially nothing about the physical form of a system of representing vehicles is implied by the fact that it resembles a set of represented objects at second-order. Contrary to the fourth objection, therefore, a theory of mental content determination that exploits second-order resemblance is compatible with physicalism.¹⁰

However, this emphasis on second-order resemblance, at least in the eyes of many theorists, takes this approach to content determination out of the frying pan and into the fire. This is because the highly abstract nature of second-order resemblance invites the charge that it entails a massive and intractable indeterminacy of mental content. And it is this fifth objection, perhaps more than any other, that accounts for the current unpopularity of resemblance theories (Sprevak 2011).

The problem here can be illustrated by returning to Dretske's thermostat. The world-mind relation that does all the heavy lifting here constitutes a second-order resemblance: the relations among the representing vehicles (the set of bi-metallic strip curvatures) systematically mirror the relations among the representing objects (the set of ambient air temperatures).¹¹ The worry embodied in the fifth objection, how-

ever, is that this same set of representing vehicles will second-order resemble not just the temperature surrounding the thermostat but any set of objects, regardless of their nature and location, that shares its relational organisation. This fact is entailed by the abstract nature of second-order resemblance. And this is a problem, of course, because it suggests that second-order resemblance is incapable of delivering determinate content. The most we can say about the thermostat's bi-metallic strip is that its curvature represents that potentially large and motley collection of objects with which it systematically corresponds. And this would seem to be a long way from saying it represents the temperature of the ambient air.

Fortunately, the triadic analysis again offers a way to surmount this difficulty. On this account, representations aren't manufactured solely from relations between vehicles and the objects they represent. Rather, the process of interpretation must also be thrown into the mix. We've seen that interpretation is discharged ultimately in terms of modifications to a system's behavioural dispositions. But not any old modifications will do—representing vehicles must modify the system's dispositions towards their represented objects. Consequently, interpretation plays an important content-limiting role. Specifically, a system's behavioural dispositions will anchor its representing vehicles to particular represented domains. Once a domain is secured in this way, second-order resemblance relations determine the content of the individual vehicles. In the case of the thermostat, for example, the behavioural dispositions of the system restrict the represented domain to ambient air temperature, and the second-order resemblance relations determine what temperature each vehicle represents.

¹¹ Notice that in this case, the second-order resemblance is sustained *structural* relations among the set of representing vehicles (i.e., the set of bi-metallic strip curvatures). This is an example of what Palmer (1978) calls *natural isomorphism*, since the second-order resemblance relations are sustained by constraints *inherent* in the vehicles, rather than being imposed *extrinsically*. Elsewhere I have used the term *structural resemblance* to describe this kind of second-order relationship and to distinguish it from *functional resemblance*, where the second-order resemblance relations are sustained by *causal* relations among the vehicles—see O'Brien & Opie (2004).

every element of V onto some element of O , and, in addition, preserves *all* the relations defined on V , then we get a strong form of resemblance known as a *homomorphism*. Stronger still is an *isomorphism*, which is a one-to-one relation-preserving mapping such that every element of V corresponds to some element of O , and every element of O corresponds to some element of V . When two systems are isomorphic their relational organisation is identical. In the literature on second-order resemblance the focus is often placed on isomorphism (see e.g., Cummins 1996, pp. 85–111), but where representation is concerned, the kind of correspondence between systems that is likely to be relevant will generally be weaker than isomorphism. For a much fuller discussion of second-order resemblance, see O'Brien & Opie (2004).

¹⁰ Two early theorists who sought to apply second-order resemblance to mental representation are Palmer (1978) and Shepard (Shepard & Chipman 1970; Shepard & Metzler 1971). More recently, Blachowicz (1997), Cummins (1996), Gardenfors (1996), O'Brien & O'Brien (1999), O'Brien & Opie (2004), and Swoyer (1991), have all defended second-order resemblance theories.

5 Conclusion: How mind matters

It is time to take stock. We began with three commonplace theses about mental phenomena and their physical realization in the brain that together generate a profound puzzle about mental causation. This is the content causation problem: that of explaining how the specifically representational properties of mental phenomena can be causally efficacious of behaviour. This problem has an air of insolubility about it because it appears to require something impossible: an explanation of the relational character of mental content that invokes only the intrinsic properties of the brain. It has been the foundational conjecture of this discussion, however, that this despair issues from the impoverished understanding of content that attends the dyadic analysis of mental representation, and that once we adopt the perspective of the triadic conception our view of the content causation problem is transformed.

The insight offered by triadicity is that the relational character of mental content is to be discharged ultimately in terms of our behavioural dispositions towards features of the world. This offers a way forward with the content causation problem because it suggests that, rather than seeking to explain some kind of mysterious action-at-a-distance, the task for a theory of content determination is to explain how the obtaining of world-mind relations can dispose cognitive systems to respond selectively to certain elements of their embedding environments.

According to most naturalistically-inclined philosophers, there are just two candidate mind-world relations available: causal relations and resemblance relations. Causal theories of content determination dominate the contemporary landscape, but our analysis confirms what many have suspected—namely, that causal theories offer no prospect of a solution to the content causation problem. The reason for this, however, is not because such theories appeal to relations that incorporate factors beyond the brain. All theories of mental representation, in their efforts to explain the relational character of mental content, are forced to invoke world-

mind relations of some kind. The problem with causal theories, at least from the triadic perspective, is the disconnect between world-mind causal relations and a system's behavioural dispositions. The obtaining of causal relations between external conditions and inner vehicles cannot explain how the latter endow systems with the capacity to respond in a discriminating fashion towards the former.

This leaves us with resemblance relations. The problem here is that resemblance theories of content determination have for many years been deeply unpopular in philosophy. But this is another point where the triadic conception of representation pays rich dividends. Most of the problems associated with resemblance theories don't look so severe when viewed from the triadic perspective. This is encouraging, because resemblance does offer some prospect of a solution to the content causation problem. The key here is that the mere obtaining of the resemblance relation entails that representing vehicles replicate their represented objects. This ensures that the former have properties that can be exploited to shape the behavioural dispositions of cognitive systems towards the latter.

Consequently, if the line of argument presented here is on the right track, then resemblance theories of mental content determination must be rehabilitated and subjected to scrutiny and development. It goes without saying that there are a great number of significant hurdles yet to be overcome. I have focused, for instance, on just one very simple example of a representation-using system. There remains, accordingly, a large question mark over whether the resemblance solution to the problem of content causation scales up to more sophisticated cognitive creatures, let alone to the immense complexities of our own mental phenomena. But we have to start somewhere. And as things currently stand, resemblance theories appear to be obligatory, since they alone offer some prospect for explaining how mind matters.

Does Resemblance Really Matter?

A Commentary on Gerard O'Brien

Anne-Kathrin Koch

In this commentary on Gerard O'Brien's "How does mind matter?—Solving the content causation problem", I will investigate the notion of *representational content* presented in the latter. With this notion, O'Brien aims at giving an explanation of how mind matters in physicalist terms. His argumentation is motivated by, and supposedly directed towards, a problem he calls *the content causation problem*. Regarding this, I am most interested in reconstructing how his account relates to the presuppositions that make this problem so pressing in philosophical enquiry. O'Brien provides a very interesting answer to the question of "why mental content matters", as motivated by the content causation problem. In particular, I will try to show that by making use of the notion of dispositions, it provides an interesting way of avoiding the presupposition that understanding content causation always requires the reduction of individual relational properties to individual intrinsic properties—probably because it is presupposed that such a reduction is impossible.

1 Introduction

Gerard O'Brien's paper "How does mind matter?—Solving the content causation problem" ([this collection](#)) is situated at the border of philosophy and cognitive science. The subject matter, as announced by the title, is the causal efficacy of mental content, especially of representational content. O'Brien approaches this subject in three argumentative steps: first he introduces us to a problem called the *content causation problem*, then he proposes a conception of representation that he calls the *triadic conception of representation*, and, third, he enriches this concept by proposing a second-order similarity theory of content determination.

In this commentary I will try to reconstruct how these three points relate to each other, focusing in particular on the role that the content causation problem plays in the other two argumentative steps. O'Brien's theory of representational content and its causal efficacy is doubtlessly interesting even when considered in isolation, as I will briefly outline in section 2. In section 3, I will try to show that the content causation problem demands us to be more specific than when just investigating the question of how mind matters. In section 4, I will try to show how O'Brien's account of the relational character of mental content, which is at the core

of his argumentation, gains its philosophical relevance from implicit assumptions that form the conceptual foundations of the content causation problem as here formulated. In an attempt to assess whether his account must really be regarded as *solving* the content causation problem, I will highlight in section 5 how important it is to be specific about what we really mean if we suppose that representation is somehow *relational* in character.

2 How mind might matter

In his paper in [this collection](#), Gerard O'Brien confronts the task of "explaining how mind matters" (p. 12). He does so, because he—rightly, I believe—identifies the fact "that our minds matter—that our beliefs and desires, and our perceptions and thoughts ultimately have a causal impact on our behaviour" as a ubiquitous and well-accepted, but unexplained phenomenon (p. 1).

O'Brien's investigation is motivated by the following question: "[h]ow can mental phenomena be causally efficacious of behaviour in virtue of their representational contents if those contents are not determined by intrinsic properties of the brain?" (O'Brien [this collection](#), p. 2) He calls this question the "content causation problem" (*ibid.*, p. 2). This specific way of approaching the matter of mental causation is set in the context of "three widely accepted theses about mental phenomena and their physical realization in the brain" (*ibid.*, p. 2): (i) the supposed causal efficacy of mental phenomena is grounded in their representational contents, which, (ii) are taken to be *relational* properties of those phenomena (*ibid.*, p. 2–3); and (iii) the results of neuroscience, which already provide us with an explanation of how behaviour is caused, only make use of the brain and its *intrinsic* properties in their explanation (*ibid.*, p. 2). Hence, there is a need for an explanation of behaviour being caused by mental phenomena in virtue of their relational properties, and this explanation cannot easily make use of the explanation of the causation of behaviour that has already been provided by contemporary

neuroscience. At first, it looks as if this shortfall is exactly what O'Brien is addressing.

Philosophical mainstream accounts of representation, O'Brien reminds us, are built on an understanding of representation as a two-place relation. Representational content is thus described in terms of *aboutness* and/or *reference*. O'Brien, however, advises us to abandon the traditional understanding of the notion of representation, i.e., the idea that representation is a two-place relation and adequately phrased in terms of one thing being *about* another (O'Brien [this collection](#), p. 3–4). Instead, he proposes a triadic conception of representation, making representation a three-place relation between a represented object, a representing vehicle, and an interpretation (*ibid.*, p. 5).

In the triadic picture, interpretation is "a cognitive effect [of the object] in the subject", thereby establishing a relationship between this subject and the represented object (O'Brien [this collection](#), p. 5). The ingenious move here, of course, is that interpretation is explained in *causal* vocabulary. We should think of interpretation as "presumably implicating the production of mental representing vehicles" possessing new properties, which should in turn be thought of as "bring[ing] the subject into some appropriate relationship to the original vehicle's represented object" (*ibid.*, p. 5), i.e., "modifying [the subject's] behavioural dispositions" (*ibid.*, p. 6). At first, when O'Brien further describes those vehicles as "hav[ing] [...] cognitive and ultimately behavioural effects" (*ibid.*, p. 6), it isn't clear exactly which category we are dealing with. I take the relata of the causation relation to be events, but understand talk of vehicles to be talk about objects.¹ I suggest that we understand the vehicles as modifying the system's behavioural dispositions insofar as, once produced, they have certain properties that are directly and specifically relevant for a causal process to take place (given that some sort of stimulus initiates the causal process). If we adopted a view of dispositions as second-order properties, i.e., the property of having certain properties that

¹ If we want to avoid reification of the "vehicles", we might look at it them as time-slices in a complex, internal chain of events, i.e., of dynamic inner processes modifying a subject's global dispositions.

can be causally relevant (cf. Choi & Fara 2014), this would allow us to think of the vehicles as modifying global dispositions of a system as a whole, in the sense of *providing new ones*—that is, by themselves having novel dispositional properties. This way, we can analyze the obtaining of the representation relation as a specific causal process having taken place: the first step of that process is the triggering of the cognitive effect by the representandum (the first relatum); the second relatum is the event of interpretation itself; and the third relatum is the new vehicle produced during the event of interpretation that provides the subject with a new behavioural disposition towards the representandum. The representational character of mental content, in this picture, just rests on what we call “content” resulting from the multi-layer causal process described above.²

O’Brien’s triadic account of representation describes the obtaining of the representation relation not in terms of our everyday intuitions about representation, but in terms of the job it is supposedly doing for us: bridging the gap between whatever is going on in the sphere of “the mental” and the external world by alluding to the causal chain that unites the two. It is thus understandable why the dyadic conception might be accused of hiding behind terms like “aboutness” or “reference”: saying that something mental is about something external is just saying that there is a gap being bridged. Saying that something external sets a three-step causal chain in motion with the result that a subject has undergone a specific change in her behavioural dispositions seems much closer to saying what the bridge is made of.

Yet we should still dispose of the vague language of “specific change in her behavioural

dispositions”. What exactly makes this change specific? It was called “specific” because it selectively relates back to the object that set the causal chain in motion in the first place and which we would like to keep calling “the represented object.”³ But how can the change in a subject’s behavioural dispositions make them pick out the exact same object from which this change originates?⁴ The answer to this lies in the theory of content determination.

When holding that the representing vehicle brings about a change in the subject’s behavioural dispositions, causal theories of content determination are supposedly to be abandoned because of a “disconnect between world–mind causal relations and a system’s behavioural dispositions” (O’Brien this collection, p. 12). An appropriate theory of content determination—so says a desideratum that we gain from the results of the triadic analysis of representation—must “explain how [inner vehicles] endow systems with the capacity to respond in a discriminating fashion towards [external conditions]” (ibid., p. 12). For fulfillment of this criterion, O’Brien turns to *resemblance theories* of content determination, which “hold that representing vehicles are contentful in virtue of resembling their represented objects” (this collection, p. 9).

Within the triadic conception of representation, O’Brien identifies two hurdles for a resemblance theory that still need to be overcome: it must be shown how the theory can be compatible with physicalism, and it must be secured that the theory does not leave content indeterminate (ibid., pp. 9–11).

In order to secure the compatibility of a resemblance theory of content determination with physicalism, O’Brien turns away from the notion of *first-order resemblance* and instead makes use of *structural* or *second-order resemblance* (ibid., pp. 10–11). He thus avoids the seemingly naive and implausible thesis that

² It might be said that this understanding of representation is plausible for paradigmatic cases of representation, like the representation of material objects, but that it is less clear whether it is also fit to capture cases that differ strongly from those paradigms, like the representation of abstract “objects”.

A similar worry, which has been pointed out to me by an anonymous reviewer, concerns cases of *fictional* representations, e.g., future events. For this specific example, she/he suggests that we allow for the causal chain to be reversed. This would make the representandum part of the final event. However, this solution applies only to those cases of fictional representation where the representandum does *not yet* exist, but leaves the majority of cases of fictional representation inexplicable.

³ I will, inspired by O’Brien’s terminology, keep referring to the representandum as the represented *object*. The term “object” is thereby used in a very wide sense and not intended to be restricted to single material objects. What exactly can take the place of an object in O’Brien’s story of representation is yet to be determined.

⁴ This question presupposes that the established representation is actually correct and not a case of misrepresentation.

mental representations must actually share properties with what they represent (*ibid.*, p. 10). Resemblance is taken to a more abstract level where, for example, something red can be mentally represented *with the representation resembling the representandum*, but *without* them both sharing the property of being red (*ibid.*, pp. 10–11).

The second hurdle might seem redundant at first glance. Explaining how content is determined is basically the job description of a theory of content determination. It is still worth mentioning this as an obstacle, however, because the reliance on second-order resemblance makes this job look particularly difficult: second-order resemblance is too easily established. If a set of mental representations second-order resembles a pattern of colour shades, it might in virtue of the same relational organization also second-order resemble a pattern of locations in a two-dimensional space. Nevertheless, O'Brien trusts that within the triadic conception of representation, second-order resemblance will do the job. The idea is that some of the possibilities for the content of a vehicle that are left open by second-order resemblance are ruled out in the process of interpretation—interpretation is “content-limiting” by “anchoring vehicles” in “domains” (O'Brien *this collection*, p. 11). The preexisting behavioural dispositions influence the newly developing ones, so that they are not directed towards all domains with a specific relational organisation, but towards a selection of these.

So far, O'Brien has provided us with an interesting account of how mental phenomena are causally efficacious in virtue of their representational contents: the property

x has representational content

is analyzed as the property

x results from a causal process that brings about behavioural dispositions towards the object that triggered the causal process.

These behavioural dispositions, given their respective stimuli, can now yield causal effects.

But if we took this as O'Brien's only accomplishment, we would miss the most interesting part of his argument. Furthermore, we would take the second step before the first.

3 Content and causation: from a question to a problem

So far, I have interpreted O'Brien's formulation of the content causation problem (“How can mental phenomena be causally efficacious of behaviour in virtue of their representational contents if these contents are not determined by intrinsic properties of the brain?” O'Brien *this collection*, p. 2) as something along the lines of “How does mental causation in virtue of representational content work, if not in the way we already know it sometimes works?” In so doing, one already engages in an interesting discussion about content causation. But closer examination reveals that this understanding of the problem is an oversimplification. The content causation problem is supposed to be much more severe. It is not a problem about finding alternative explanations to the ones we already have, but about the *consistency* of all available explanations. A better understanding of the problem will help us to evaluate whether O'Brien's suggestions, which are doubtlessly interesting, are really motivated by the problem at hand.

The three theses, that (i) the causal efficacy of mental phenomena is grounded in their representational contents, that (ii) these “are not determined by the intrinsic properties of the brain” (O'Brien *this collection*, p. 2), and that (iii) the brain's causal efficacy for behaviour is grounded only in its *intrinsic* properties, supposedly “form an inconsistent triad” (*ibid.*, p. 2). Yet, strictly speaking, they are not inconsistent: why not say that what we do in theses (i) to (iii) is gathering information about (human) behaviour—our object of enquiry—but on two levels of description? On both levels, we attempt, metaphorically speaking, to travel back along the causal chain that brings behaviour about. On the one level, we then discover that intrinsic properties of the brain are responsible for it to cause behaviour (*ibid.*, p. 2, thesis 3). On another level, we trace behaviour back to

mental phenomena, which owe their capacity to cause it to their representational contents (*ibid.*, p. 2, thesis 1). Why not assume that these two levels both provide us with (true) formulations of what is happening, but which—since they depend on two conceptual frameworks that are not intertranslatable—must be regarded as *nomologically incommensurable*? If so, they could never both be part of a unified causal theory (see Davidson 1970). This picture seems perfectly intelligible at first. But on both levels, we talk about causes of (presumably the same) behaviour.

Within a physicalist framework, we take behaviour to fall, in the end, under the description of a physical event. As such, it is subject to *the principle of causal closure*: if it is caused, it has a sufficient physical cause (Kim 1989, p. 43). Hence, we should pay close attention to the fact that “our best neuroscience informs us that the changes to musculature that constitute our behavioural responses are wholly determined by the intrinsic properties of the brain to which they are causally connected” (O’Brien *this collection*, p. 2). Thus it is not only assumed that the brain *can be* causally efficacious of behaviour in virtue of its intrinsic properties, but also that *whenever* behaviour is caused, it is *always* caused in the brain and in virtue of the brain’s intrinsic properties. Yet mental phenomena, which are of a non-physical kind, are also mentioned in (i) as a cause of behaviour. But with brain states already providing a sufficient cause for behaviour, what role in causation can they possibly play (Kim 1989, pp. 43–44)? As long as we cannot answer question, we are forced to reject the possibility that behaviour is *over-determined*, or, in other words, we are forced to accept both mental phenomena and brain states as two *separate* causes of behaviour. So causally efficacious mental phenomena should be reducible to the physical cause already provided by the states of the brain, or we must conclude that they are not a cause at all. In the latter case, this would mean that we would have to deny “that our beliefs and desires, and our perceptions and thoughts ultimately have a causal impact on our behaviour” (O’Brien *this collection*, p. 1) and we would

have to accuse every discipline accepting this tenet—O’Brien names folk psychology and the computational theory of mind (*ibid.*, p. 2)—of operating with a faulty ontology, pointing out causes that do not really exist.⁵

Now we have made explicit a metaphysical constraint that was left implicit in the formulation of the content causation problem: mental properties and all their capacities, e.g., their capacity to cause behaviour, must be reducible to properties of the physical brain. Knowing this, we see where the supposed inconsistency comes from: we traditionally think of representational content not as determined by the brain’s intrinsic properties, but rather as determined by what it is about (O’Brien *this collection*, p. 2–3). But if the content causation problem dares us to integrate these two things, namely the description of mental phenomena as causing behaviour in virtue of their representational contents and our theory of the same behaviour being caused by processes in the brain in virtue of the brain’s *intrinsic* properties, then we might conclude with O’Brien:

A solution to the content causation problem requires something that *prima facie* appears impossible: an explanation of the relational character of mental content that invokes only the intrinsic properties of the brain. (*this collection*, p. 3)

This is what turns the content causation problem as formulated by O’Brien from an interesting question into an urgent philosophical problem. The apparent impossibility of a solution relies on the idea of a sharp distinction between relational and intrinsic properties. If our best shot at understanding whatever we describe as the “relational character” of representational content is to understand it as a relational property,⁶ then its irreducibility to intrinsic properties of the brain is built into it—and so is the insolvability of the content causation problem, given the metaphysical constraint just men-

⁵ The threat lurking in the background is, of course, eliminative materialism (cf. Churchland 1981).

⁶ Remember that this kind of property is even referred to as “not determined by the intrinsic properties of the brain” (O’Brien *this collection*, p. 2).

tioned. Nevertheless, O'Brien aims to provide a solution.

4 The relational character of representational content

We see now that an attempt to solve the content causation problem must address the question of how the specific character of representational content can be analyzed in a way that invokes only the intrinsic properties of the brain (instead of being understood as “being a relational property and not an intrinsic property of the brain”). However, O'Brien advertises a theory of content determination that draws on second-order similarity between mental vehicles and the outside world as necessary for a solution to the content causation problem. In fact, he admits that “all theories of mental representation, in their efforts to explain the relational character of mental content, are forced to invoke world-mind relations of some kind”, where the latter term seemingly refers back to “relations that incorporate factors beyond the brain” (O'Brien [this collection](#), p. 12). But how does this relate to the explicit goal of providing “an explanation of the *relational* character of mental content that invokes only the *intrinsic* properties of the brain”, which would only “*prima facie* [appear]” to be, but not—as the content causation problem is supposed to have a solution—actually *be* “impossible” (O'Brien [this collection](#), p. 3)?

The answer to this might lie in a view which can be found in O'Brien & Opie:

Von Eckardt observes that the triadicity of representation in general, and mental representation in particular, can be analysed into two dyadic component relations: one between representing vehicle and represented object (which she calls the *content grounding* relation); the other between vehicle and interpretation [...] This suggests that any theory of mental representation must be made up of (at least) two parts⁷: one that explains how the content

of mental vehicles is grounded, and a second that explains how they are interpreted. (2004, p. 5)

When O'Brien writes that every theory of representational content, including his own, must make use of factors extrinsic to the brain, he most likely refers to the content grounding relation—in his case, second-order resemblance. Yet when he promises us “an explanation of the relational character of mental content that invokes only the intrinsic properties of the brain” (O'Brien [this collection](#), p. 3), the scientific explanation mentioned most likely refers to the other part of the theory of mental representation: the internalist theory of interpretation. If O'Brien takes it that only this theory, which provides us with a reconstruction of the causal processes involved in mental representation, needs to be presented in terms of intrinsic properties of the brain, then he provides an account within the “narrow content program” (*ibid.*, p. 3): this research program accepts the thesis that “[t]he representational contents of mental phenomena are not determined by the intrinsic properties of the brain” (*ibid.*, p. 2) but—quite plausibly, I think—relaxes the metaphysical constraint made explicit in section 3 insofar as it only demands “an account of mental phenomena according to which (*at least the causally relevant component of*) *their representational properties* are determined by intrinsic properties of the brain” (*ibid.*, p. 3, my emphasis).

If this is a correct reconstruction of O'Brien's steps towards a solution to the content causation problem, then he has reached his goal if he:

- a) has provided an account of the causally-relevant components of representation that makes use of only the intrinsic properties of the brain, and
- b) can make sure that this account still deserves to be called an account of representation, i.e., captures the specific characteristics of representational content that we have so far called “relational”.

O'Brien claims that “[t]he insight offered by triadicity is that the relational character of mental

⁷ A third relation that one might want to look at when “taking apart” the triadic relation of representation is the relation between interpretation and represented object.

content is to be discharged ultimately in terms of our behavioural dispositions towards features of the world” ([this collection](#), p. 12). While it might not be clear at first sight why this provides a solution to the problem at hand, I am convinced that a view of dispositions as second-order properties—such as the property of having a property that becomes relevant for the causing of a certain manifestation once a certain stimulus is provided—helps us to see how O’Brien’s account provides a solution. I hope to have shown in section 2 how the adoption of the view that dispositions are second-order properties fits into his picture of representation. Thus I believe that it allows us to regard the first of the two requirements mentioned above as fulfilled: I see no reason why such a second-order property should not be understood as an intrinsic property of the brain. Furthermore, I hold that this view allows us to regard the second requirement as fulfilled, too: the dispositions in question seem to deserve the label “relational” insofar as, when combined with a certain stimulus, they are manifested in terms of overt, observable behaviour of a biological organism. When so manifested, they turn into concrete chains of events linked by causal *relations*. One can now argue that these potential relations are what let us intuitively characterize representation as relational. So understood, O’Brien’s explanation does justice to the project of providing an account that captures the specific character that makes representational content deserve the label “representational”, but without characterizing its causally efficacious components as being relational properties.

5 The content causation problem and second-order resemblance relations

If this is to be seen as a successful analysis of representational content in terms of intrinsic properties of the brain, we can conclude that the triadic picture alone—with its analysis of the relational character of representational content in terms of dispositions—already solves the content causation problem. Hence, this problem, by itself, offers criteria that could be turned into an argument for or

against any specific theory of content determination.

Such a theory, as I understand it, serves two purposes: it explains how the contentful vehicles of which the theory of interpretation makes use are individuated, and it explains “how relations between mental vehicles and their represented objects can endow subjects with the capacity to respond selectively to those very features of the world” (O’Brien [this collection](#), p. 6). It thus provides the background information necessary for understanding why the theory of interpretation is able to do what is required of it. The second desideratum is only made clear if the triadic account of content causation is adopted. According to O’Brien, it can only be fulfilled if we adopt the resemblance theory of content determination, because “[t]he obtaining of causal relations between external conditions and inner vehicles cannot explain how the latter endow systems with the capacity to respond in a discriminating fashion towards the former” (*ibid.*, p. 12), whereas “resemblance does offer some prospect of a solution to the content causation problem. The key here is that the mere obtaining of the resemblance ensures that the former have properties that can be exploited to shape the behavioural dispositions of cognitive systems towards the latter” (*ibid.*, p. 12).

Let us recapitulate the steps that took us from the content causation problem to the second-order resemblance theory of content determination. The content causation problem motivates the triadic account of representation if we assume that it is a problem about reduction and if we assume that there is a sharp distinction between relational and intrinsic properties that forbids an analysis of the former in terms of the latter, thus preventing the reduction of a theory of causally efficacious mental phenomena to a theory of brain-based causation of behaviour. The triadic account of representation solves this problem by showing us that we need not assume that representational content owes its specific character to relational properties. Dispositions, understood as non-relational second-order properties, do justice to our concept of “relational character”. The triadic ac-

count then needs to be enriched by a theory of content determination, and its use of the concept of a “disposition” leads to a new requirement: to explain how inner vehicles can enable a subject to respond selectively towards external objects. Supposedly, only second-order resemblance can fulfill this requirement. Thus understood, a second-order resemblance theory of content-determination is only indirectly relevant to a solution of the content causation problem.

Yet I would like to point out a way in which the second-order resemblance theory itself relates to the content causation problem. Second-order resemblance between vehicles and objects tells us that there is a mapping from objects to vehicles that is pattern-preserving or, in other words, some objects and some vehicles are alike in some of their relational properties. Nevertheless, the kind of pattern involved is to be “sustained by constraints inherent in the vehicles, rather than being imposed extrinsically” (O’Brien [this collection](#), p. 11, footnote 11). The relations constituting a structure or pattern collectively supervene on the distribution of intrinsic properties of objects and vehicles, although individual extrinsic (and specifically relational) properties of objects and vehicles do not. This strategy of explanation is in principle also available to our understanding of content: contents, fixed by a structural organisation of vehicles, are relational in the same, completely unproblematic sense. Representational contents may not *individually* be determined by intrinsic properties of the brain, but there is a sense in which they are so collectively. But this might count as evidence against the second thesis of the content causation problem: that “[t]he representational contents of mental phenomena are not determined by the intrinsic properties of the brain” (*ibid.*, p. 2). One might then even say that content is *not relational at all*, and that the puzzle that actually troubles us is the question of how representations can have something to which they are applied, namely a “*target*” (Cummins 1996, p. 8).⁸ This could still be accounted for by the triadic picture of represent-

ation, but it would then not amount to *solving* the content causation problem, but to rejecting it.

6 Conclusion

In his target article, Gerard O’Brien addresses the question of “how the specifically representational properties of mental phenomena can be causally efficacious of behavior” ([this collection](#), p. 12). When he does so, there are two parts of the problem to be considered: the first is explaining how mind matters, and the second is showing how an answer can prevail in the light of the content causation problem. Considering the first part in isolation, O’Brien provides an interesting answer. He translates our talk of representation into causal vocabulary, thereby making it possible to reach a concept of causally efficacious representational content. In order to understand how O’Brien’s account needs to be assessed with regard to the second part, one first needs to reconstruct which background assumptions make the content causation problem so pressing.

I am convinced that the issues of *reduction* and the *relational/intrinsic property distinction* need to be addressed in order to understand whether and how the content causation problem can motivate an account like O’Brien’s. His account takes as a starting point that representational content has a relational character, but should not be understood in terms of relational properties. Rather, as we have seen, it should be understood in terms of dispositions—which can, if manifested, establish causal relations, but are not relational by themselves. I hope to have provided a reconstruction of how this starting point is used to reach the conclusion that, as O’Brien formulates it, “resemblance theories appear obligatory, since they alone offer some prospect for explaining how mind matters” ([this collection](#), p. 12).

If this is correct, there remains one question: whether resemblance theories of the proposed kind might themselves indicate that the content causation problem rests on a mistake. The problem presupposes further problems about the role of relational and intrinsic proper-

⁸ I owe this point to an anonymous reviewer.

ties that need not be addressed in order to account for the causal efficacy of representational content. The content causation problem's not arising in the first place would, of course, not undermine O'Brien's highly interesting account. It is only that this problem could no longer be used to motivate the argumentative steps he takes. Still, his account is illuminating for many other reasons, such as translating mysterious talk about "being about" into naturalistic terminology. However, whether we can regard the content causation problem as solved or rather as successfully rejected is not clear; but instead of worrying about this problem, we might now turn towards the details of O'Brien's account. An interesting starting point for such further inquiry might be to try to reach a better understanding of the role and the kind of *dispositions* and *vehicles* involved in causal processes, for they form two of the key concepts in O'Brien's theory.

Rehabilitating Resemblance Redux

A Reply to Anne-Kathrin Koch

Gerard O'Brien

Anne-Kathrin Koch's insightful commentary places a great deal of pressure on the connection between my deployment of the triadic analysis of representation to solve the content causation problem and my contention that it makes mandatory the rehabilitation of the resemblance theory of mental content determination. She argues that if the relational character of mental content can be captured in terms of brain-based behavioural dispositions, as I claim, then this manoeuvre in its own right solves the content causation problem and hence offers no support for resemblance or any other theory of content determination. In this reply, I argue that the relation between the proposed solution to the content causation problem and the resemblance theory of content determination is stronger than Koch allows.

1 Introduction

There is a paradoxical air surrounding mental content. On the one hand we take it to be a localized property of our minds—of our mental states—distinct from the world in which we are embedded. Yet on the other hand, it is the means by which our minds reach out and make “cognitive contact” (Kriegel 2003) with this surrounding environment. How is such action-at-a-distance possible? The standard solution to this conundrum is to assume that the **relational character** of mental content can be explained by the fact that mental content is a **relational property** of our mental states. This line of thought leads to **content externalism**, accord-

ing to which mental content is determined in part by factors beyond our heads. But once content externalism is combined with a couple of unexceptional theses about (i) the role of content in mental causation and (ii) the brain-basis of the causal determinants of behaviour, we encounter the **content causation problem**—the problem of explaining how the content of mental states can be causally efficacious of behaviour when it doesn't supervene on what's in our heads.

The solution I offered in my target paper was to sever the connection between the relational character of mental content and the as-

sumption that the latter is a relational property of our mental states (O'Brien [this collection](#)). My suggestion was that unlike a **dyadic** story that seeks to explain representation solely in terms of relations between vehicles and their represented objects, a **triadic** account of representation opens up space to explain the relational character of mental content in terms of brain-based behavioural dispositions—specifically, dispositions to respond selectively to specific features of the external environment. According to this triadic account, the **aboutness** of mental content is not some mysterious relational property that brings our minds into contact with various aspects of the surrounding environment; it is the relatively straightforward cognitive capacity, bestowed by the intrinsic properties of our brains, to regulate our behaviour in response to specific environmental conditions.

In her insightful commentary, Anne-Kathrin Koch, after carefully rendering explicit some of the background assumptions on which I rely, focuses on the connection between the proposed solution to the content causation problem and my further contention that it makes mandatory the rehabilitation of the resemblance theory of mental content determination (Koch [this collection](#)). Her counter claim is that if the relational character of mental content can be successfully captured in terms of the brain's behavioural dispositions, then this manoeuvre in its own right solves the content causation problem and hence offers no support for resemblance or any other theory of content determination. In this reply, I will show that the relation between the proposed solution to the content causation problem and the resemblance theory of content determination is stronger than Koch allows.

2 Rejecting resemblance (and content causation)

The great insight of Charles Sanders Peirce's analysis of representation is his claim that aboutness can't be explained solely in terms of relations between representing vehicles and represented objects (Hardwick 1977). Instead, vehicles are about their objects in virtue of hav-

ing a certain kind of effect on a cognitive subject—specifically, vehicles either trigger thoughts about objects (in cases of public representation) or they engender behavioural dispositions towards them (in cases of mental representation). According to Peirce, it is this additional relatum—known as **interpretation**—that renders representation triadic.

But once interpretation is added into the representational mix, it has the potential to overwhelm any content-grounding relations that may obtain between vehicles and objects. This is the thread that Koch astutely pulls on in her commentary. To the extent that one can appeal to the manner in which a representing vehicle modifies a subject's behavioural dispositions in order to capture the relational character of content, it seems as though one can also appeal to these dispositions to fix the content of this vehicle. In short, the triadic account would appear to make those theories of content determination that appeal to vehicle-object relations—such as resemblance—redundant (or, at least, “only indirectly relevant”, as Koch charitably puts it; [this collection](#), p. 8).

Koch is not alone in drawing out this consequence from the triadic nature of representation. It is precisely this idea about the role of behavioural dispositions in content fixation that forms the foundation of the instrumentalist approach to mental representation that Daniel Dennett has defended over many years (1978; 1987). Dennett was one of the early proponents of triadicity, insofar as he argued that it was only in virtue of their roles in cognitive systems that representing vehicles can be interpreted as bearers of information:

There is a strong by tacit undercurrent of conviction [...] to the effect that only by being rendered explicit [...] can an item of information play a role. The idea, apparently, is that in order to have an effect, in order to throw its weight around, as it were, an item of information must weigh something, must have a physical embodiment [...]. I suspect, on the contrary, that this is almost backwards. [Representing vehicles]... are by themselves quite inert as

information bearers [...]. They become information-bearers only when given roles in larger systems. (Dennett 1982, p. 217)

Dennett has also famously argued that the consequence of taking the triadic account seriously is the rejection of any story that takes mental content to be determined independently of a cognitive creature's patterns of behaviour.

Dennett's instrumentalist approach to mental representation, however, has another famous consequence. If the full burden of content determination falls on the shoulders of interpretation—if, that is, it is a cognitive system's behavioural dispositions ultimately fix the content of its representing vehicles—then content is a product of cognition, not an ingredient, and hence cannot be casually implicated in the production of behaviour.

This last point, of course, represents Dennett's own solution to the content causation problem: he abandons the thesis that mental phenomena are causally efficacious of behaviour in virtue of their representational contents (see O'Brien [this collection](#), fn. 1). This is also what Koch is hinting at when she indicates that my proposal to invoke the triadic account of representation might be better interpreted as **rejecting** the content causation problem rather than **solving** it (Koch [this collection](#), p. 8). That is, far from showing that rehabilitation of the resemblance theory of content determination is mandatory, her (implicit) objection is that my proposed solution to the content causation really shows that there is no such thing as content causation in the first place.

3 Rehabilitating content causation (and resemblance)

To reiterate, the problem associated with the triadic analysis of representation is that once behavioural dispositions are invoked in order to explain the relational character of mental content, they threaten to overwhelm any other story about mental content determination. But if mental content is determined by such behavioural dispositions, it can't play a robust causal role in their production. In short, the triadic ac-

count seems to suggest that there is no content causation **problem** because there is no **content causation**.

In this context, however, it is pertinent to note that, despite his insistence that representation is triadic, Peirce expends a good of effort investigating the relations between representing vehicles and represented objects. His analysis of public forms of representation famously yields three different kinds of vehicle-object relations—convention, causation, and resemblance—associated with symbols, indexes, and icons, respectively (see Hardwick 1977 and Von Eckardt 1993, Ch. 4). If content determination is ultimately just a matter of interpretation, why would Peirce have been so bothered about these vehicle-object relations?

The answer, of course, is that Peirce was concerned not just with the fact that public representing vehicles effect interpretations in cognitive subjects, but with **how** they do so. The point here is that interpretation isn't magic—it requires explanation. Consider, for example, Leonardo da Vinci's **Mona Lisa**. According to the triadic story, the painting that hangs in the Louvre is not about anything on its own. Its standing as a representing vehicle hinges on its capacity to trigger interpretations in cognitive subjects. When we look at this painting it causes us to think about a dark-haired woman with a famously enigmatic smile. But what is it about this painting that endows it with this capacity? Part of the explanation here invokes our recognition of the resemblances between the painting and a woman with a certain kind of physical appearance. The painting wouldn't have the same impact on us if these resemblances didn't obtain. So a complete account of the painting's aboutness must go beyond the fact that it triggers certain thoughts in us to include an explanation of how it does so. And it is here that vehicle-object relations such as resemblance are compulsory.

The general lesson to take away from this (far too brief) analysis is that the interpretation of public forms of representation cannot be disconnected from the cognitive subject's (conscious or unconscious) recognition of what are generally known as **content grounding** rela-

tions between vehicles and represented objects. And what goes for the interpretation of public representing vehicles also goes for the interpretation of mental vehicles. On the triadic story being entertained here, mental vehicles, just like the **Mona Lisa**, aren't about anything considered in isolation. Their aboutness is a consequence of the multifarious behavioural dispositions they create in us towards selective features of the world—dispositions to physically interact with these features, for example, or to make utterances about them. Since this form of interpretation likewise isn't magic, a complete account of mental representation must explain how mental vehicles establish these behavioural capacities. And just as with the case of public representing vehicles, it is impossible to do this without recourse to content-grounding relations (something that is demonstrated by even exceedingly simple representation-using devices such as the humble thermostat—see O'Brien [this collection](#), pp. 7–9).

Precisely because content-grounding relations must be invoked to explain how the former endow cognitive systems with behavioural dispositions towards the latter, content causation is back in business. But what kind of vehicle-object relations can turn this trick? This, of course, was one of the central questions that animated much of my discussion in the target paper (O'Brien [this collection](#)). Of the three grounding relations that Peirce found to be implicated in public forms of representation—convention, causation, and resemblance—the first is widely assumed to be unavailable for mental representation since it violates the naturalism constraint.¹ Despite its popularity in contemporary philosophy, the second, I argued at some length, is actually powerless to explain how mental vehicles create the requisite behavioural

dispositions ([this collection](#), pp. 6–7). This just leaves us with resemblance. Fortunately, this third vehicle-object relation is up to the task, or at least so my argument went, since the structural properties of mental vehicles that ground second-order resemblance relations can be exploited to shape the behavioural dispositions of a cognitive system towards worldly objects ([this collection](#), p. 8). This is where the rubber of resemblance meets the road of content causation. And it is why a resemblance theory of content determination is mandatory if we are to explain why mind matters.

¹ This is the requirement that mental representation be explained without appeal to further forms of representation. If a vehicle is related to its object by convention, the cognitive subject must deploy a *rule* that specifies how the vehicle is to be interpreted. In the case of non-mental representation, where for example the vehicle is a word in a natural language, the application of such a rule is a cognitive achievement that must be explained in terms of processes defined over mental representing vehicles. When this same account is applied to mental vehicles, therefore, it would seem to generate an infinite regress of further representing vehicles, and hence interpretation is never achieved (see Von Eckardt 1993, p. 206).

Conscious Intentions

The Social Creation Myth

Elisabeth Pacherie

What are intentions for? Do they have a primary purpose or function? If so, what is this function? I start with a discussion of three existing approaches to these questions. One account, associated with Michael Bratman's planning theory of agency, emphasizes the pragmatic functions of intentions: having the capacity to form intentions allows us to place our actions more firmly under the control of deliberation and to coordinate our actions over time. A second account, inspired by Elizabeth Anscombe's theory of intentions, emphasizes their epistemic function and their contribution to self-knowledge. A third account, developed by David Velleman, suggests instead that the capacity for intentions may be an accident or a spandrel, that is, a byproduct of some more general and fundamental endowments of human nature. I argue that these accounts are at best partial and largely overlook two important dimensions of intention. I introduce and motivate a further pragmatic function of intentions, namely their role in the control and monitoring of ongoing action and argue that acknowledging the existence and importance of this function allows us to plug gaps in these accounts. I further argue that this pragmatic function of intentions plays a crucial role in contexts of joint action where agents must align their representations in order to coordinate their actions towards a joint goal. I speculate that a capacity for conscious control might have become established because of the role it served in solving inter-agent coordination problems in social contexts and because of the benefit conferred by the forms of cooperation it thus made possible.

1 Introduction

What are conscious intentions for? What do we gain from having a capacity for intentions as opposed to simply a capacity for desire-belief motivation? Do intentions have a function not just in the sense that they have a causal role but in the normative sense in which having this function confers benefits on intention-forming creatures that explain why these creatures have this capacity. In other words, do intentions have a teleofunction? Is there something they are for? And if so, what is this teleofunction?

Roughly, the notion of intention is that of a mental state that represents a goal (and means to that goal) and contributes through the guidance and control of behavior to the realization of what it represents. Thus, my intending to go to my office will control and guide my behavior (e.g., leaving my house, taking the bus, walking from the bus stop to my office), thus contributing to the realization of the goal represented by the intention. Many philosophers hold the view that if we do something intentionally, we must be aware of what we are doing.

Therefore, they consider that it is of the essence of intentions to be conscious. I have argued elsewhere (Pacherie 2008) in favor of a notion of motor intentions whose contents may not always be accessible to consciousness. On my view then, the phrase “conscious intentions” need not be pleonastic. Here, however, my focus will be on intentions qua conscious states and I will use “conscious intentions” and “intentions” interchangeably.

In his 2007 paper, “What good is a will?”, David Velleman considers the question whether the human will, understood as the capacity for (conscious) intentions, has a purpose or teleofunction. He discusses two accounts that assume that the will has a purpose but disagree on what this purpose is. On one account, associated with Bratman’s planning theory of agency, the primary function of intentions is pragmatic: having the capacity to form prior intentions is good because it allows us to place our actions more firmly under the control of deliberation and to coordinate our actions over time. On the other account, inspired by Anscombe’s theory of intentions, the primary function of intentions is epistemic. Intentions are good because they provide self-knowledge: an intention on which one acts provides us with a special kind of knowledge of what one is doing.

David Velleman is himself skeptical that the attitude of intention has a teleofunction. Rather, he suspects that the human will is an accident or a spandrel, that is a byproduct of some more general and fundamental endowments of human nature. Velleman suggests, however, that our hypotheses about the origins of the will, including his own, must be closer to creation myths than to scientific theories. Talk of myths, of course, has both negative and positive connotations. On the negative side, myths are, if not downright false or unfounded, at least ultimately unverifiable. On the positive side, myths are dramatization devices that serve to highlight, and make sense of, the value or function of a practice, of an institution or, in the case at hand, of a cognitive capacity. Here, I will offer my own creation myth for intentions, a myth that emphasizes the social dimension and social function of conscious intentions. The

main claim I will defend is that having conscious intentions is a good thing in large part because it facilitates coordination and cooperation with others and because cooperation is itself fitness enhancing. My aim in proposing this social creation myth is not to entirely displace other creation myths, but rather to complement them, to highlight an important facet of conscious intentions that traditional philosophy of action has tended to neglect and to plug some holes in the stories told in other myths.

Here’s how I will proceed. In section 2, I will present the two creation myths considered and rejected by Velleman and discuss some difficulties they raise. In section 3, I will discuss Velleman’s own creation myth. In section 4, I will introduce and motivate a pragmatic function of intention largely overlooked by these creation myths, namely their role in the control and monitoring of ongoing actions. In section 5, I will tell my own social creation myth. I’ll argue that this pragmatic function of intentions plays a crucial role in contexts of joint action where agents have to align their representations in order to coordinate their actions towards a joint goal. I’ll speculate that the main evolutionary benefit conferred by a capacity for conscious intentions is that it enables a considerable increase in the possibilities for joint action and cooperation.

2 Two teleological creation myths

Velleman (2007) points out a methodological assumption common in functionalist psychology, namely the assumption that our attitudes or cognitive faculties have a function not just in the sense that they have a causal role but in the sense that they have a purpose, something they are designed to do and thus ought to do. Functions in this latter sense are commonly called teleofunctions. This methodological assumption needs not entail a belief in some intelligent designer. Instead, it can be cashed out by appealing to evolutionary theory and to natural selection as a blind designer. Typically, the evolutionary story goes like this: a trait has the teleofunction of producing effect E just in case producing this effect conferred some benefit that

contributed to the reproductive success of organisms endowed with the trait and, thereby, to the propagation of the trait itself. This methodological assumption, when it guides our inquiry into intentions, leads us to take the question what intentions are for, i.e., what purpose are they meant to serve, as necessarily meaningful and demanding an answer.

Velleman discusses two teleological stories meant to answer this question. He links the first story to [Bratman's](#) theory of intentions (1987) and the second to [Anscombe's](#) theory (1963). I start with the story inspired by Bratman's theory.

We are, in Bratman's words, planning agents regularly making more or less complex plans for the future and guiding our later conduct by these plans. This planning ability appears to be if not unique to humans at least uniquely developed in the human species. People can, and frequently do, form intentions concerning actions not just in the near but also in the distant future. Why should we bother forming future-directed intentions? What purposes can it serve? What benefits does it bring us? What features of future-directed intentions allow them to serve these purposes?

Bratman offers two complementary answers to that challenge. The first stems from the fact that we are epistemically limited creatures: our cognitive resources for use in attending to problems, gathering information, deliberating about options and determining likely consequences are limited and these processes are time consuming. As a result, if our actions were influenced by deliberation only at the time of action, this influence would be minimal as time pressure isn't conducive to careful deliberation. Forming future-directed intentions makes advance planning possible, freeing us from that time pressure and allowing us to deploy the cognitive resources needed for successful deliberation. Second, intentions once formed commit us to future courses of action, thus making the future more predictable and making it possible for agents to coordinate their activities over time and to coordinate them with the activities of other agents. Making deliberation and coordina-

tion possible are thus the two main benefits that accrue from a capacity to form future-directed intentions.

What makes it possible for future-directed intentions to yield these benefits is, according to Bratman, the fact that they essentially involve commitments to action. Bratman distinguishes two dimensions of commitments: a volitional dimension and a reasoning-centered dimension. The volitional dimension concerns the relation of intention to action and can be characterized by saying that intentions are "conduct-controlling pro-attitudes" ([Bratman 1987](#), p. 16). In other words, unless something unexpected happens that forces me to revise my intention, my intention today to go shopping tomorrow will control my conduct tomorrow. The reasoning-centered dimension of commitment is a commitment to norms of practical rationality and is most directly linked to planning. What is at stake here are the roles played by intentions in the period between their initial formation and their eventual execution. First, intentions have what Bratman calls a characteristic stability or inertia: once we have formed an intention to A, we will not normally continue to deliberate whether to A or not. In the absence of relevant new information, the intention is rationally required to resist reconsideration: we will see the matter as settled and continue to so intend until the time of action. Intentions are thus terminators of practical reasoning about ends or goals. Second, during this period between the formation of an intention and action, we will frequently reason from such an intention to further intentions. For instance, we reason from intended ends to intended means or to preliminary steps. When we first form an intention, our plans are typically only partial, but if they are to eventuate into action, they will need to be filled in. Thus intentions are also prompters of practical reasoning about means. Third, because intentions are commitments to action, our intentions should be jointly executable. Finally, taken together the volitional and the reasoning-centered dimensions of commitments help explain how intentions can promote coordination. They provide support for the expectation that agents will act as they intend to and these ex-

pectations are central in turn to both inter- and intra-personal coordination. In particular, this is what motivates the rational agglomerativity requirement on intentions, i.e., the requirement that my intentions be jointly executable.

The benefits that accrue from a capacity for intentions are, ultimately, pragmatic benefits. As Bratman puts it, future-directed intentions “enable us to avoid being merely time-slice-agents” (1987, p. 35). Instead of constantly starting from scratch in our deliberations and simply weighing current belief-desire reasons, intentions allow us to become temporally extended agents. They provide a background framework that allows us to expand the temporal horizon of our deliberation while at the same time narrowing its scope to a limited set of options. In so doing they contribute in the long run to our securing greater desire-satisfaction than simple desire-belief practical reasoning would.

Velleman (2007) sees three main problems with Bratman’s pragmatic account of what intentions are for. The first problem concerns the status and role of present-directed intentions. On Bratman’s account, a future-directed intention requires a present-directed intention to convey its motivational force and guide the action once the time to act is seen to have arrived. Bratman identifies no further role or function of present-directed intentions beyond conveying the motivational potential of future-directed intentions. At the same time, he insists that intentional actions, whether or not they are preceded by future-directed intentions, always involve present-directed intentions. This leaves us with a potentially large class of spontaneous intentional actions that involve present-directed intentions but are not preceded by future-directed intentions. These intentions do not incorporate the results of any prior deliberation, they don’t set the stage for any further planning and they don’t provide a basis for any coordination. The first worry raised by Velleman is thus that these intentions do not seem to serve any of the pragmatic purposes that, on Bratman’s account, constitute the *raison d’être* of intentions. Second, Velleman points out that a similar worry arises for the intentions involved in various cases of planning. He illustrates his point

with a voting example. He argues that while there may be good reasons for my starting to think about my vote in advance, such as giving me sufficient time to deliberate, there doesn’t seem to be any good reason for settling in advance of my arrival in the voting booth whom I will vote for. On the contrary, settling in advance seems to carry potential costs, by making me resistant to reconsideration, without procuring any benefits, since the actual act of casting my ballot doesn’t require any particular prior preparation. Thus, at least in these cases where no further planning is needed once one has settled on a course of action, it is unclear what purpose settling in advance could serve.

Velleman’s third worry relates to Bratman’s view that intention need not imply belief. Bratman indeed maintains that “there need be no irrationality in intending to A and yet still not believing one will”, but that, in contrast, “there will normally be irrationality in intending to A and believing one will not A” (1987, p. 38). According to Velleman, this view of Bratman’s leaves much of his functional account of intentions unmotivated. In particular, it becomes unclear why in intending to A, an agent should be rationally required to identify means of A-ing or to rationally constrain her subsequent practical reasoning by ruling out options inconsistent with her A-ing, if she is agnostic whether she will in fact carry out her intention. Similarly, it becomes unclear why we should impose an agglomerativity requirement on intentions. As Velleman points out, it is unclear why intentions should be jointly executable if the agent can be agnostic as to whether they will be executed.

In my view, Velleman’s third worry is exaggerated. Firstly, while Bratman indeed maintains that an intention to A does not require belief that one will A, he insists at the same time that an intention to A normally supports the belief that one will A. Secondly, Bratman also makes the point that agnosticism about whether one will act as intended does not directly undermine coherent planning but makes it more complex, leading us to form conditional intentions and plans for both failure and success to act as intended. Of course,

the viability of such a move depends on agnosticism being the exception rather than the rule; otherwise, we would have an unmanageable proliferation of conditional branching in our plans.

Velleman's first and second worries run deeper. If the only purposes of intentions are the pragmatic functions Bratman identifies, then there appear to be many instances where intentions don't serve these purposes or where serving them is actually counterproductive. This may be taken to indicate that Bratman's account is incomplete and that he has overlooked some of the functions intentions serve. This line of thought can be pursued in two different directions. On the one hand, we may try to identify further pragmatic functions that intentions, including present-directed intentions, could serve; on the other hand, we may look for non-pragmatic functions that intentions could serve. As we will now see, Velleman explores the second option, turning to Anscombe's theory of intentions in search of an answer. In contrast, what I will do myself later in this paper is explore the first option, giving it a social twist.

Velleman argues that Bratman's account of intentions misses an important function of intention, a function that is a central theme in Anscombe's theory of intention. In her book *Intention* (1963), she argues that intentions provide us with a special kind of self-knowledge and claims that this knowledge is special in two ways. It is knowledge of our own intentional actions, i.e., knowledge not just of what one is attempting to do, but of what one is actually doing, and it is knowledge without observation. Much philosophical ink has been spilled on how exactly these two claims should be interpreted. Following Falvey (2000), Velleman favors a reliabilist interpretation of these claims. According to this interpretation, knowledge of one's own intentional actions is non-observational because it is given by the content of our intentions and intentions in turn normally constitute (practical) knowledge of our own intentional actions because they reliably cause the facts that make them true. Note also, that on this reliabilist reading, Anscombe's claim is not that the content of our intentions provides us with infallible

knowledge of what we are doing. To say that there normally exists a reliable connection between our intentions and actions is not to say that there cannot be cases when this connection does not obtain. However, as Velleman emphasizes, on Anscombe's account, failures of reliability undermine not just the epistemic status of intentions, they also undermine the intentionality of actions. If my intending to *A* does not reliably cause my *A*-ing, then, on the one hand, my intending to *A* will not amount to knowledge that I am *A*-ing and, on the other hand, my *A*-ing when it happens will be an accident rather than an intentional action. According to Anscombe, intentional actions are those "to which the question 'Why?' is given application" (1963, p. 9) and having practical knowledge is knowing a description of what one is doing, has done or is proposing to do that answers the question "Why?". Thus, the basic epistemic function of intentions is to provide us with a form of self-knowledge and self-understanding qua intentional agents.

According to Velleman, acknowledging this epistemic function of intentions does much to alleviate the worries raised by Bratman's practical account. With respect to the first worry – that present-directed intentions serve no purpose – one can now argue that while they might serve no practical purpose they still serve an epistemic function. With respect to the second worry – that on many occasions making one's mind in advance serves no pragmatic purpose –, one can now reply that in matters that are important to one's self-conception, uncertainty about one's future behavior is both uncomfortable and undesirable and that forming an intention allows us to gain self-knowledge and avoid this mental discomfort. With respect to the third worry – that absent a strong enough connection between intention and belief, it is unclear why intentions should be subject to the practical rationality requirements emphasized by Bratman –, Anscombe's theory regarding the epistemic function of intentions lets us see how the epistemic role of intentions could support their pragmatic functions.

The story as told so far suggests that we should think of the epistemic and pragmatic

functions of intentions as complementary. However, as Velleman points out, it still leaves us with two possible hypotheses or creation myths about the origin and ultimate purpose of intentions. On the pragmatic creation myth, the ultimate purpose of intentions would be pragmatic and their epistemic function would be subservient to their pragmatic functions, but may occasionally exemplify re-purposing: “That is, intention might have been designed to embody self-knowledge for the sake of facilitation coordination, but it might then be used on occasion, for the sake of self-knowledge alone, when coordination isn’t necessary” (Velleman 2007, p. 208). By contrast, on the epistemic creation myth, the ultimate purpose of intentions may be to embody self-knowledge, and the pragmatic functions of intentions might have emerged simply as a fortuitous by-product of self-knowledge.

While Velleman has more sympathy for the epistemic than for the pragmatic creation myth, he thinks both should ultimately be rejected. In the next section, I’ll consider his reasons for rejecting them, discuss the alternative story he proposes, and advance my own reasons for being skeptical about this story.

3 Velleman’s spandrel

Despite their differences, the epistemic and the pragmatic creation myths rest on the common assumption that intentions have a teleofunction, some ultimate purpose they are designed to serve. Velleman thinks it is more plausible that their existence is an accident, that is to say, that they are the byproduct of some more general endowments of human nature. In other words, Velleman is tempted to think of the human will as, in Gould & Lewontin’s phrase (1979), a spandrel, a feature formed not by design but as an accidental byproduct of some other designed feature or features. This leads him to be skeptical about both teleological myths. In telling his own creation myth, Velleman pursues two aims. His first aim is to show that the assumption behind the two teleological myths can be dispensed with. His second aim is to show that the accident that led to the emergence of the human will more closely approximates

ates the epistemic than the pragmatic creation myth.

Velleman’s own account of intentions characterizes them as an agent’s commitment to the truth of some act-description of his or her forthcoming behavior that reliably causes this act-description to come true. He argues that this account of intentions “posits nothing more than the predictable consequences of two motivational states whose utility in the design of a creature is far more general than that of the human will” (Velleman 2007, p. 211). In other words, the human will is a spandrel, a feature arising from the accidental confluence of two designed features. What are these two features? The first, according to Velleman, is curiosity, defined as the creature’s drive to understand what goes on in its environment. The second is self-awareness, through which the creature realizes that it is part of its environment and that its own behavior is part of what goes on in this environment. Self-awareness thus allows a creature to acquire an objective conception of itself. A creature that is both curious and self-aware will in turn be driven to understand its own behavior, that is, to understand “how the egocentrically conceived world of doing things is connected to the objectively conceived world of things understood” (Velleman 2007, p. 211). In understanding this, it will have acquired the capacity for intentions.

We can now see why Velleman thinks his own creation myth has more affinities with the epistemic than with the pragmatic creation myth. Curiosity is an epistemic drive and self-awareness is an epistemic capacity. As their byproduct, the capacity for intentions inherits this essential epistemic dimension. We can also understand why he means his own myth as an antidote to the methodological assumption inherent to the idea that intentions serve a specific teleofunction. Curiosity and self-awareness are, Velleman claims, designed for far more general purposes than that of the human will.

I think, however, that this is also where the creation myth told by Velleman reaches its limits. Important questions are left unanswered: What are these more general purposes served by curiosity and self-awareness? What good is curiosity?

What good is self-awareness? Unless he is willing to consider the will as a spandrel of spandrels, Velleman owes us answers to these questions. From an evolutionary point of view, it is unclear what benefits knowledge of their environment and knowledge of themselves could confer on creatures endowed with curiosity and self-awareness unless this knowledge found some behavioral expression. It isn't too difficult to see how a better understanding of their environment can promote more effective behavior, enhance the satisfaction of desires and needs, and ultimately have a differential impact on reproductive success in creatures endowed with curiosity. One should note, however, that pushing Velleman's story one step further in his direction has the effect of undermining his claim that his own myth has strong affinities with the epistemic creation myth for it suggests that the epistemic function of curiosity is ancillary to its pragmatic function, rather than the reverse.

It is less obvious how we should answer the question what good is self-awareness, what purposes it is designed for. My aim in the next two sections will be to remove two obstacles that prevent us from looking in the right direction for an answer to this question. The first obstacle lies in the fact that philosophers have tended to neglect an important pragmatic function of intentions. Thus, Velleman notes, rightly in my view, that Bratman's account of the pragmatic functions of intentions leaves many present-directed intentions without a purpose. However, rather than looking for some further pragmatic purpose intentions may serve, beyond scheduling deliberation and enhancing action coordination over time, Velleman turns his attention to epistemic functions. I will argue in section 4 that they both neglect a further important pragmatic function of intentions, namely their role in the online monitoring and control of action. The second obstacle lies in the fact that one central feature that makes us human, our deep sociality, is either ignored or at best a peripheral concern in philosophical accounts of intentions. Of course, I am not denying the obvious: many philosophers, and Bratman prominently among them, have explored joint agency and collective intentionality. Typically, however, their focus has been on whether or not joint agency should be seen as continuous with individual agency and thus on

whether or not the conceptual framework developed to account for individual intentions could be fruitfully extended to shared intentions.¹ Rarely if ever, however, do they consider the possibility that shared intentions may shed light on some of the features and functions of individual intentions. In section 5, I will argue that the control and monitoring function of intentions plays a crucial role in contexts of joint action. I will further argue that this function might indeed be the primary function of intentions and might have become established because of the role it serves in solving the coordination problems that arise in joint action and because of the benefit thus conferred on creatures capable of solving these coordination problems.

4 Control: A further pragmatic function of intentions

Bratman (1987) considers future-directed intentions as the central case of intending to act and contrasts this approach to intention with an alternative approach that gives priority to immediate intentions or intentions in action. He notes that this second approach naturally leads to the idea that intentions in action reduce to complexes of beliefs and desires, i.e., that what makes it the case that an agent acts with a certain intention are simply facts about the relation between the agent's actions and his beliefs and desires, and that this in turn tempts us into thinking that the same reductive strategy can be extended to future-directed intentions.² Focusing instead on future-directed intentions as the central case of intending allows us to identify functions of intentions that cannot easily be accommodated within a belief-desire model and thus makes the reductive strategy much less appealing. This would account for Bratman's emphasis on the deliberative and coordination functions of intentions. The flip side of the coin, however, is that present-directed intentions are then seen as little more than transmission belts needed to convey the motivational force of future-directed intentions. As noted by

1 See e.g., Bratman (2014) for a positive answer to these questions and Gilbert (1992, 2009) for a negative answer.

2 See for instance Davidson (1980, Essay 1) and Goldman (1970) for belief-desire reductive models of intentions.

Velleman, this leaves us with a potentially large class of actions where present-directed intentions appear to have no role to play, namely all these actions that are intentional yet not preceded by future-directed intentions. What belief-desire reductive approaches, Bratman's account and Velleman's account all seem to overlook is a specific pragmatic function of intentions in action or present-directed intentions, namely their role in the guidance, control and monitoring of action execution.

Harry Frankfurt (1978) was one of the first philosophers to criticize this oversight and insist on the importance of this pragmatic function of intentions. He emphasized that "a person must be in some particular relation to the movements of his body during the period of time in which he is presumed to be performing an action" (Frankfurt 1978, p. 157) and characterized this relation as one of guidance. Other philosophers have since shared his insight. For instance, Brand (1984), Bishop (1989) and Mele (1992) all insist that an adequate account of intentions should incorporate the guiding and monitoring roles of intentions in order to properly capture the close and continuous connection between intention and ongoing action.

The main reason why this connection between intention and ongoing action is needed is that human agents are neither infallible nor omniscient. Their expectations about the circumstances in which the action is to take place may not always be correct and they may fail to anticipate some of the relevant aspects of the situation of action. In other words, their situational beliefs may be incorrect or incomplete. The same goes for their instrumental beliefs. Suppose, for instance, that I intend to visit a colleague in her office. I may be wrong in thinking that this is the door to her office (incorrect situational belief) or unsure which door is her office door (lack of relevant situational belief). Similarly, I may also be wrong in thinking that I should pull the door to open it (incorrect instrumental belief) or unsure whether to push or pull (lack of relevant instrumental belief). If intentions are to reliably produce behavior matching their representational content (e.g., visiting my col-

league in her office), they should have some flexibility and incorporate monitoring processes to detect deviations that jeopardize the success of the action and correction processes to trigger compensatory activity.

This emphasis on control finds a strong echo in the literature on motor cognition (see, e.g., Jeannerod 1997, 2006). Indeed, it is in this literature that we can find the most precise characterization of the monitoring and control functions of intentions and of the mechanisms that support them. According to the very influential internal model theory of motor control, motor control strategies are based on the coupling of two types of internal models: inverse models and forward models (Frith et al. 2000; Jordan & Wolpert 1999; Wolpert 1997). Inverse models compute the motor commands needed for achieving a desired state given the current state of the system and of the environment. An efference copy of these commands is fed to forward models, whose role is to make predictions about the consequences of the execution of these commands. The control of action is thought to depend on the coupling of inverse and forward models through a series of comparators: error signals arising from the comparison of desired, predicted, and actual states (monitoring) are used for various kinds of regulation (control). In particular, they can be used to correct and adjust the ongoing action in the face of perturbations, as well as to update both inverse and forward models to improve their future functioning.

Recent experimental work in motor cognition also suggests, however, that much of action control is automatic and proceeds independently of conscious awareness. For instance, in an experiment (Castiello et al. 1991) participants were asked to reach for and grasp a target as quickly as possible and their hand trajectories were recorded. On some trials, though, the target shifted position after the movement had started. When this happened, participants were instructed to correct their movement in order to reach accurately for the target and to signal the time at which they became aware of its displacement by shouting "Tah!". The experiment showed that the participants started correcting

their movements more than 300ms before they signaled awareness of the target displacement. A subsequent study (Pisella et al. 2000) was especially instructive. In a first experiment they used a similar paradigm but introduced a condition where participants were requested to interrupt their movement when the target changed location. Despite the instruction, the participants could not prevent themselves from correcting their movements instead of stopping for a good 200 ms. In contrast, however, in a second experiment green and red targets were presented simultaneously in the two positions and the participants' task was to point at the green one. On some trials, the color of the two targets could be unexpectedly interchanged at movement onset. When this happened, one group of participants was instructed to interrupt their ongoing movement and the other group to correct it. In contrast to what happened in the first experiment, no automatic corrective movements were observed in the group instructed to interrupt their movement and in the other group corrections involved a significant increase in movement time. Thus, these results suggest that while corrections made in response to spatial perturbations are under automatic control, corrections in response to chromatic perturbations require intentional control.

On the one hand, the mere fact that some or much of action control can be automatic is not a sufficient reason to deny a control function to intentions. The experimental studies presented in the previous paragraph suggest that action control can indeed operate automatically and outside of conscious awareness and that when there is a conflict between automatic and intentional control, automatic control may take precedence over intentional control. Yet, they also provide evidence that some corrections cannot be carried out automatically but depend on intentional control. On the other hand, the mere fact that intentional control seems needed to compensate for chromatic perturbations may not provide sufficient ground for considering that the intentional control of action execution is a central function of intentions. One would want a more systematic account of the respective roles of automatic and intentional con-

trol. Recent developments of the internal model approach to motor control may constitute a useful guide.

While the internal model approach to motor control was initially introduced to account for fine-grained aspects of motor control, more recent versions of this approach emphasize the hierarchical nature of motor control (Hamilton & Grafton 2007; Jeannerod 1997; Kilner et al. 2007). They propose that internal inverse and forward models are arranged in a hierarchy and that error signals generated at one level of the hierarchy can propagate to the next level when correction mechanisms at this level are not able to make the necessary compensations. I have suggested elsewhere (Pacherie 2008) that one can distinguish three broad levels in an action specification hierarchy. At the highest level, action representations represent the whole action as a unit, in terms of its overarching goal and of the sequence of steps or subgoals needed to achieve that goal. At this level, the action may still be represented in a rather abstract format. The second level is concerned with the implementation of each step in the action plan and involves selecting an appropriate motor program given the immediate goal and contextual information about the current state of the agent and the current state of its environment. In other words, processes at this level are in charge of anchoring the successive steps of the action plan in the current situation and of selecting appropriate motor programs. Finally, once a motor program has been selected, the exact values of its parameters must still be set. This is done at the third level, where incoming sensory information about external constraints is used to specify these values.

Acknowledging the existence of different levels of action control corresponding to these different levels in the action specification hierarchy may allow us to accommodate both automatic and intentional action control processes. As long as error signals can be reduced by automatic corrections made at lower levels in the hierarchy, there is no need for the intervention of intentional control. However, there are two classes of cases where automatic corrections may not be sufficient to put an action back on

track. First, important external perturbations can lead to discrepancies that are too large to be automatically compensated. In such a case, error signals would propagate upwards, we would become aware of them and shift to a conscious, intentional compensation strategy. Second, in some instances there may also be discrepancies in the ways the action is or can be specified at different levels of the action representation hierarchy (inter-level representational misalignment). Thus, the study by Pisella and colleagues (Pisella et al. 2000) suggests that action specification at the sensorimotor level does not encode chromatic information and uses spatial information as a proxy for it. When chromatic information and spatial information vary independently, as they do in one of the conditions of the experiment, representations at different levels of the action representation hierarchy become misaligned and the intervention of conscious control becomes necessary to realign them.

Importantly, on this conception of intentional control and as Frankfurt had already noted, what is essential for actions to be intentionally controlled is not that intentional control processes actually affect their course, but that these control mechanisms would have intervened to adjust the action had the need arisen. In other words, an action may be intentionally controlled even though automatic rather than voluntary control mechanisms intervene to compensate for deviations, provided these voluntary control mechanisms would have kicked in, had automatic corrections proved insufficient.

Even more importantly, if action control is an essential function of intentions, then we should stop thinking of intentions as simply mental representations of goals somehow triggering motor processes that, if everything goes well, will yield the desired outcome. Rather, we should think of monitoring and control processes as intrinsic to intentions, that is, of intentions as encompassing not just representations of goals but also a specific set of monitoring and control processes organizing and structuring the motor processes that themselves generate movements.

In this section, I argued for the idea that the control of action execution is an important pragmatic function of intentions. Acknowledging the existence and importance of this function allows us to plug gaps in the creation myths considered earlier. First, it allows us to attribute a specific pragmatic function to present-directed intentions rather than considering them as mere transmission belts in charge of conveying the motivational force of future-directed intentions. We can thus assuage one of the main worries raised by Velleman against Bratman's pragmatic account of intentions and the pragmatic creation myth derived from it. Second, Anscombe's and Velleman's accounts of intentions both assume that intentions reliably cause behavior that matches their representational content. Human agents, however, are neither infallible nor omniscient. Their situational and instrumental beliefs can be incorrect or they can lack situational and instrumental beliefs that are relevant to the successful execution of their intentions. Thus, the reliability demanded by Anscombe's and Velleman's accounts largely depends on our having powerful and flexible control processes allowing us to put our actions back on track when perturbations deviate their course.

One may agree that the conscious control of individual action is a function of intention in the sense that intentions have this causal role, but still be skeptical that this is the role intentions are designed for, or to put it in other words, that it is a teleofunction of intentions. Thus, one could argue that very large external perturbations are rare and that inter-level representational misalignment is the exception rather than the rule. If so, most of action control would be automatic anyway and intentional action control would play at best a marginal role. It would therefore be unlikely to confer on intention-forming creatures benefits important enough to warrant the claim that intentions are designed for action control. As I have tried to argue in this section, the benefits conferred by online conscious control over actions are not as negligible as this deflationary view implies. In addition, I think we can build a very strong case that conscious action control confers im-

portant benefits if we consider joint activities rather than just individual actions. Acting jointly demands that we solve coordination problems that do not arise (or arise only in a very attenuated form) in individual action. In what follows, I will argue that online conscious control plays a crucial role in solving these coordination problems. I will further speculate that conscious online control over actions might indeed have become established as the primary function of intentions because of the role it served in solving these coordination problems and because of the benefit this conferred on creatures capable of solving these coordination problems and thus of acting jointly in an efficient and flexible way.

5 The social creation myth

Humans have been characterized as the ultra-cooperative species (Tomasello 2009, 2011). This ultra-cooperativeness has made us one of the most successful species on earth, spreading all over the planet, creating and developing cultural artifacts and practices that are themselves culturally transmitted and accumulate over time, thus giving us a further competitive edge over other species. According to Tomasello, underlying humans' ultra-cooperativeness are a set of species-unique skills and motivations for shared intentionality, involving "such things as the ability and motivation to form shared goals and intentions with others in collaborative activities, and the ability and motivation to share experience with others via joint attention, cooperative communication, and teaching" (2011, p. 6).

The gist of the social creation myth I am proposing in this section is that the main benefits associated with intentions and with the kind of control over actions they make possible arise in social cooperative contexts where agents have to coordinate their actions to achieve a shared goal. I start with an examination of the special demands for coordination acting jointly with others creates. I then explain how the capacity to form conscious intentions is a crucial component of our ability to meet these demands.

Successful joint action depends on the efficient coordination of participant agents' goals, intentions, plans, and actions. As I argued elsewhere (Pacherie 2012), it is not enough that agents control their own actions, i.e., correctly predict their effects, monitor their execution and make adjustments if needed. They must also coordinate their actions with those of their co-agents so as to achieve their joint goal. For that they must monitor their partner's intentions and actions, predict their expected consequences and use these predictions to adjust what they are doing to what their partners are doing. The implication of these processes, however, is not unique to joint action nor enough to promote their success. In competitive contexts they also play an important role. For instance, in a fight being able to anticipate your opponent's moves and to act accordingly is also crucial. What is furthermore required in the case of joint action is that co-agents share a goal and understand the combined impact of their respective intentions and actions on their joint goal and adjust them accordingly. In competitive contexts, an agent should typically aim at predicting his opponents' moves, while at the same time endeavoring to make his own moves unpredictable to his opponents. In contrast, in cooperative contexts mutual predictability must be achieved for efficient coordination towards a shared goal to be possible. Agents should be able to align their representations of what themselves and their partners are doing and of how these actions together contribute to the shared goal.

Various forms of uncertainty can undermine mutual predictability, the alignment of representations and hence coordination. They can be organized into three broad categories. The first category involves motivational uncertainty: we can be unsure how convergent a potential partner's interests are with our own interests and thus unsure whether there are goals we share and can promote together. The second category involves instrumental uncertainty: even assuming that we share a goal, we can be unsure what we should do to achieve that goal, or, if we have a plan, unsure how roles should be distributed among us, or, yet, unsure when and where we should act. The third category involves common ground uncertainty: we can be

unsure how much of what is relevant to our deciding on a joint goal, planning for that goal and executing our plan is common ground or mutually manifest to us.

Philosophical accounts of joint agency, including Bratman's (2009, 2014) do not ignore these challenges but they are essentially concerned with high-level processes involved in making decisions about whether or not to act together and in advance planning. Their focus is on the coordination of agent's intentions prior to acting and they pay little heed to the processes enabling people to coordinate during action execution. In contrast, in the last decade, cognitive scientists have investigated joint action by focusing on lower-level online coordination processes in relatively simple joint tasks and on the factors that affect these coordination processes. In what follows, I will argue that there are important limitations to what these advance and online coordination processes can achieve and that high-level online intentional control is crucial to overcoming these limitations. First, however, let us consider the main characteristics of the two sets of coordination processes philosophers and psychologists typically focus on.

Bratman's account of shared intentions is a good illustration of the way philosophical accounts approach coordination issues in joint action. In addition, its explicitness makes it possible to see clearly what advance coordination involves and how it is achieved.

Bratman (2009) proposes that shared intention involves the following conditions as its main building blocks:

1. Intentions on the part of each in favor of the joint activity.
2. Interlocking intentions: each intends that the joint activity go in part by way of the relevant intentions of each of the participants.
3. Intentions in favor of meshing subplans: each intends that the joint activity proceed by way of subplans of the participants that are co-realizable and can be consistently agglomerated.
4. Disposition to help if needed: given that the contribution of the other participants to the

joint activity is part of what each intends, and given the demands of means-end coherence and of consistency that apply to intentions, each is under rational pressure to help others fulfill their role if needed.

5. Interdependence in the persistence of each participant's relevant intention: each believes that the persistence of the other participants' intention in favor of the joint activity depends on the persistence of his own and vice-versa.
6. Joint-action-tracking mutual responsiveness: each is responsive to each in relevant subsidiary intentions and in relevant actions in a way that tracks the joint action.
7. Common knowledge among all participants of all these conditions.

Let me offer some comments on these conditions. First, Bratman offers these conditions as a set of sufficient conditions for a shared intention, leaving it open that shared intentions may be realized in other ways, in particular in cases of joint activities involving institutions. Second, conditions (1), (2) and (5) are meant to deal with motivational uncertainty. Bratman points out that the concept of a joint activity that figures in the contents of the intentions in (1) should be understood in a way that is neutral with respect to shared intentionality. So condition (1) only insures that agents share goals in a weak sense of the notion. Rather it is condition (2) that is in charge of insuring that the motivational states of the agents align in the way required for joint cooperative activity: it is the fact that for each participant, the content of their intention refers to the role of the intentions of other participants that, for Bratman, captures the intentional jointness of their actions. Condition (5) in turn specifies how these motivations stay aligned. Third, conditions (3), (4) and (6) relate to means-end uncertainty and are meant to reduce it. According to Bratman, they can be derived from condition (2) taken together with the norms of practical rationality that already govern individual planning and acting. Bratman's key idea is that the interlocking and interdependent intentions of individual participants, in responding to the norms of

practical rationality governing individual planning agency, will also respond to the norms of social agglomeration and consistency, social coherence and social stability shared intentions are subject to. This would involve, in Bratman's terms, commitments to mutual compatibility of relevant sub-plans, commitments to mutual support, and joint-action tracking mutual responsiveness. Finally, the function of condition (7) is, rather obviously, to reduce common ground uncertainty.

Bratman's basic idea is thus that this structure of interlocking and interdependent intentions, when it functions properly, frames relevant bargaining and shared deliberation and thus supports and guides coordinated planning and action in pursuit of the intended shared activity. Unsurprisingly, since Bratman's theory of joint agency is continuous with his planning theory of individual intentions, it is in virtue of the pragmatic functions intentions already serve in the individual action case that the interlocking and interdependent intentions of individual participants can also support coordination in the joint action case.

While Bratman, in his condition (6), stipulates that agents should be mutually responsive not just in their relevant intentions and subsidiary intentions but also in relevant actions in a way that tracks the joint action, his account doesn't tell us by what means mutual responsiveness in action is achieved. To know more about this, we have to turn our attention to recent psychological work on joint agency. In contrast to philosophical approaches, cognitive psychology studies of joint action typically focus on the perceptual, cognitive, and motor processes that enable individuals to coordinate their actions with others online.

Knoblich and colleagues (Knoblich et al. 2011) distinguish between two broad categories of coordination processes, emergent and planned. In emergent coordination, coordinated behavior occurs due to perception-action couplings that make multiple individuals act in similar ways. One source of emergent coordination is entrainment, the process of synchronizing two or more actors' rhythmic behaviors with respect to phase (e.g., Richardson et al. 2007). A second

source of emergent coordination is perception-action matching, whereby observed actions are matched onto the observer's own action repertoire and can induce the same action tendencies in different agents who observe one another's actions (Jeannerod 1999; Prinz 1997; Rizzolatti & Sinigaglia 2010; Knoblich & Sebanz 2008). Importantly, emergent forms of coordination are independent of any joint plans or common knowledge, which may be altogether absent. They support basic forms of motor and representational alignment that can facilitate mutual responsiveness in action, but they do not ensure that the agent's actions track a joint goal. Indeed, the successful performance of some joint actions may require that these automatic coordination processes be inhibited. For instance, the performance of composer Steve Reich's famous piece, *Drumming*, based on the technique of phasing, requires the musicians to play the same rhythmic pattern out of sync.

In planned coordination, agents plan their own actions in relation to the joint goal and also to some extent to their partners' actions. As emphasized by Knoblich et al. (2011), shared task representations play an important role in planned coordination. Shared task representations do not only specify in advance what the respective tasks of each of the co-agents are, they also provide control structures that allow agents to monitor and predict what their partners are doing, thus enabling interpersonal coordination in real time. Empirical evidence shows that having shared task representations influences perceptual information processing, action monitoring, control and prediction during the ensuing interaction (Heed et al. 2010; Schuch & Tipper 2007; Sebanz et al. 2006; Tsai et al. 2006). Furthermore, several studies (Sebanz et al. 2005; Sebanz et al. 2006) have shown that actors may form shared representations of tasks quasi-automatically, even when it is more effective to ignore one another.

Several researchers have also suggested that joint attention provides a basic mechanism for sharing representations of objects and events and thus for creating a perceptual common ground in joint action (Tomasello & Carpenter 2007; Tollefsen 2005). To act jointly, it is often

necessary not only that the co-agents identify the objects to be acted upon, their location as well as the location of possible obstacles, but also be mutually aware that they do. Joint attention may thus play an important role in ensuring that co-agents track the same objects and features of the situation and be mutually aware that they do. In a recent study, Böckler et al. (2011) showed that attending to objects together from opposite perspectives makes people adopt an allocentric rather than the default egocentric frame of reference. These authors suggest that taking an allocentric reference may support the efficiency of joint actions from different spatial orientations. Independently of mutual manifestness, being able to assess what others are perceiving, or can or cannot perceive at a given moment in time may also facilitate coordination. For instance, a study by Brennan and colleagues (Brennan et al. 2007) demonstrated that co-agents in joint visual search space were able to distribute a common space between them by directing their attention depending on where the other was looking and that their joint search performance was thus much more efficient than their performance in an individual version of the search task.

There are, however, important limitations to what these emergent and planned on-line coordination processes can achieve. First, to the extent that they exploit perceptual information, they can be of no help unless a certain amount of common perceptual information is indeed available to co-agents. Second, even when common perceptual information is available, there are limits to our processing capacities. An agent may be able to simultaneously track what a small number of other agents are currently doing or attending to, but when the number of agents increases, this capacity soon finds its limits. Our capacity to co-represent the actions, goals, and intentions of other agents we observe acting encounters similar limitations. Understanding of actions through motor resonance and mirroring works only to the extent that the observed actions are part of the action repertoire of the observer. Similarly, when actions are relatively

novel, agents may not yet have formed sufficiently detailed shared task representations. Finally, unexpected effects of action execution or failures of coordination may reveal various forms of misalignment between partners' representations or indicate that their representations, though aligned, were inaccurate.

When pre-alignment is insufficient or breakdowns occur due to misalignment in the action execution phase, the deliberate and conscious production of social signals aimed at aligning or realigning relevant representations becomes crucial. Agents cannot count on alignment arising spontaneously. They have to make it happen. Intentional communication, whether verbal or not, is then needed to make it happen.

As emphasized by Herbert Clark (2006), joint activities can typically be partitioned into two sets of actions: a basic joint activity and coordinating joint actions. The basic joint activity comprises all the actions essential to achieving the basic joint goal, while the coordinating joint actions consists in the set of communicative acts about the basic activities that insure relevant representational alignment. To study this partitioning of joint activities, Clark and his co-workers ushered two people in a small room, gave them the parts of a kit for a TV stand and asked them to assemble the stand, videotaping them and recording their verbal exchanges while putting they did it. Here's a short extract of their exchanges, taken from Clark (2006, p. 128):

Ann Should we put this in, this, this little like kinda cross bar, like the T? like the I bar?

Burton Yeah ((we can do that))

Ann So, you wanna stick the ((screws in)). Or wait is, is, are these these things, or?

Burton That's these things I bet. Because there's no screws.

Ann Yeah, you're right. Yeah, probably. If they'll stay in.

Burton I don't know how they'll stay in ((but))

Ann Right there.

Burton Is this one big enough?

Ann Oh ((xxx)) I guess cause like there's no other side for it to come out.

Burton M-hm.

[8.15 sec]

Burton ((Now let's do this one))

Ann Okay

First, it should be noted that, as often happens in daily life, this joint activity was not planned in advance. Instead, Ann and Burton discover that they have to assemble a TV stand and work out together what they should do as they go along. Second, Clark points out that Ann and Burton's coordinating joint actions are structured in what he calls projective pairs, comprising a proposal and an uptake (i.e., full acceptance, altered acceptance or rejection of proposal). Third, the exchanges can be gestural as well as verbal. For instance, instead of, or concomitantly with, asking verbally whether Burton is ready to fasten the screws, Ann may present him with the screwdriver and his taking it count as acceptance. Fourth, the contents of these exchanges show that they are aimed at reducing instrumental uncertainty. Typically, they are about what should be done and how, who should do what, and when and where it should be done. When the task presents difficulties, they may also serve to reduce motivational uncertainty. For instance, Burton might ask whether they should give it a last try and Ann either acquiesce or reject the proposal. Finally, the structure of the projective pairs shows that at the same time they aim at reducing common ground uncertainty. Proposals are about potential alignments and full acceptance confirms alignment and common ground. Tellingly, with altered acceptance uptakes, projective pairs evolve into projective triads, the third element of the exchange being the proposer's uptake on the alteration.

Importantly, to negotiate and achieve alignment in this way, we must be aware of our own and others' intentions and beliefs and this at two levels, corresponding to the two sides of the partitioning characterized by Clark. On the one hand, it is essential to the fulfillment of communicative intentions that they be recognized as such by the addressee (Grice 1957; Recanati 1986; Sperber & Wilson 1986). On the other hand, what agents communicate in these contexts is information about their beliefs and intentions regarding the joint action. This suggests that the development of self-consciousness and consciousness of other minds, of intentional communication, and of increasingly complex forms of coordinated joint action go hand in hand.

The success of both individual and joint action depends on representational alignment. In the case of individual action, representation alignment takes two main forms. First, at a given level of action specification, a match should be achieved between representations of desired, predicted and actual states. We can call this first form of alignment intra-level alignment. Second, inter-level alignment is also necessary; that is, despite differences in representational format and resources, action specifications at different levels of the action representation hierarchy should be kept aligned. Conscious online control may be needed to restore alignment when severe intra- or inter-level discrepancies occur. However, it may be argued that in the individual case alignments are taking place within a single cognitive system and that this system is normally sufficiently integrated or unified that serious misalignments are rare and thus that the need for online conscious control is limited.

The main difference between individual and joint actions lies in the coordination demands essential to joint action. Thus, a third form of representational alignment becomes crucial in joint action. In addition to individual intra- and inter-level representational alignment, inter-agent representational alignment is necessary to meet coordination demands. Inter-agent alignment may be achieved in part through advanced planning, as proposed by Bratman. It

can also be achieved in part through online emergent and planned coordination processes of the types explored and described in the recent psychological literature. However, there are important limitations to what these coordination processes can achieve. Advance planning, when it takes place, may help define a shared background framework for the joint action, but at this stage it is typically impossible to anticipate all the coordination demands that will arise at the execution stage. Some of these demands may be met by the kinds of online coordination processes reviewed earlier in this section, but, as I pointed out, there are also important limitations to what they can achieve. In many instances, the progress of a joint action is hindered or the action breaks down due to various forms of misalignment between agents' representations. In such instances, individual corrections do not suffice to put the joint action back on track. Rather, to overcome these failures, agents need to align or realign their representations. This process calls for what Clark calls coordinating joint actions, that is, communicative acts about the basic joint activity. These communicative acts in turn are intentional and aim at communicating information about the agents' intentions and beliefs with a view to achieve alignment. But one can only communicate intentionally about one's beliefs and intentions if one is aware of them. Conversely, one can only understand the communicative acts of other agents if one realizes that these agents have a capacity for intentions. Finally and crucially, as already emphasized by Velleman (2007) in his discussion of Bratman's account, intentions could not serve their pragmatic functions unless they also had an epistemic role. In other words, if my having the intention to *A* didn't count as a form of practical self-knowledge and didn't give me grounds to believe that I would act as intended, my communicating (sincerely) about my intention to *A* would not license other agents to form beliefs about my future actions and thus would not yield the kind of inter-agent representational alignment needed to achieve coordination.

To recap, joint actions create more comprehensive demands for representational align-

ment than individual actions, since their success depends not just on individual intra- and inter-level representational alignment but also on inter-agent representational alignment. New resources are needed to meet these demands. On the social creation myth proposed here, a capacity for conscious intentions is crucial to inter-agent representational alignment. Having conscious intentions allows us to communicate about them and engage in coordinating joint actions that create common ground and promote the success of basic joint activity. The answer this myth offers to the question what is the purpose of conscious intentions is then that it is to enable more efficient inter-personal coordination in joint action and thus reap the benefits that come with increasingly complex and flexible forms of coordinated actions. The social creation myth doesn't deny intentions an epistemic role. On the contrary, it acknowledges that intentions couldn't serve their inter-personal coordination function if they did not at the same time provide us with a form of self-knowledge. However, it views their epistemic function as subservient to their coordination function. The social creation myth does not deny either that conscious intentions play a role in the online control of individual action. Rather, it proposes that conscious control of individual action may be a by-product of a capacity for conscious control that became established in social contexts because of the role it served in solving inter-agent coordination problems and because of the benefit conferred by the forms of cooperation it made possible.

6 Conclusion: Relating creation myths

The Bratmanian creation myth is pragmatic but also diachronic and individualist. Intentions have a purpose or teleofunction. This function is pragmatic insofar as the main benefit attached to intentions is to allow us to secure greater desire satisfaction. The way intentions secure this benefit is by allowing us to organize and coordinate our actions diachronically, in other words to become planning agents. As noted by Velleman, this emphasis of diachronicity and future-directed intentions leaves present-directed

intentions without a clear function. Finally, this myth is to a large extent individualist. While planning agency also enables inter-individual coordination, the social dimension of intentions remains secondary in Bratman's account and again his main concern is with diachronically organized joint actions.

While the social creation myth also sees intentions as having a pragmatic purpose, in contrast to the Bratmanian myth, it emphasizes the social and synchronous dimension of intentions. Instead of self-coordination over time, it emphasizes cooperation and flexibly coordinated joint action as the main route to greater desire satisfaction. It thus reverses the Bratmanian perspective in proposing that intentions are designed to enable a more efficient online coordination of joint action and in considering future-directed individual or joint planning as derivative or secondary functions of intentions.

Because its main emphasis is on synchronicity rather than diachronicity, the social creation myth has no problem attributing a pragmatic control function to present-directed intentions. It is thus impervious to one of the attractions of the Anscombian creation myth. We need feel no temptation to attribute an epistemic function to present-directed intentions for lack of any other plausible option. The social creation myth, however, does not dispense with epistemic functions altogether, quite the reverse. Not only is the fact that intentions embody a form of self-knowledge essential to their role in the coordination of joint actions, but in addition the way intentions play their coordinative role is by contributing to the alignment of representations with co-agents and thus to the production of shared knowledge. Thus, on the social creation myth, the epistemic function of intentions is not just to provide us with self-knowledge about our intentions and actions, it is also to contribute to the formation of shared knowledge. However, the social creation myth remains closer to the pragmatic than to the epistemic creation myth in considering that the epistemic function of intentions is ancillary to its pragmatic purpose.

Finally, is the social creation myth a teleological myth or, like Velleman's myth, the

story of a spandrel? I must admit that I am not sure what the answer to this question is or should be. Indeed, this was one of the reasons why I chose to call my story a creation myth. One thing is sure though, if it is a story about a spandrel, this spandrel is not the same as Velleman's. His spandrel is a by-product of curiosity and self-awareness. This spandrel, if it is one, would involve a third element, sociality or cooperativeness. Social theories of consciousness (Frith 2010; Graziano & Kastner 2011) propose that consciousness has evolved to facilitate social interactions and enhance social cooperation. On the one hand, a capacity for consciousness is of course a much more general capacity than a capacity for conscious intentions and this may suggest that the latter, as a by-product of this more general capacity, is itself merely a spandrel. On the other hand, if the ultimate purpose of consciousness is to enhance social cooperation, then conscious intentions are a key element in making this possible and calling our capacity for intention a spandrel would fail to do justice to their role.

Conscious Intentions: Do We Need a Creation Myth?

A Commentary on Elisabeth Pacherie

Andrea R. Dreßing

We experience ourselves as agents, performing goal-directed actions in the world. In her paper about *Conscious Intentions: The social creation myth* Pacherie develops a creation myth about the function of conscious intentions, based on her hierarchical concept of individual motor actions and joint action. In this creation myth, conscious intentions are not understood as internal mental states with a teleo-functional role. Having a conscious intention exerts a specific contribution to motor control and conscious intentions might have a potential causal power in this myth.

In this commentary I want to postulate, that Pacherie's social creation myth is more than a myth but rather the search for an explanation of the function of conscious intentions in the physical world. It tries to explain the feature of the intention *being conscious* that endows it with its particular causal function. Yet — speaking about a causal function — the potential analytical and neuroscientific limitations of a causal function of conscious intentions in the social creation myth have to be analysed with regard to the argument of causal closure and results of experimental approaches to the causal relevance of conscious intentions. I argue that despite these limitations the social creation myth could be an important step on the way of finding an explanation about the function of conscious intentions, if the question about the *function* of conscious intentions is slightly adjusted and is not understood in a strictly causal way.

Causal closure | Conscious agents | Conscious intention | Creation myth | Intentional action | Joint action | Mental causation | Neuronal correlates of conscious intention

1 Introduction

We experience ourselves as agents, performing goal-directed actions in the world. This can be a short-term goal of a motor action like grasping a glass of water, or long-term goal, like the plan to call someone later on. One crucial point in both cases is that we know what we do or want to do. We are aware of our goals before and during acting. This awareness constitutes a conscious intention to act. Even further, we seem to

control our actions — at least most of the time — through our intentions. We also have a sense of agency for our actions, which is an immediate feeling of control and authorship (Gallagher 2005). Common sense teaches us that consciousness of our intentions seems to be of unquestionable relevance for our everyday acting.

This experience raises two kinds of questions: *Why* do we experience our intentions as

Table 1: Overview over the different approaches to the explanation of the function of conscious intentions

Anscombe 1963	
Epistemic creation myth	Conscious intentions “provide us with a special kind of self-knowledge” (Pacherie this collection , p. 5)
Bratman 1987	
Pragmatic creation myth	Conscious intentions “[turn us into] temporally extended agents” (Pacherie this collection , p. 3)
Velleman 2007	
Conscious intentions as a spandrel	Conscious intentions are a “by-product of some more general endowments of human nature” (Pacherie this collection , p. 6)
Pacherie this collection	
Social creation myth	conscious intentions “[..are] not just representations of goals but also [...] a specific set of monitoring and control processes, organizing and structuring motor processes that themselves generate movements” (Pacherie this collection , p. 10)

conscious? What is the function of the phenomenal experience of conscious intentions and *how* do intentions exert their role in our acting? These questions address the problem of conscious intentions at two levels. One is about identifying the function and benefits of conscious intentions for our human nature — it is about a myth. The other seems to be above that about understanding, having to do with how the conscious intention exerts its function. It is an attempt to find a scientific, mechanistic explanation about the function of conscious intentions in not only analytical, but also empirical terms (see also [Anderson this collection](#), and [Craver this collection](#)).

In her target article, [Conscious Intentions: The social creation myth](#), Elisabeth Pacherie wants to elucidate the function of conscious intentions and reviews teleological approaches on the role of conscious intentions offered by Velleman, as well as his interpretations of Bratman and Anscombe. In addition, she addresses above-mentioned question about the “how” of the causal role of intentions. Based on her hierarchical concept of individual motor actions and scientific data about joint action, Pacherie develops her own approach to the function of conscious intentions. Her idea is supported by the consideration of the potentially striking role of conscious intentions in joint actions (inter-indi-

vidual actions) regarded as one of the major achievements of the human species. Pacherie’s idea is that conscious intentions have the function of controlling motor action and to intra- and inter-individually align our actions with each other.

Answering the initial question of whether we need a creation myth or not, I would like to answer: no, we do not need a myth. We need, as Pacherie tries to give in her target paper, an explanation. What I perhaps like best about the paper is her focus on the role of conscious intentions in action, while the other creation myths described in her paper only consider a more abstract level. We experience the function of conscious intentions strongly and immediately in individual and joint action. Understanding the function of conscious intentions in this context might therefore be one of the most difficult but promising approaches, as it is so essential for human existence. Her social creation myth has the aim to find an explanation of the function and potential causal role of conscious intentions. The importance of this approach, to my mind, is strengthened by Pacherie’s attempt to combine empirical data and analytical considerations about motor action and motor control.

In what follows, the teleological and social creation myths are first summarized. Postulating that Pacherie’s social creation myth is more

Figure 1: Pacherie’s model of intentional action.

than a myth, it should nevertheless fit the current philosophical conceptions and empirical knowledge about the nature of conscious intentions and their causal function. I therefore analyse it according to contemporary approaches in philosophy of mind and I incorporate knowledge of experimental approaches. I argue that according to these approaches, there might arise some difficulties concerning the causal function of conscious intentions in individual and joint action, postulated in Pacherie’s social creation myth. Discussing a potential solution, how to understand the “causal” role of conscious intentions in the social creation myth despite those limitations, this commentary could serve as a complementary approach to the social creation myth of Pacherie. I want to argue that a creation myth cannot answer the relevant question, *how* conscious intentions play a role in our acting, without considering the nature of conscious intentions and thereby simultaneously focusing on their causal role.

2 Different myths about conscious intentions

According to [Bratman](#)’s pragmatic teleological creation myth (1987), intentions are future-directed action plans, offering humans the capacity to “become temporally extended agents” ([Pacherie this collection](#), p. 3). By forming an intention, which is inert and stable, we are able to predict the future and our future planning and form the basis for further intentions. Pacherie criticizes the future-directedness of conscious intentions and says that the pragmatic account of Bratman is incomplete, as it leaves non-pragmatic and present-directed intentions out of sight. Answering to the non-pragmatic function of conscious intentions, [Anscombe](#)’s teleological creation myth is (1963). [Anscombe](#) (1963) gives the whole debate about conscious intentions a highly interesting epistemic turn; her idea of conscious intentions is that they “provide us with a special kind of self-

knowledge” ([Pacherie this collection](#), p. 5). Her view of conscious intentions is that they provide immediate knowledge of our intentional actions as they provide an immediate non-observational and direct access to the content of our intention. [Velleman](#)’s myth about the function of conscious intentions is different (2007). He proposes that conscious intentions are a spandrel and do not have a teleological function on their own, they are a mere “accidental by-product” ([Pacherie this collection](#), p. 6) of two features of human nature: curiosity and self-awareness. From these features arises the concept of intentions that allows human individuals to understand their actions in the world. Pacherie argues that Velleman’s approach only shifts the problem of the function of conscious intentions to the function of curiosity and self-awareness.

Pacherie’s suggestion is an approach based on empirical knowledge and conceptual considerations about motor cognition. The central element is the suggestion that conscious intentions have a function in motor control. She proposes a three-step hierarchical concept of generation and control of motor actions, developed elsewhere ([Pacherie 2008](#)). Motor actions are controlled in an inverse and forward model, comparing error signals on different levels with each other. On the highest level I-Intentions are formed, referring to an abstract goal. These I-intentions allow for the selection of a fitting motor programme, the P-intention. Based on the P-intention the action underlies an online motor control via the M-Intention.

Although providing evidence for unconscious motor control on the lowest level, [Pacherie](#) argues that a control function of intentions cannot be denied and remains a “central function of intentions” ([this collection](#), p. 9), mainly on the highest level. Unconscious corrections are sufficient for small misalignments on the lowest level, whereas conscious intentions are necessary in the case of large misalignment between the different levels of motor control. [Pacherie](#) declares that “[i]n such case[es] of large

misalignment, error signals would propagate upwards, we would become aware of them, and would shift to a conscious, intentional compensation strategy” ([this collection](#), p. 10). Pacherie also offers a new definition of intentions. She thinks

of monitoring and control processes as intrinsic to intentions, that is, of intentions as encompassing not just representations of goals but also as a specific set of monitoring and control processes, organizing and structuring motor processes that themselves generate movements. ([Pacherie this collection](#), p. 10)

To summarize, one can understand Pacherie’s conscious intentions as having a causal function.

One step further Pacherie suggests that conscious intentions have a coordinative and communicative function in joint action on the basis of her idea that they arise through a hierarchical action control mechanism. Joint action between humans needs a common goal, and success of the joint action is based on our capacity to coordinate actions and share goals, and also to correct and control the individual actions according to the co-agent’s actions. Shared actions can, in analogy to the hierarchical model of individual motor control, be controlled on a sub-conscious low-level. In planned action, however, a hierarchical high level of motor control is needed with which agents represent other’s actions and control their own actions according to a shared goal. Mechanisms for joint action discussed in recent empirical science focus on a perceptual framework with joint attention and allocentric spatial orientation ([Tomasello & Carpenter 2007](#); [Böckler et al. 2011](#) cited from [Pacherie this collection](#)). The question however, is whether this perceptual information is sufficient for successful joint action. Pacherie concludes that *the conscious intention* is necessary to control intra-individual and inter-individual alignment of actions. One major aspect in joint action is communication of joint goals—so the *conscious* intentions help us to communicate our intentions to others and the other way round, to receive information about the inten-

tion of others and to represent them. The influence of other’s intentions then guides our own intentions and the following actions.

After this overview over the different creation myths, we should think about the concept of a “myth” itself. A myth in general tries to find an explanation for a phenomenon that we cannot entirely understand. There seems to be a missing piece of knowledge, a gap, which is filled with an idea—the myth. Defining characteristics of a myth since ancient philosophy are its narrative or descriptive character, without being completely irrational. A myth in Plato’s sense can neither be falsified nor empirically verified ([Partenie 2014](#)). So a myth offers a possible explanation about a phenomenon, without making a claim about truth and without offering a potential empirical approach to the content of the myth. A creation myth about specific functions of conscious intentions is developed, as they seem so unquestionable in our everyday life, and nevertheless, we do not understand, why we have them. The myth—however—does not necessarily need to fit the rules of the physical world.

The social creation myth endows conscious intentions with the important function of a structuring and organizing part in motor action. To my mind, Pacherie develops even more than a myth. The above mentioned characteristics of a myth do not fit Pacherie’s empirically based approach. She wants to understand and explain the function of conscious intentions, and her myth wants to *prepare* us for such a deeper understanding. That is an important step, yet it brings certain difficulties. An explanation has to fit into the framework of current scientific knowledge. Most creation myths and most explanation myths make some implicit or explicit assumptions about the nature of conscious intentions, so do the above-described myths. To make full use of Pacherie’s contribution, we now should begin by *adding* constraints. [Pacherie](#) herself knows these limitations and discusses some of them in her recent paper ([2014](#)). What I want to add is a step-by-step-comparison of the empirical and analytical, metaphysical constraints and her hierarchical model in the following sections.

3 Conceptual constraints: The problem of mental causation

Folk psychology tells us that our bodily movements, our actions, are guided by our intentions. One prominent conception of this assumption was developed as part of a non-reductive approach taken by Searle. For Searle, an action is “a causal and intentional transaction between mind and the world” (1983, p. 88). Searle distinguishes between two kinds of intentions, a *prior intention* and an *intention-in-action*. This distinction serves to preserve the difference between an intention as a basic idea or plan, preceding an action and an intention while carrying out an action. If a person *P* has a prior conscious intention for an action *A*, *P* has a representation of *A* without actually doing *A*. This is—according to Searle—a deliberative state and represents the *action as a whole*. Contrary, the *intention-in-action* occurs simultaneously with the action, representing the actual *conditions of the action*. Conditions can be regarded as certain steps, an action needs to be carried out. *P* has an intention-in-action-while *A*. But, the prior intentions are causally responsible for the intention-in-action and the action itself (Searle 1983).

This is, what—to my understanding—Pacherie’s social creation myth stresses as well. At the beginning of Pacherie’s paper about conscious intentions, a crucial point is made about the causal connection between intentions and actions: “Roughly, the notion on intentions is of a mental state that represents a goal (and a means to that goal) and contributes, through the guidance and control of behaviour, to the realization of what it represents” (this collection, p. 1). Her considerations about intentionality are about practical intentionality, as they concern conscious intentions in action, not only theoretical or cognitive intentions as mental representations. On the level of metaphysics, her statement could be interpreted along the lines of two kinds of property dualism. First it could be interpreted in a functionalist way in which conscious intentions are *abstract* mental properties possessing a causal role for our actions, in which they have a neuronal realisation

or implementation in the background (Lycan 1987; Clark & Chalmers 2002). Secondly, it could be interpreted in a way that declares conscious intentions to be non-reducible, non-physical mental properties, to be local instantiations, which are preceding or accompanying our actions. This notion of conscious intentions describes the conscious intention as a supervening or emerging mental property, which has a physical basis but is not identical or causally dependent with it (Davidson 1980; Kim 1998).

These non-reductional understandings are challenged from a variety of directions. Psychophysical correlations can also be conceptually interpreted using metaphysical models like identity theory (Feigl 1967; Place 1960; Smart 1959) or reductive or eliminative materialism (Churchland 1981), leaving no room for any causal function of conscious intentions. So, according to the most popular models developed after World War II, no conscious intention is a distinct mental entity or an ontological substance in a Cartesian sense. Nevertheless, different assumptions about the nature and the causal function of conscious intentions do exist. To present these in a provocative and simplified way, conscious intentions can either be a mental phenomenon in a physical world and have a causal role (compare: functionalism or non-reductive approaches), or they are causally irrelevant, since they are a by-product of our actions, an epiphenomenon, and as such non-existent (compare this to eliminative materialism).

I now want to focus on non-reductive approaches, as they seem to be relevant for the understanding of Pacherie’s social creation myth. Non-reductive approaches, which are supported by the common sense of conscious intentions and intentional action, and which all suggest that our conscious intention initializes the following action, however, might lead to a dilemma. As Heil and Mele put it: “We confront a dilemma. Either we concede that ‘purposive’ reason-giving explanations of behavior have only a pragmatic standing, or we abandon our conception of the physical domain as causally autonomous” (Heil & Mele 1995, v). The intuition that mental states have causal power is opposed by the rule of causal closure of the

physical world. Kim develops one notion of causal closure with the argument of causal exclusion and supervenience in his essay: *Mind in a Physical World* (1998). In a physical world, in which we do not have a complete physical monism but a non-reductive physicalism with supervenience, two premises are true: (1) every mental property M needs a physical basis P, which is sufficient for the existence of M and on which it supervenes and (2) every physical effect has a sufficient physical cause. Suppose M causes another mental property M*. M* has a physically sufficient basis P*. The problem which arises then is that M and P* as a causally sufficient basis are both responsible for the occurrence of M*, so M has to cause the physical basis P* of M* in a way of mental-to-physical causation. This result conflicts with the premise of causal closure of the physical world, according to which every physical event that has a cause has a *physical* cause (P causes P*). Facing now an over-determination of P*, with two different causally sufficient events *competing* for the causation of P* (M and P), and as P is causally sufficient for M, P seems to be causally sufficient for P*, and M does not have any causal effect itself. A mental phenomenon, according to this view, seems to be causally irrelevant. This is a rather short version of the causal closure-argument; the whole discussion about mental causation and causal closure cannot be displayed here (for an overview see e.g., Heil & Mele 1995). But the causal closure argument seems to be a problem for both: non-reductionist and functional approaches.

What consequences have to be drawn from these considerations about the causal function of conscious intention? Asking for the function of conscious intentions, the different creation myths face the problem of causality in a different way. Both the pragmatic (Bratman) and the epistemic (Anscombe) creation myths are set on a rather abstract mental level of description. Now, coming back to the two-level distinction of intentions introduced by Searle, both teleological myths are about prior intentions. One could say that neither teleological myths require any assumptions about causality, as they do not involve a mind-world directed causality, but

rather an intra-mental causality. In the pragmatic creation myth, intentions are preceded and followed by other intentions or intentions to act. Intentions are merely theoretical intentions as they only have a representational character. We can think of the pragmatic creation myth without any real action going on, as an abstract framework for an explanation of the existence of conscious intentions. The epistemic creation myth does not affect the debate about mental causation either. As only a correlation between conscious intention and action is necessary for the epistemic creation myth, it only draws conclusions about self-awareness and does not make any claim about a causal relation of this self-awareness and an action. In Vellemann's view, conscious intentions are a spandrel, a by-product. This model does not imply any explicit claim about causality either. One could go even one step further and postulate that these myths only address the structure of phenomenological experience of conscious intentions and not the intention itself.

In Pacherie's social creation myth, one cannot deny a causal role of conscious intentions any more. This is what I outlined above, referring to Pacherie's definition about conscious intentions. Intentions are not "just" a representation of abstract goals, but of ongoing control and they structure motor processes and "themselves generate movements" (Pacherie this collection, p. 10). Even more, if conscious intentions are needed to modify a joint action, the perception of goal-directed movements of others leads to a mental representation of this action and the formation of a conscious intention for another action follows from this. The problem with conscious intentions in Pacherie's social creation myth could arise when we understand—as outlined above—the I-Intention as purely functional or supervening mental properties in a non-reductive metaphysical framework. Regarding Searle's distinction between *prior intentions* and *intentions-in-action*, I assume that in Pacherie's model the I-intentions could be regarded as *prior intentions* and the P- and M-intentions rather correspond to *intentions-in-action*. To be more precise in this comparison we should talk about the experience of an inten-

tion as conscious mental representation (I-intention). As outlined above, one major analytical constraint against this understanding is the argument of causal closure. If the conscious intention (the I-intention) as a mental phenomenon or a mental representation has a causal function in action, we have to accept downward causation to understand this (which would be against the rule of causal closure). If the I-intentions only supervenes or emerges from its neuronal activity, or is identical with it, then the intention as a conscious mental representation is causally irrelevant and not necessary for the function of motor control. My claim here is that Pacherie's social creation myth needs the causal function of conscious intentions as mental representations to work. Yet requires that we accept the idea of mental causation. As long as the social creation myth is only a myth, we can break the rules of causal closure easily and just offer the gist or general structure of a potential explanation about the function of conscious intentions. Yet if the myth is an explanation, it has to fit the rules of causal closure, and we have to reconsider either the myth or our understanding of causal closure. Last, we could try to create a myth fitting our physical knowledge, yet have to deny the causal effect of the conscious intentions in motor control.

4 Empirical constraints: Current neuroscientific knowledge about the status of conscious intentions

The question about the function of conscious intentions cannot be answered by conceptual considerations alone. The status of practical conscious intentions can be analysed in motor action—as it is done by Pacherie as well—but not only on the level of theoretical hierarchical models of motor initiation and control but on a mere neurophysiological level. Let's begin with a classical example—the Libet-experiments (Libet et al. 1983, 1985) and their modified versions by Haggard & Eimer (1999). Libet and his colleagues designed an experiment to investigate the temporal connection between a voluntary motor activity and the conscious decision—the conscious intention—for this action. They in-

structed their test persons to voluntarily move their hand and to detect the time at which the urge or the conscious intention to move their hand developed. In parallel, muscle activity was detected via electromyography (EMG) and the readiness potential, a neuronal potential at the beginning of a motor action, was recorded using electroencephalography (EEG). Libet and his colleagues found that the readiness potential can be detected in average 350ms earlier than the test persons experienced the *urge to move* and postulated that according to this finding the decision to move cannot be causally responsive for the action due to a time-based difference. One interpretation of the experiments is that neuronal activity (the readiness potential for the motor activity) occurs before the conscious knowledge of the action itself. So, the conscious intention itself cannot be responsible for a volitional motor action as it occurs later than the subconscious neuronal changes. These findings initiated an on-going debate about the connection between motor activity and the being conscious about this activity, with many neuroscientists supporting the initial hypothesis. Haggard & Eimer detected a lateralized readiness potential (1999). Libet's experiment has been replicated in various alternations, supporting the view that conscious intentions follows pre-conscious brain activity fitting to the movement (Trevena & Miller 2002; Siguru et al. 2004; Rigoni et al. 2011). Similar results were shown for the inhibition of an action (Filevich et al. 2013). fMRI studies (Lau et al. 2004; Soon et al. 2008; Haggard 2008) and transcranial magnetic stimulation-studies postulated a neuronal preceding to motor action similar experimental paradigm (for reviews see Haggard 2005; Shields 2014). One recent fMRI-study for example, reported successful prediction of free choices (addition or subtraction) in the study persons due to fMRI data analysis (Soon et al. 2013). Even single-cell recording in humans—as an objective approach to the self-initiated action—detected neuronal recruitment prior to the intention to act (Fried et al. 2011). The conclusion of above-mentioned experiments frequently is, that the conscious intention of a movement is either an illusion or a post-hoc attribution, generated by the movement itself.

On a conceptual level, there exist other models about conscious motor control besides Pacherie's hierarchical model. An important idea is the idea of intentional binding (Haggard et al. 2002), where an intentional action is causally linked with a certain sensory outcome. In this case, the action and its subsequent effect are perceived as being closer together in time, this generates the phenomenology of causing and independently originating the action, without an actual causal function of the conscious intention. Another current neurobiological theory of motor control is often referred to as comparator model (Frith et al. 2000). Every action consists of two kinds of representations: inverse models that specify motor commands according to sensory perception and forward models that represent the predicted sensory consequences of the movement. When a comparator signals that the sensory consequences of the movement match those predicted by the forward model, we experience this action as consciously intended. Here again, the conscious intention is not causally responsible for the action.

Transferred to the terminology of intentions, this interpretation could mean that a *prior intention* (or I-intention) cannot be causally responsible for an *intention-in-action* (lower level intention) as the neuronal activation pattern for the prior intention was earlier detected than the intention was reported as conscious. What would be the conclusion regarding the social creation myth? As a conscious intention itself—according to the above mentioned interpretation—is not regarded to be causally responsible for the initiation of a motor activity (only the subconscious neuronal activity is responsible) the conscious mental representation of a motor activity in individual or joint action is not causally involved in the processes of motor control. The function of conscious intentions in the social creation myth either stays a myth, as it contradicts the empirical findings, or the myth fits the nature of conscious intentions and we have to reconsider the interpretation of the experiments.

To support the later alternative, one recent study using transcranial magnetic stimula-

tion, a method which allows generating movements by transcranial stimulation of the neurons of the motor cortex, postulated that motor activity is initiated by conscious intentions. A transcranial stimulus was set in the right motor cortex and introduced a tiny muscle twitch, only recordable by EMG. When test persons intended to move their left hand prior to the transcranial stimulus, the transcranial-induced involuntary movement induced a stronger visible motor response. The authors postulated that the conscious intention prepares volitional motor actions by increasing the excitability of the cells in the motor cortex that can produce the movement intended (Zschorlich & Köhling 2013).

There are further some major limitations to the studies, e.g., the subjectivity of the report of the urge to move, and the highly artificial/constructed experimental situation in which the intentional action is carried out. One common objection against an interpretation of the data in the way of Libet and colleagues is that conscious intentions (e.g., the *prior intentions*) are not comparable to the urge to move in an experimental setting but rather are comparable to the decision to participate in the whole experiment. The urge to move would rather be an *intention-in-action* and by this not comparable to a conscious deliberation about an action. Following from the data, a conscious intention is unnecessary or irrelevant (as it occurs “too late”) in conscious motor initiation and control could be a too far-reaching conclusion.

5 The problem of causality and the search for a new myth

The aims of the commentary were first to understand, why Pacherie's social creation myth is more than a myth. Second, I elucidated whether it could, in principle, lay the foundations for an explanation based on and in line with philosophical and experimental ideas about mental causation. This discussion was based on the more general question: do conscious intentions have a causal function in the world? To my mind this question cannot yet be answered conclusively, at least according to our current

knowledge. Postulating a lack of causal function of conscious intentions, as based on analytical considerations and empirical data, might be the only possible solution of the problem. The argument from causal closure postulates that a conscious intention as a mental phenomenon is causally irrelevant, because it is not needed to explain a following physical phenomenon. The experimental data might suggest that an intention becomes conscious only after the neuronal activity is detected. Yet, there still is the strong experience of a causal function for our behaviour.

Now, I want to summarize the problems for the social creation myth, based on the above mentioned discussion and I want to consider possible ways to keep and develop the social creation myth as a potential explanation about the function of conscious intentions. The general question about the function of experienced conscious intentions, as [Pacherie](#) puts it, is the question about “the normative sense, in which having these functions confers benefits on intention-forming creatures that explains why these creatures have this capacity” ([this collection](#), p. 1). This general question is one of the interpretation and explanation of human nature and not a question about causality. The creation myths of Bratman and Anscombe mainly address the question of why we experience our intentions as conscious and goal directed. The question about real-world, physical causality seems unessential for a pragmatic or epistemic benefit for our being and self-awareness, because the pragmatic or epistemic benefit of conscious intentions arises from the experience of a conscious intention and not from its causal effect. The intentions remain theoretical intentions or mental representations and no downward causality is needed. This does not mean that they cannot have a specific and more complex function, but a strong claim about a localized control-function in motor action is simply not possible. In addition, the epistemic and the pragmatic creation myth as well as conscious intentions considered as a spandrel remain “narrative” accounts and even if they would break the causal closure of the physical world, this would not matter in the context of a myth.

Pacherie’s social creation myth first seems to be of a similar kind, explaining human nature and human interaction on the basis of mutual representation of others’ actions and formation of joint actions, which do not necessarily have to be causal for joint action, but only for communication intentions and our understanding joint action. The social creation myth is based on the conceptual, hierarchical model of motor initiation and control. It explains conscious intentions not only in a teleological way, but in an analytical way. It is about practical intentionality. Yet, this confronts it with neuroscientific findings and philosophical considerations about causality:

- Conscious intentions in Pacherie’s social creation myth exert an organizing and structuring function in the motor process and therefore might have a causal function.
- According to standard metaphysical models for psychophysical relations, the conscious intentions in the myth could be interpreted as a non-reducible mental phenomenon. But if this is the right interpretation, we are confronted with the argument of causal closure and they are either causally irrelevant or we have to deny causal closure of the world.
- According to neuroscientific data, we only know little about the nature of conscious intentions, yet nevertheless we have a strong general trend underlying empirical research, a trend that increasingly supports the assumption of a generation of the wanting or the urge to move from neuronal activation, simultaneously or after, but not prior to the movement.

What does this mean for the social creation myth? Regarding the outlined considerations about causality, the problem of the social creation myth about the function of conscious intentions can be solved in different ways. Either we could regard it as a myth in line with the teleofunctional creation myths, only trying to answer the “why”-question about conscious intentions and leaving questions about causality aside. This could sidestep the problem of causality in an easy yet unsatisfy-

ing way. But if we stick to a myth without acknowledging the physical rules of the world we live in, then we will never achieve more detailed knowledge about the nature and the function of conscious intentions. There will be no epistemic progress after the formulation of the myth itself.

Or we try to preserve Pacherie's approach and keep searching for an explanation about the function of conscious intentions. Yet, if conscious intentions have a structuring and organizing function in individual and joint motor action but—according to the common interpretation of above mentioned empirical data—cannot have distinct causal function, how else can the function be described?

One possible solution is, that we might have to overcome the problem of causality in another way. Most interpretations of neuroscientific experiments and the analytical argumentation of causal closure are based on a temporal, linear one-way causality in the way that A causes B because A precedes B. Additionally, one single intention is typically regarded as the cause of the action in a quasi-linear model. My claim is that the common interpretation that a conscious intention—qua being conscious—can only be causally relevant if the conscious intention precedes the motor action, has to be revised. A first motivation for this claim is the fact that there are multiple theoretical and practical limitations regarding the experiments themselves (e.g., [Mele 2011](#); [Radder & Meynen 2012](#); [Pacherie 2014](#)).

But even if the common conceptual interpretation was right, there might be a further terminological problem. In the whole debate about conscious intentions in the social creation myth, we seem to assume that there must be a certain effect of the *being conscious* of the intention. *Because* an intention is conscious, it has an effect to align and control motor action. If it was not conscious, it would not have this effect. To overcome these problems in the debate of the function of conscious intentions, I suggest that a different concept of causation should be considered. This alternative refers to a parallel generation of a con-

scious intention and movement planning. As it is a parallel process and we might be confronted with two aspects of one and the same process, the conscious intention neither precedes nor follows the action generation, but occurs simultaneously and both are influenced reciprocally ([Desmurget 2013](#)). Even further steps may have to be taken. It has been postulated that we cannot trace back the motor action onto one I-Intention in a linear model or to one single place of neuronal activity in the brain. We rather face a semi-hierarchical, parallel and dynamic network from which the motor action arises, without single, identifiable conscious intentions in a direct line of causality but rather fluctuating activity ([Schurger 2014](#)). This would mean that various intentions exist and each of them can influence, control and generate motor action on a neuronal level in parallel, these intentions are among others generated through the observation and interaction with others. Multiple goal representations might form a context for each other. On a conceptual level there would be different I-intentions and different motor programmes going on at the same time. But let us assume that only some of these I-intentions are conscious. Being conscious, for Pacherie, is a necessary condition to exert a motor function and to align actions with others; being conscious is necessary for the causal role in her creation myth. Maybe the function of being conscious could exert a certain weight to an I-intention, not in the way of a linear causality but in a way of dynamic modelling a given social context.

This could save the social creation myth and sheds new light on the interpretation of neuroscientific findings. Whether or not this move answers the question about the function of conscious intentions remains open. The aim should be to further integrate the analytical definitions of mental phenomena and mental causation into neuroscientific research about conscious intentions and try to find a working definition and a concept of what a conscious intention is like. The focus should be on the function of practical conscious intentions and analyse their causal role and function for the hu-

man nature on a neuronal level. Maybe future attempts to arrive at a satisfactory explanation should try to address the causal power of a conscious intention *while* being conscious and not *because of* being conscious.

6 Conclusion

So, do we need a creation myth after all? One thing is certain: conscious intentions unquestionably exist in our experience. We have at least the phenomenal experience of a conscious intention in our acting. As conscious intentions seem so relevant for our human nature we do need a myth about them. But we need even more. Pacherie's social creation myth to my mind is more than a myth; it is one approach, which combines empirical knowledge with a myth about the function and its history. I have only analysed the question of causality from an empirical and metaphysical point of view and its relevance for the social creation myth. In conclusion, we might have to satisfy some further analytical and empirical constraints. Yet, just denying any function of the experience of conscious intentions due to some experimental data or analytical considerations seems premature. A possible solution could be the reconsideration of the concept of causality, to find an explanation of the function of conscious intentions in individual and joint action. Maybe the creation myth and the experimental approach have to be adjusted and be brought together in concept and content, in order to understand the deeper function of conscious intentions. The search for a creation myth should start with creation facts. These facts should help us to elucidate why and how intentions are conscious or at least achieve their phenomenal character, to define the neural correlates or neural correlation in terms of self-organizing, dynamic networks underlying conscious intentions and the causal function in human action, without the limitations of temporal or linear causality and in a more realistic framework of intentional action.

The Causal Role(s) of Intentions

A Reply to Andrea R. Dreßing

Elisabeth Pacherie

In her commentary ([Dreßing this collection](#)) on my target article ([Pacherie this collection](#)), Dreßing suggests that the story I offer is not just a creation myth but also an attempt to give an explanation of the function of conscious intentions in the physical world and as such answerable to both metaphysical and empirical constraints. Here, I try to clarify which of my claims should be understood as simply speculations about the origins of our capacity of intentions and which I take to be empirical claims. In response to the metaphysical and empirical challenge Dreßing raises, I argue that Dretske's distinction between structuring and triggering causes may help us see how explanations in terms of physical properties and explanations in terms of mental properties may not compete but rather complement each other. I argue that this distinction may also help us assuage certain worries raised by neuroscientific findings.

1 Introduction

In her commentary, [Andrea Dreßing](#) ([this collection](#)) suggests that I might have been too timid in calling the story I tell about the social function of intentions in my target article ([Pacherie this collection](#)) a creation myth. She encourages me take a bolder stance, claiming that the story I offer is not just a myth but also an attempt to give an explanation of the function of conscious intentions in the physical world. Indeed, part of my story is intended as more than a myth and so my first task here will be to clarify where I

draw the line between empirical claims and myths.

Dreßing also points out that an explanation, as opposed to a mere myth, has to fit into the framework of current scientific knowledge and is therefore subject to both metaphysical constraints and empirical constraints. I concur. In what follows, I will argue, however, that my general predicament with regard to conceptual or metaphysical constraints is not so different from the predicament of the other myth-tellers I

discuss in my article, as Dreßing suggests. Nor indeed is it direr than the predicament all philosophers of mind working within a naturalistic framework face. Finally, certain empirical findings have been interpreted as showing that conscious intentions play no role in action initiation. I also try to address this challenge.

2 Myths vs. empirical claims

In my target article, I use the phrase “creation myth” first as a dramatization device. Typically, we do not feel the urge to formulate myths about things we deem insignificant. Talking of a social creation myth was thus a way of emphasizing the importance of the social function of intentions, a function largely neglected in traditional accounts of intentions. Second, I also wanted, following Velleman (2007), to convey a note of caution. A myth, as Dreßing points out, can neither be falsified nor empirically verified. It offers a possible explanation about a phenomenon, without making a claim about truth. But I perhaps wasn’t clear enough what I was trying to be cautious about and where I drew the line between empirical claims and ultimately unverifiable explanations. So let me now draw this line more firmly.

To do this, let me distinguish three different questions about intentions and examine how they may relate. The three questions are: *what* roles or functions (in a non-teleological sense) do intentions play in human agency? *How* can intentions play these roles? *Why* do we have intentions in the first place? In my view the *what*- and *how*-questions are both empirical questions for which mythical answers won’t do. The *why*-question, as I understand it, is a question about the origins of capacity for intention. How come we have such a capacity? Why was it established?

The focus of the account I proposed, as well as the focus of the alternative accounts by Bratman (1987), Anscombe (1963), and Velleman (2007) with which I contrast it in my article, is on the *what*- and *why*-questions. However, I offered my story as a creation myth only to the extent that it was meant to address the *why*-question. As answers offered to the *what*-

question, my claims were meant as empirical claims. I take it that the claims made by Bratman, Anscombe, and Velleman about the epistemic and pragmatic functions of intentions, when understood as answers to the *what*-question, should also be interpreted as empirical claims.

Now, how do the *what*- and the *why*-questions relate? One way to relate them is by assuming that intentions do not just have a function or functions in a value-neutral sense—things that they do—but a teleofunction in the evolutionary sense, that is, something that they do that confers some benefit or advantage on creatures with a capacity for intentions, and in this sense explains why these creatures have this capacity.

Velleman cautions us against this teleofunctional move. First, as his discussion of Bratman’s and Anscombe’s accounts makes clear, the *what*-question about intentions can be given complementary answers in terms of both pragmatic and epistemic roles, leaving us with several possible teleological stories. Second, Velleman also warns us against assuming direct links between answers to the *what*-question and answers to the *why*-question. The spandrel story he tells is meant to suggest that a capacity for intentions may only be a by-product of other capacities and thus that our capacity for intentions could be nothing more than an (admittedly very fortunate) accident. Finally, in calling his own story a creation myth as well, Velleman is also pointing out that our speculations about the origins of intentions are most likely beyond falsification or empirical verification.

Similarly, in offering my social function story as an answer to the *why*-question, I was not making a claim to truth. Rather, I was trying to broaden the terms of the debate to also include consideration of the social dimension of intentions. If we are considering what possible teleofunction intentions could have, then we should pay more attention to the benefits we derive from being able to act jointly in a flexible manner. If we are tempted by a story that views a capacity for intention as simply a by-product of more general capacities, then, among these more general capacities, we should pay

serious heed to our capacity for sociality and cooperativeness.

Turning now to the relations between the *what*-question and the *how*-question, I take it that the empirical standing of an answer to the *what*-question ultimately depends on whether this answer can be backed up by a convincing answer to the corresponding *how*-question. The validity of any empirical claim about the causal roles of intentions in human agency will remain in doubt unless one can see how it is at all possible for intentions to play these roles (Dreßing's metaphysical constraints), and it will also remain in doubt if appears to be in contradiction with well-established empirical facts (Dreßing's metaphysical constraints).

Since my claims about the functions of intentions qua answers to the *what*- rather than the *why*-question are intended as empirical claims, they are not insulated from these metaphysical and empirical worries. Let me address them in turn.

3 Metaphysical worries

Dreßing points out that my claim that intentions have a causal role to play in the online control of action confronts me with the problem of mental causation. She also suggests that this problem is more pressing for me than it is for the accounts of the functions of intentions proposed by Bratman and Anscombe. While I agree that the problem of mental causation is an issue for me, I disagree with her assessment that it isn't as serious a worry for these accounts.

First, let me clarify that when I talk about conscious intentions and their causal role, I am concerned with what [Ned Block \(1995\)](#) calls access consciousness rather than with phenomenal consciousness. In other words, my claims are about intentions qua conscious states exploiting and conveying information globally available in the cognitive system for the purposes of reasoning, speech, and high-level action control. My account thus faces the “easy” problems of consciousness rather than the “hard” problem ([Chalmers 1995](#)). I share [Chalmers](#) sanguine assessment

about phenomena pertaining to access consciousness:

There is no real issue about whether these phenomena can be explained scientifically. All of them are straightforwardly vulnerable to explanation in terms of computational or neural mechanisms. ([1995](#), p. 201)

This is not to say, however, that in confining oneself to phenomena of access consciousness one can eschew all metaphysical conundrums. In particular, as pointed out by Dreßing, the mere fact that Cartesian dualism has fallen out of favour and that the vast majority of philosophers and cognitive scientists are nowadays willing to embrace some form of materialist monism doesn't insure the dissolution of philosophical worries about mental causation. The version of the problem of mental causation that non-reductive physicalists, whatever their exact persuasion, are confronted with is the Causal Exclusion Problem: how could mental properties play a causal role given that they appear to be screened off by their physical realizers?

Dreßing argues that this problem is more pressing for my view than for the pragmatic (Bratman) or the epistemic (Anscombe) creation myths, the reason being that these latter two teleological myths are about prior intentions and that neither “require any assumption about causality, as they do not involve a mind-world directed causality, but rather an intra-mental mental causality” ([Dreßing this collection](#), p. 6). Dreßing also claims that Velleman's view does not imply any explicit claim about causality either, since on this view intentions are a spandrel or a by-product.

I disagree with this assessment for three reasons. First, as I explained in section 2, while the speculative character of these stories qua answers to the *why*-question may justify labelling them as creation myths, the stories also offer answers to the *what*-question. In that regard their claims about the epistemic or pragmatic roles of intentions should be taken as empirical claims. Thus, even if we go along with Velleman's claim that a capacity for intentions

is a spandrel and that the epistemic and pragmatic functions of intentions are not teleofunctions, they are nevertheless functions in the ordinary functionalist sense and we still need an explanation of how intentions can play these epistemic and pragmatic roles.

Second, the Causal Exclusion Problem is a problem for anyone espousing a non-reductive form of materialist monism,¹ whether their primary concern is with intra-mental causation or with mind–world causation. Suppose that a state *S* has the mental property *M* (e.g., the property of being an intention to go to London on Monday) and a physical basis *P*, suppose that *S'* has the mental property *M'* (e.g., the property of being an intention to buy a train ticket to London) and a physical basis *P'*, and suppose that *S''* has the mental property *M''* (e.g., the property of being a belief that one will go to London on Monday) and a physical basis *P''*. On a Bratmanian pragmatic account of intentions, I would want to be able to say that my intention to go to London on Monday causes, via further means-end reasoning, my intention to buy a ticket to London. But how can the mental property *M* of *S* play a causal role in bringing about a state *S'* with mental property *M'*, given that they appear to be screened off by the physical properties *P* and *P'*? Similarly, with regard to the epistemic function of intentions, how could I say that my intention to go to London on Monday causes my belief that I will go to London on Monday, given that mental properties *M* and *M''* appear to be screened off by the physical properties *P* and *P''*?

Third, while it is true that on Bratman's account future-directed intentions may only cause behaviour through the mediation of present-directed intentions, still Bratman insists that the whole point of having a capacity for intentions is to produce behaviour that contrib-

utes in the long run to our securing greater desire-satisfaction. Similarly, on a reliabilist reading of Anscombe's epistemic claim that intentions embody knowledge of our actions, they do so because intentions reliably cause what they represent. As Velleman puts it, “[u]nless an intention with the content ‘I’m going to move my toe’ reliably causes my toe to move, it won’t amount to practical knowledge” (Velleman 2007, p. 201). Thus, Bratman, Anscombe and Velleman cannot be exonerated from the task of explaining how mental states can cause behaviour.

With respect to the problem of mental causation, we are all in the same boat. The metaphysical standing of my account is no less or more precarious than the standing of these other accounts. Are we then all metaphysically doomed? Readers should not hold their breath; I have no new, unassailable solution to the problem of mental causation to offer. Yet, it would certainly be premature to claim that the problem of mental causation is insoluble. Many lines of response have been proposed and are currently being explored (for a review, see Robb & Heil 2014). I cannot discuss all these accounts here. Let me just say that the approach I find most congenial stems from Fred Dretske's work (Dretske 1988, 2004) on psychological explanations of behaviour. Dretske distinguishes between triggering causes and structuring causes, where a triggering cause is an event that initiates or triggers a causal chain of events, and a structuring cause the cause of the process or setup that makes a given triggering cause produce the effect it does. To take an example from Dretske (2004), moving a computer mouse is the triggering cause of cursor movement, but hardware and programming are the structuring causes of cursor movement. Dretske's central claim is that mental states and events are best analysed as structuring rather than triggering causes of behaviour. On this view there is no competition between physical and psychological or mental explanations, since they have different explananda. While the triggering physical properties explain bodily motion, i.e., explain why bodily motions occur at a certain point in time, the structuring mental properties explain

¹ While this issue is not at the heart of Bratman's preoccupations, I think we can safely assume that he would want his account of intentions to be compatible with physicalism. I won't dwell here on Anscombe's metaphysical view, except to say that she was no materialist herself but was also highly suspicious of Cartesian dualism (Anscombe 2008). Suffice it to say that many of the philosophers who nowadays embrace the view that intentions have an epistemic function, would want this claim to be compatible with a physicalist stance.

behavior, i.e., they explain why in circumstances of a certain sort, bodily motions of this kind rather than that kind are produced.

Much work remains to be done in order for us to understand more precisely how structural causes operate and in particular how they can do so in the dynamic way needed to account for the plasticity and flexibility of human behaviour. In this respect, Dretske's account remains largely under-developed (for recent work on this issue, see e.g., [Slors 2015](#); [Wu 2011](#)). Dretske's approach in terms of structuring causes has the great merit, however, of offering a potential solution to the Causal Exclusion Problem and to let us see how explanations in terms of physical properties and explanations in terms of mental properties may not compete but rather complement each other. As we will now see, thinking of intentions as structural causes of action rather than triggering causes can also help us assuage certain empirical worries.

4 Empirical worries

The claim that conscious intentions play a causal role in action production should be compatible with our best empirical knowledge on how action is produced. The main empirical worries this claim confronts come from neuroscientific findings that have been interpreted as showing that the time of onset of conscious intentions is not compatible with their being the initiators of actions.

The most famous of these experiments are Libet's studies on "readiness potential" ([Libet et al. 1983](#); [Libet 1985](#)). In these studies, subjects were asked to flex their wrist at will and to note when they felt the urge to move by observing the position of a dot on a special clock. While subjects were both acting and monitoring their urges (intentions, decisions) to act, Libet used an EEG to record the activity of prefrontal motor areas. On average, participants reported the conscious intention to act, which Libet called the W-judgement, about 200ms before the onset of muscle activity. By contrast, the EEG revealed that preparatory brain activity, termed by Libet type II readiness potential

(RP), preceded action onset by about 550ms. In other words, their brains started preparing the action at least 350ms before the participants became aware of their intention to act. This led Libet to the conclusion that the wrist-flexing actions in his experiments were not initiated by conscious intentions but were initiated instead by the (unconscious) RPs.

These experiments and Libet's interpretation of his findings have been widely discussed (see e.g., [Banks & Pockett 2007](#); [Bayne & Pacherie 2014](#); [Mele 2009](#); [Nahmias 2002](#); [Pacherie 2014](#); [Roskies 2011](#)) and commentators have pointed out a number of methodological problems with Libet's paradigm as well as conceptual problems with his interpretation of his results. Let me focus first on one methodological problem and one attempt to address it. I will then consider one conceptual problem

Libet argues that it is the RP rather than the conscious intention that initiate the agent's action. If RPs are the initiators of the action, there should be a robust correlation between them and the actions they cause: we should expect RP events to be "immediately" followed by the appropriate action, or, to put it the other way round, we should expect that when there is no movement, there is also no RP event. As several commentators have observed (e.g., [Mele 2009](#); [Roskies 2011](#)), the back-averaging techniques used in the experiment do not allow us to ascertain whether this is indeed the case. Because the RP on any one trial is obscured by neural noise, what is presented as "the RP data" is determined by averaging the data collected on a large number of trials. In order to compute this average, the EEG recordings on different trials need to be aligned, and this requires some fixed point that can be identified across trials. Since in Libet's experiments action onset serves as the needed fixed point for the alignment of EEG recordings, any RPs that are not followed by an action simply won't be measured, and so we don't know how robust the correlation between the RP and Libet-actions is.

In a recent experiment, Schurger and colleagues ([Schurger et al. 2012](#)) used a modified Libet task to circumvent the limitations of back-averaging techniques. Their aim was to

test the proposal that RPs correlate with pre-decision activity rather than, as Libet proposed, with activity that coincides with, or is subsequent to, the agent's decision. Schurger and colleagues proceeded on the assumption that the decisions of the participants in Libet's experiment can be modelled—as neural decision tasks typically are—in terms of an accumulator-plus-threshold mechanism: decisions are made when relevant evidence accumulated over time reaches a certain threshold. Given that in Libet's task subjects are explicitly instructed not to base their decision on any specific evidence, Schurger and colleagues proposed in this instance that the decision process amounts to simply shifting premotor activation closer to the threshold for initiation of the movement and waiting for a random threshold-crossing fluctuation in RP. Thus, Schurger and colleagues predicted the same premotor activation build-up as Libet when a movement is produced. However, whereas on Libet's post-decision interpretation of this build-up there should be no premotor activity (and hence no RPs) when no movement is produced, on Schurger and colleagues' stochastic decision model there should be continuous random fluctuations in RPs even when no movement is produced. Schurger and colleagues reasoned that it should be possible to capture these fluctuations by interrupting subjects in a Libet task with a compulsory response cue and sorting trials by their reaction times. On the assumption that the interrupted responses arise from the same decision accumulator as the self-initiated ones, and on the assumption that close-to-threshold activity reflects spontaneous fluctuations of RPs rather than mounting preparation to move building over the course of the entire trial, slow and fast reaction times should be distributed equally within trials. In their *Libetus Interruptus* task, they found, as they had predicted, that slow and fast responses to interruptions were distributed equally throughout the time span of the trial.

These results cast serious doubt on Libet's claim that the neural decision to move coincides with the onset of the RP, since spontaneous fluctuations of RPs happen all the time. There-

fore, they also cast doubt on his further claim that since RP onset precedes the urge to move by 350ms or more, conscious intentions can play no role in the initiation of the movement. If instead the neural decision to move coincides with a much later threshold-crossing event, it remains at least an open possibility that this event coincides with and constitutes the neural basis of a conscious urge to move. Schurger and colleagues take no stand on the exact relation between the conscious urge to move and their threshold-crossing event. They insist, however, that this threshold-crossing event should not be interpreted as *the* cause of the movement but rather as just one of the many factors involved in the causation of self-initiated movements. This leads me to my final point.

One conceptual problem with Libet's interpretation of his findings and also, as Dreßing points out, with most interpretations of neuroscientific experiments and a large part of the philosophical debates on mental causation and causal exclusion lies in the conception of causality that is assumed, “namely a temporal, linear, one-way causality” (Dreßing [this collection](#), p. 10). I agree with Dreßing's suggestion that a different concept of causation should be considered, one that allows for multiple causal processes to operate in parallel and to exert influence on one another. This is indeed the spirit of the dynamical model of intentions I have proposed elsewhere (Pacherie 2008). In particular, I insisted that a distal intention does not cease to exist and play a role once a corresponding proximal intention has been formed (and the same goes for proximal and motor intentions). What I suggested is that all three levels of intentions operate simultaneously, each exerting its own form of control, as well as operating together with unconscious processes. Following Dretske's lead, we can think of intentions as structuring rather than as triggering causes of action. On the dynamic hierarchical model of intentions I have proposed, we can further think of the structures set up by intentions as nested. This means that we don't need intentions to initiate actions for them to play a causal role in the production of action. This also means that the intentional online control that I argued was an

important pragmatic function of intention may be best conceived as a form of re-structuring, necessary only when the initial structuring is inadequate.

5 Conclusion

In her commentary, Dreßing suggested that the story I told about intentions should be viewed not just as a creation myth but as an attempt to give an explanation of the function of conscious intentions in the physical world. I tried to clarify exactly what I offered as merely a creation myth, namely the story given in answer to the question “*Why* do we have intentions in the first place?” and what I offered as empirical claims, namely my story as an answer to the question “*What* roles do intentions play in human agency?”

Dreßing also stresses that as an account of the roles intentions play in agency, my story has to meet both metaphysical and empirical constraints. In particular, she suggests that my claims about the role of intentions in action control makes the Causal Exclusion Problem more pressing for me than for other myth-tellers. I argued that the problem is actually equally pressing for all of us who want their views to be compatible with physicalism. I suggested that Dretske’s distinction between structuring and triggering causes and his view that mental properties should be understood as structuring causes may offer a solution to this metaphysical problem. Finally, Dreßing remarks that my claims concerning the role of conscious intentions appear to clash with certain findings from neuroscientific experiments. In response, I briefly discussed the most famous of these experiments, Libet’s RP experiments, and pointed out some of their limitations. I also questioned, together with Dreßing, the conception of causation with which these debates tend to operate, and suggested that Dretske’s distinction between structuring and triggering causes may also help to reconcile neuroscientific findings and claims about the causal roles of intentions.

Naturalizing Metaethics

Jesse Prinz

Decades ago, it was suggested that epistemology could be naturalized, meaning, roughly, that it could be treated as an empirically-informed psychological inquiry. In more recent years, there has been a concerted effort to naturalize ethics, with a focus on questions in moral psychology, and occasional normative ethics. Less effort has been put into the naturalization of metaethics: the study of what, if anything, makes moral judgments true. The discussion presents a systematic overview of core questions in metaethics, and argues that each of these can be illuminated by psychological research. These include questions about realism, expressivism, error theory, and relativism. Metaethics is beholden to moral psychology, and moral psychology can be studied empirically. The primary goal is to establish empirical tractability, but, in so doing, the paper also takes a provisional stance on core questions, defending a view that is relativist, subjective, and emotionally grounded.

Keywords

Error theory | Expressivism | Metaethics | Moral realism | Naturalism | Relativism | Sentimentalism

1 Introduction

Moral philosophy has taken an empirical turn, with experimental results being brought to bear on core questions in moral psychology (e.g., is altruism motivated by empathy?) and normative ethics (e.g., how plausible are the presuppositions of virtue theory?). Some of the recent empirical work also bears on core questions in metaethics. Metaethical questions are varied, but they broadly concern the foundations of moral judgments. What is the basis of such judgments? What, if anything, could render them true? Here I will argue that these questions can be empirically addressed, and longstanding debates between leading metaethical theories may ultimately be settled experimentally. I will describe empirical results that bear on core metaethical questions. I

will not present these results in detail here. My goal is programmatic: I seek to establish the empirical tractability of metaethics. Some of the experiments I describe are exploratory pilot studies, presented in an effort to motivate more research. Even with such preliminary results, we will see that some metaethical theories already enjoy greater empirical support than others. I will argue that the best-supported theory at this stage of inquiry is a form of relativist sentimentalism. Defending this position is subsidiary to my primary goal of advertising the value of empirical methods in metaethical theorizing. There has already been an empirical turn in ethics, but metaethics has been less explicitly targeted by these new approaches.

Talking about “an empirical turn” clearly alludes to another turn in the recent history of

philosophy: the linguistic turn. When philosophers turned their attention to language, there was an effort to recast philosophical problems as linguistic in nature. A new set of technical tools was brought into the field: formal semantics. Logic has been part of philosophy historically, but after the linguistic turn it was perceived to be an essential component of philosophical training. Just as formal semantics increased philosophical precision with the linguistic turn, empirical methods have dramatically augmented our tool chest, and stubborn debates may begin to give way. The empirical turn is as momentous as the linguistic turn, and perhaps even more so. Formal semantics allowed us to articulate differences between theories, and empirical methods provide new opportunities for theory confirmation. Neither turn rendered traditional approaches to philosophy idle, but rather supplemented them. Within metaethics, this supplementation may offer the best hope of settling which competing theories are true.

In calling for a naturalist metaethics, it is important to avoid confusion with two other views. “Naturalism” is sometimes construed as a metaphysical thesis, and also sometimes as a semantic thesis. Metaphysically, “naturalism” refers to the view that everything that exists belongs to the natural world, as opposed to the non-natural, or supernatural world. This is sometimes presented as a synonym for physicalism, which can be defined as the view that the world described by the physical sciences is complete, in that any physical duplicate of this world would be a duplicate simpliciter. The causal closure of the physical world and the success of physical science are taken as evidence for this metaphysical view. Semantic naturalism attempts to reductively analyze concepts from one domain in terms of another, which is considered more likely to be natural in a metaphysical sense. In philosophy of mind, this might involve defining psychological concepts in neural or causal terms, while in ethics it might involve defining moral properties in terms of psychological, logical, or social terms (such as hedonic states, principles of reason, or social contracts). Here I will be concerned with methodological naturalism, which has recent roots in the work of

W.V.O. Quine, who grew skeptical about philosophizing through linguistic analysis, and emphasized the empirical revisability of philosophical claims (1969). Quine drew on the methods of John Dewey, and insisted that “knowledge, mind, and meaning [...] are to be studied in the same empirical spirit that animates natural science” (1969, p. 26). More succinctly, methodological naturalism can be defined as follows:

Methodological naturalism =_{Df} the view that we should study a domain using empirical methods.

This is the kind of naturalism that has long been advocated, but too rarely followed, in the domain of epistemology (Kornblith 1985). Neither metaphysical nor semantic naturalism are equivalent to methodological naturalism. Metaphysical naturalism is a view about what exists, not about how to study it. Indeed, some non-naturalists in this metaphysical sense believe that empirical methods can be used to study non-physical or supernatural entities. Semantic naturalism is a view about how to state theories (viz., in reductionist terms), but practitioners have rarely used empirical science in defense of such theories (consider so-called naturalistic semantics). Methodological naturalism has been deployed in discussions of both first-order ethics (e.g., Brandt 1959; Flanagan 1991; Doris 1998; Greene 2007) and in metaethics (e.g., Railton 1993; Prinz 2007b). As Railton points out, a naturalist methodology could result in a reductionist theory of morality, but it need not (see also Boyd 1988). In principle, science could support traditional intuitionism, which is not naturalistic in either of these other senses.

1.1 Methodological preamble

Philosophy has always been methodologically pluralistic. Some use intuitions to arrive at necessary and sufficient conditions for the application of concepts (e.g., Plato’s early dialogues). Some try to systematize and revise a large set of beliefs using reflective equilibrium (e.g., Rawls on justice). Some use transcendental ar-

guments to figure out preconditions for thought and action (e.g., Kant). Some use aphorisms or stories to reveal facts about ourselves or to envision possible alternatives (e.g., Nietzsche and the existentialist tradition). Some propose historical analyses of prevailing institutions and values (e.g., Hobbes, Rousseau, and Foucault). Some disclose hidden social forces that buffer prevailing categories (e.g., Marilyn Frye on gender). Some analyze case studies (e.g., Kuhn), probe the structure of experience (e.g., Husserl), or propose formalizations (e.g., Frege). These and other methods suggest that philosophy is a many-splendored thing, and among its many forms one can also find the deployment of empirical results. Examples include Descartes and James on the emotions, Merleau-Ponty on embodiment, and Wittgenstein on aspect perception. Empirical observations have often guided philosophical inquiry. Locke was inspired by corpuscular physics, Marx took solace in Darwinian biology, and Carnap incorporated ideas from behaviorism.

The term “empirical” is used in different ways. In its broadest application, it refers to observational methods. Observation can include an examination of the world, both inner and outer, with and without special instruments. Even introspection can be regarded as a form of observation, as the etymology of the term suggests, and in this sense, the introspection of intuitions is an observational method. Philosophers who use intuitions in theory-construction can be characterised as doing something empirical in this broad sense. Linguistics has used such intuitions to construct syntactic theories, and few would deny that syntax is an empirical field. But the term “empirical” is also used more narrowly to refer to the use of scientific methods, which involve the design of repeatable observation procedures, and the quantification and mathematical analysis of data. The empirical turn in philosophy has been marked by a dramatic increase in the use of scientific results.

Many philosophers have long held a positive attitude toward science, but the frequent use of scientific results (outside of the philosophies of science) is a recent phenomenon. It became popular in naturalized epistemology, which

draws on the psychology of decision-making, and philosophy of mind, which has drawn on psychology, computer science, and artificial intelligence. Over the last decade, empirical methods have also become widely used, and widely contested, in ethics.

The resistance to empirical methods in ethics is often chalked up to the fact that ethics is a normative domain, and empirical methods provide descriptive results. This can only be part of the story, however, as there has been little uptake of empirical methods in metaethics. Metaethics is a descriptive domain; it does not tell us how to act morally, but rather explores the semantic commitments and metaphysical foundations of such claims. I suspect the reason for resistance is less interesting and more sociological. Psychology is a young profession, which grew out of philosophy and physiology but then acquired its own institutional standing in the academy, and it has had to fiercely guard its status as a science by distancing itself from the humanities. Meanwhile, philosophy underwent an analytic turn, which led to a preoccupation with conceptual analysis, and an anxiety about psychologism. On this vision, the field began to model itself on logic or mathematics, which were, in turn, taken to be *a priori* domains. I think this is a fundamental mistake. In many domains, the concepts that matter most are grounded in human usage, not in a transcendental realm like (allegedly) mathematics. The arbiters of conceptual truth include both the inferences we are inclined to draw and our linguistic behavior, both of which can be studied empirically. I will not argue directly against *a priori* approaches, but will instead make an empirical case, or better yet an invitation, by attempting to illustrate how empirical findings make contact with traditional philosophical questions in metaethics.

One manifestation of the empirical turn has been the rise of experimental philosophy. This term most often refers to the work of philosophers who conduct studies that probe people’s intuitions about philosophical thought experiments. Strictly speaking, much of this work is not experimental, since the term “experiment” is often reserved in psychological re-

search for studies in which researchers attempt to manipulate the mental states of their participants—experimental conditions are compared against control conditions. Experimental philosophy often explores standing intuitions, rather than the factors that influence those intuitions (e.g., [Mikhail 2002](#)). For example, some trolley studies simply poll opinions about the permissibility of certain actions. That is a survey rather than an experiment. One can use survey methods to conduct experiments, however. For example, one could conduct a trolley study in which some vignettes use evocative language in an effort to manipulate participants' emotions. Few experimental philosophy studies do anything like this. Most ask for opinions without manipulating psychological states. Thus, experimental philosophy characteristically examines the *content* of people's concepts and beliefs, rather than the underlying psychological processes. In this sense, experimental philosophy is an extension of conceptual analysis. For those interested in underlying processes, it can, to this extent, be of limited interest. Some experimental philosophy has also been criticized for failing to meet standards of reliable behavioral research ([Woolfolk 2013](#)). That said, conceptual questions are often important for philosophical theorizing, and methodological problems with experimental philosophy can be addressed by conducting better and better experiments. Often the first efforts (including much of the work I will describe below) are best regarded as analagous to pilot studies, in need of refinement but successful enough to warrant more careful investigation. In addition, many philosophers draw on (and increasingly conduct) studies that qualify as genuine experiments and meet the standards of good social science. There is a long tradition of philosophers using research published in social science journals to defend philosophical positions. For those who find paradigm cases of experimental philosophy too limiting (because they are based on conceptual intuitions or fail to meet certain standards), there are many other empirical results that can provide illumination. The term "empirical philosophy" can be used as a broader label to cover both opinion polls and experimental manipula-

tions. As I use the term, it refers to the use of scientific results, whether obtained by a philosopher or not, to address philosophical questions. The empirical turn should not be dismissed as philosophy-through-opinion-polls; it is a multi-pronged effort advance philosophical debates by drawing upon observational methods of any kind.

The motivations for the empirical turn are varied, but the most general impetus is the belief that some questions cannot be resolved by more traditional philosophical methods. For example, philosophers interested in the physical basis of consciousness cannot rely on introspection or on an analysis of the concept "conscious." And even those interested in analysis of concepts have worried about the limits of introspection. There are basically three different theories of what concepts are: Platonic entities, emergent features of linguistic practice, or psychological states. None of these can be completely investigated by introspection. Even psychological states can be difficult to introspect, because much mental activity is unconscious, and because introspection may be prone to error and bias. Moreover, even if a philosopher could perfectly introspect her own concepts, she would not know thereby that others shared the same concepts, and this would greatly limit the scope of her theories. Some experimental philosophers have argued that philosophers' intuitions are not shared by laypeople. When philosophers and laypeople do agree on intuitions, there is still no guarantee that these accurately reflect reality. For example, most people (at least in the West) find it intuitively plausible that human action derives from character traits, but some empirical philosophers (most notably Owen Flanagan, John Doris, and Gilbert Harman) have drawn attention to psychological research that challenges this assumption.

Traditional and empirical approaches to philosophy are sometimes placed in opposition, but they can also be regarded as interdependent. On one division of labor, traditional methods are used to pose questions and to devise theories that might answer those questions. Empirical methods can then be used to test these theories. This is an over-simplification, of course, because observa-

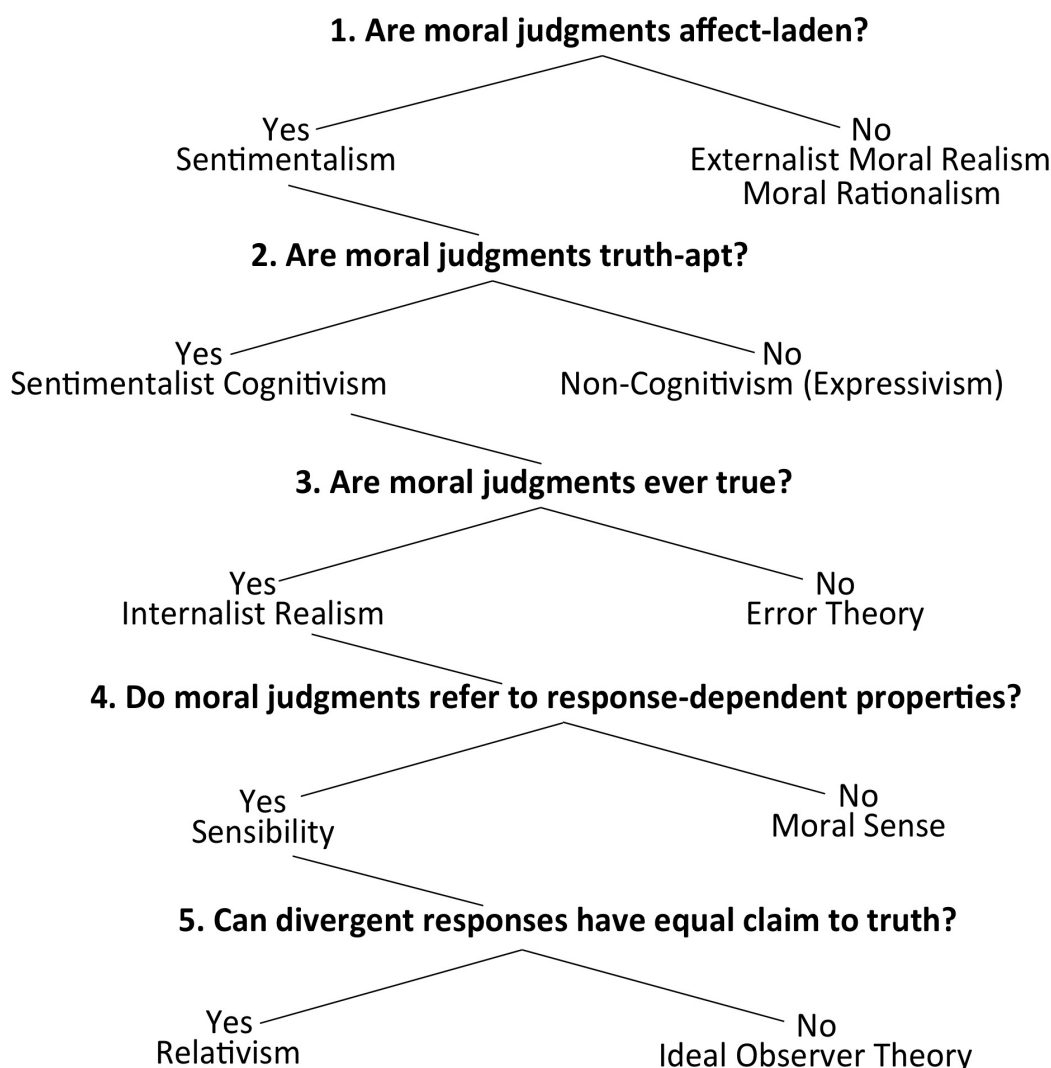

Figure 1: A Metaethics decision-tree

tions can inspire theories, and traditional methods can sometimes refute theories (Gettier cases are a parade example in epistemology), but the proposed division of labor is a decent approximation. Traditional methods have limited testing power because theoretical posits are often difficult to directly observe, and empirical methods have limited power in constructing theories, because theories outstrip evidence. In what follows I will test theories derived from philosophical reflection against the tribunal of empirical evidence.

1.2 A roadmap to metaethics

Let us turn now to the focus of discussion: metaethics. Metaethical questions concern the nature of the moral domain. Metaethicists ask: what kinds of things are we talking about when

we make moral judgements? Put differently, metaethics concerns the truthmakers of moral judgements: what kinds of facts, if any, make moral judgements true? That is a metaphysical question but it is normally approached semantically by exploring what we are semantically committed to when we make moral judgements. Metaethics differs from first-order ethics, which concerns the content, derivation, and application of such judgements.

There are many different metaethical theories, and a complete survey here would be impossible. I will focus on major theories that have emerged over the last two hundred and fifty years, with emphasis on proposals that dominated discussion in the twentieth century. To be clear from the outset, my goal is not to consider specific theories that have been ad-

vanced by currently active authors in metaethics. Rather, I will survey broader classes of theories that have been around for some time (decades or centuries) in an effort to establish the relevance of empirical work. An adequate examination of any recent theory would require a narrower focus than I am after here, since each theory makes empirical commitments, if at all, in different places.

To facilitate discussion, I will map out the theories of interest using a decision tree (Figure 1). The tree could easily be arranged differently. Almost any branch could be the starting place, with other nodes occurring higher or lower than they are in this rendition. As we will see in a moment, I begin with a question about “affect” or emotions. This may seem odd to some contemporary metaethicists. Some contemporary metaethicists discuss emotions (such as [Alan Gibbard 1990](#), and [Simon Blackburn 1998](#)), but others do not (for example, emotions are discussed less among moral realists). Historically, however, emotions have been a central focus in metaethics. British moralists, who advanced many of the questions that continue to drive the subfield, often begin their analyses with a discussion of moral sentiments. Indeed, the most famous controversy in metaethics before the twentieth century is probably the dispute between British sentimentalism and Kantian rationalism. Even in the twentieth century, some of the most discussed debates concern emotions, such as the debate between emotivists and their opponents. Moreover, the recent empirical turn was triggered, in part, by discoveries linking emotions to moral judgement. So this starting point has considerable historical depth and great relevance to the methodological sea-change that I am interested in here. That said, I don’t intend this tree to be anything like a complete map of meta-ethics. One could begin elsewhere and branch out in further directions (I expand the tree leftward, but interesting questions also come up on the right). Though incomplete, the nodes of this tree encompass much of what one might cover in an introduction to metaethics in the Anglophone analytic tradition.

The first question in the metaethics decision tree is, I note, a question about emotions. More precisely, we can ask: are moral judgments affect-laden? The term “affect” is used instead of “emotion” here, because it is broader. I intend the term to cover any conative state, such as a preference, desire, or pro-attitude. For most of this discussion, I will focus on emotions rather than these other affective constructs, because emotions are implicated in the empirical work I will be considering.

The other key term in question 1 is “moral judgments.” By “moral judgments” I mean atomic judgments using thin moral concepts, such as *wrong*, *bad*, or *immoral*. The judgment expressed by “Shoplifting is wrong” would be an example. There are many other judgments that arise in moral contexts, including judgments containing thick concepts, such as *cruel* or *unjust*. One can also ask whether these are affect-laden. On one analysis, thick concepts are hybrids that have both a descriptive and an evaluative component, the latter of which may implicate the emotions. For the sake of simplicity I will ignore that debate here.

Notice that judgements are not sentences but rather the thoughts that sentences express. To propose that such thoughts are affect-laden is to say that each token instance involves an emotion or other conative state. There are different forms of “involvement” that have been discussed in metaethics. On some theories, moral judgments contain conative states as constituent parts. This was the view of Francis Hutcheson, David Hume, and some other British moralists. One might weaken this by saying that moral judgments do not contain emotions, but refer to them. In this vein, John McDowell, David Wiggins, and Alan Gibbard suggest that moral judgments reflect the conviction or norm that it would be warranted to feel certain emotions. Both of these approaches have gone under the heading “sentimentalism,” with the prefix “neo-” for the views that say the link between moral judgments and emotions is second-order. Here is a definition:

Sentimentalism =_{Df} Moral judgments essentially involve affective states, such as emotions, in one of two ways: such states are constituent parts of moral judgments (traditional sentimentalism); or moral judgments are judgments about the appropriateness of such states (neo-sentimentalism).

Those who deny that moral judgments are affect-laden fall into different categories, but two of the most important metaethical theories of this kind are externalist moral realism and (some forms of) rationalism. Moral realists say that there are moral facts, which is to say that some states of affairs are truly right or wrong (cf. [Sayre-McCord 1988](#)). Externalist moral realists add a further requirement, namely mind-independence:

Externalism moral realism =_{Df} There are moral facts and these obtain independently of our recognition of them.

If moral facts are mind-independent, it also follows that we can come to know them without being moved by them. Like scientific facts, we can know that they obtain without feeling any way towards them. Cornell realists, some intuitionists, and many divine command theorists fall into this category. Moral rationalism is a view about how the epistemology or normative status of moral truths:

Moral rationalism =_{Df} Moral truths can be discovered and justified through a purely rational decision procedure.

[Kant \(1797\)](#) is traditionally read this way, though he also claimed that moral judgments involve moral feelings.

The remainder of my metaethics decision tree concerns those who think that moral judgments are affect-laden. Among those who say that moral judgments essentially involve conative states, there is a divide between those who think that moral judgments are nevertheless truth-apt and those who deny this. This is the second division of the tree. A judgment is truth-

apt if it is the kind of thing that can be evaluated as true or false. Some affect-laden judgments may turn out to have a merely expressive function. If I say, “Disco sucks!” I may not be attempting to represent a fact, but merely expressing how I feel. Expressivists follow this analogy:

Expressivism =_{Df} Moral assertions express mere feelings or non-assertoric attitudes, and do not purport to convey facts.

Charles Stevenson and A. J. Ayer are credited with devising the emotivist theory of morality, which is the simplest theory of this kind. A more sophisticated variant has been developed by Simon Blackburn, who proposes that moral judgments aspire for quasi-truth, but not truth, and thus an ontologically neutral stand-in—which can explain why moral judgments have an assertoric form. Alan Gibbard says that moral judgments do not directly express feelings, as emotivists claim, but rather express the acceptance of norms according to which feelings such as anger and guilt would be appropriate. All these theories have been broadly classified as expressivist.

Those who say that moral judgments are affect-laden and truth-apt need not deny that moral judgments are expressive, but they insist that they more than express feelings; they assert facts. If so, moral judgments can be true or false. Subjectivism falls into this camp:

Subjectivism =_{Df} the truth of the judgment that something is morally good or bad depends on the feelings or other subjective states of someone who makes that judgment.

For instance, one might propose that “killing is wrong” means “I disapprove of killing.” That judgment is true, if the speaker disapproves of killing, and false otherwise. As we will see, there are also more sophisticated forms of subjectivism. Subjectivists are internalist moral realists: they believe in moral facts, but they deny that those facts obtain independently of our attitudes.

The term “cognitivism” has been used to refer to any view on which moral judgments are truth-apt, which is to say they can be assessed for truth. Expressivists are non-cognitivists, and both subjectivists and external moral realists are cognitivists. One could also have a cognitivist theory and nevertheless insist that all moral judgments are false. This would be an error theory.

Error theory =_{Def} Moral judgments are truth-apt, but they are never true.

The most famous error theory comes from J. L. Mackie. Mackie argues that moral judgments are incoherent. On the one hand, they presuppose that moral facts are objective, which is to say mind-independent. On the other hand, moral judgments presuppose that moral facts are action guiding, and that suggests that they directly motivate us. This suggests that moral judgments must be affect-laden, or otherwise dependent on our subjective states. Since nothing can be both objective and subjective, moral judgments can never be true. Opponents of the error theory deny this and insist that some moral judgments are true. They are, in this sense, moral realists. Moral realists who also claim that moral judgments are affect-laden must take Mackie’s challenge head on, showing that truth is compatible with being action-guiding.

Such sentimentalist realists face an immediate question. They can accept Mackie’s claim that moral judgments represent objective properties, and find some way to circumvent the incoherence, or they could say that moral judgments refer to properties that are subjective, or response-dependent. The first option might seem untenable, since it accepts that moral judgments are both objective and subjective, an apparent contradiction. But the contradiction can be mitigated by distinguishing between sense and reference. One might say that moral concepts have affect-laden senses—that is, we grasp them by means of feeling—and objective referents. Consider, for example, Kant’s aesthetics, according to which beauty consists in a kind of purposeful purposelessness that causes a free-

play of the understanding, which results in aesthetic pleasure. A work may have purposeful purposelessness without our recognizing that this is so, but when we recognize it, we feel a certain way. Within ethics, Francis Hutcheson may have held a view that was objectivist and subjectivist in just this way. He suggests that moral facts are established by divine command, but God has furnished us with a moral sense, and that sense works by means of the emotions; when we see objectively bad actions, we feel disapprobation. This has been called a moral sense theory, because it treats our moral passions as a kind of sensory capacity that picks up on real moral facts.

In contrast to this view, one might argue that moral facts are not objective, as Mackie has maintained, but rather are dependent on our responses. This need not imply that moral judgments are mere expressions of feeling; one might say instead that moral judgments refer to response-dependent properties. The idea of response-dependent properties derives from John Locke’s notion of secondary qualities. Primary qualities, such as shape, for Locke, exist independently of being perceived, whereas secondary qualities consist in the power that certain things have to cause responses in us. Colors, for Locke, are not out there in the world, but consist in the fact that objects cause certain sensations in us. The moral analogue of this view has been called the sensibility theory, and its adherents include John McDowell, David Wiggins, and David McNaughton. They resist the causal language found in Locke’s theory of colors, but say something close:

Sensibility theory =_{Def} moral properties are those that warrant moral emotions.

Strictly speaking, the sensibility theory is a form of subjectivism, since it says that moral judgments refer to subjective properties (the property of warranting moral emotions), but the notion of warrant allows these theorists to avoid a pitfall or simple subjectivism. For a simple subjectivist it makes no sense to wonder whether something that I disapprove of is really wrong, but for the sensibility theories I can en-

certain such doubt because I can wonder whether an event really warrants what I happen to feel. The notion of warrant here is not unproblematic, and it often goes unanalyzed. There is one notable exception, however, and that is the ideal observer theory (Firth 1952; Brandt 1959):

Ideal observer theory =_{Def} The morally good or bad is that which an observer would regard as good or bad under ideal circumstances.

Such circumstances might involve acquiring the status of a moral sage (or consulting a moral sage), as on some virtue theoretic theories, or an ideal version of myself (Smith 1994). Ideal observer theorists are committed to response-dependence; they say that responses determine moral truth, and they further require that those responses come from certain kinds of epistemic agents.

Ideal observer theories offer a negative answer to the final question in the metaethics decision tree. They specify conditions of ideal observation in order to find an authoritative set of responses among a diversity of moral opinions. The hope is that one set of judgments will emerge as epistemically superior to all others; on this view, all moral judges converge under ideal conditions. Here, moral truths work out to be universal. This, of course, is a controversial claim. Suppose we define ideal observers as those who are free from bias, aware of pertinent non-moral facts, and reasoning carefully. It could turn out that, two such observers could still disagree on moral matters. This prognosis leads toward the view that there is no way to arrive at moral consensus. Those who think that moral judgments are rendered true by a judge's response but deny consensus under optimal epistemic conditions end up saying that moral judgments are relative. This view can be stated as follows:

Metaethical relativism =_{Def} Two judgments expressed using tokens of the same word types, and grasped by tokens of the same mental attitude types can have different

truth-values if they are made by different observers.

I will now try to show that each question on the decision tree can be empirically illuminated. Some of the empirical results that I will present come from unpublished, exploratory studies. My goal here is not a detailed documentation of scientific findings, but rather to establish, by means of example, ways in which empirical methods might be brought to bear on the foregoing questions. The hope is that the studies described here might be taken up by others and improved upon.

2 Empirical resolutions to metaethical debates

2.1 Sentimentalism vs. rationalism and externalism

Let's begin with the first question on the metaethics decision tree: are moral judgments affect-laden? No question in ethics has received more empirical attention than this. Dozens of studies have attempted to determine whether emotions play a central role in morality, and the evidence has consistently shown that they do. Let me begin with an unpublished study of my own and then offer a brief review of the empirical literature.

To begin with, let's consider folk intuitions. Do ordinary people use emotions as evidence when attributing moral judgments? To test this, I conducted a simple vignette study, which pitted emotions against verbal testimony. A group of college undergraduates taking an introductory-level philosophy class responded to the following probe:

Fred belongs to a fraternity and his brothers in the fraternity sometimes smoke marijuana. Fred insists that he thinks it's morally acceptable to smoke marijuana. He says, "You guys are not doing anything wrong when you smoke." But Fred also feels disgusted with his frat brothers when he sees them smoking. One day, to prove that he thinks smoking is okay, he smokes marijuana himself. Afterwards, he feels incredibly ashamed about smoking the drug.

Which of the following seems more likely:

1. Fred says he morally approves of marijuana smoking, but in reality he thinks it is morally wrong.
2. Fred feels badly about smoking marijuana, but in reality he thinks it is morally acceptable.

In my small sample, 68.4% chose answer 1, suggesting that the majority of them take emotions as evidence for moral values, even when that directly contradicts self-report. This suggests that many people take emotions to be a sufficient evidence for attribution moral attitudes. An even more dramatic result was obtained when another twenty participants assessed this scenario:

Frank belongs to a fraternity and his brothers in the fraternity sometimes smoke marijuana. Frank insists that their actions are morally unacceptable. He says, “You guys are doing something wrong when you smoke.” But Frank does not feel any anger or disgust when he sees his frat brothers smoking. One day, when they are not around, he smokes marijuana himself. Afterwards, he doesn’t feel any shame about smoking the drug.

Which of the following seems more likely:

1. Frank says he morally opposes marijuana smoking, but in reality he thinks it is morally acceptable.
2. Frank doesn’t feel badly about smoking marijuana, but in reality he thinks it is morally wrong.

Here, 89.5% of participants chose response 1, indicating that they take emotions to be necessary for the attribution of moral attitudes. Absent the right feelings, verbal testimony is treated as an unreliable indicator of a person’s values.

This study has at least four serious limitations: people may not trust self-reports; the results were far from unanimous; it fails to distinguish evidence for moral attitudes and essence of moral attitudes; and folk beliefs about moral judgments may be wrong. To get around these

limitations we must move beyond experimental philosophy, and look for more direct evidence that emotions actually are sufficient and necessary for moral judgments. But the study is still revealing, because it shows that emotions are used as evidence in moral attribution. Most participants make attributions that fall in line with sentimentalism.

To show that emotions actually do contribute to moral cognition, we can look at three kinds of evidence: cognitive neuroscience, behavioral psychology, and pathology. In each domain, sentimentalism finds support. There have now been dozens of neuroimaging studies on moral judgment tasks, and every one of them, to my knowledge, shows an increase in activation in brain structures associated with emotion, when moral decisions are compared to non-moral decisions. Key structures include the posterior cingulate, temporal pole, orbitofrontal cortex, and ventromedial prefrontal cortex. There are only two groups of studies that even appear to depart from this pattern. [Joshua Greene et al. \(2001\)](#) report that emotions play more of a role in deontological judgments than in consequentialist judgments, but their data show that, as compared to non-moral judgments, emotions are involved in both (see their Figure 1). Moreover, Greene et al. use moral dilemmas in which the common denominator is saving lives—they manipulate the nature of the harm necessary in order to save five people in danger. Thus, each moral judgment condition presumably elicits the judgment that it would be good to help people in need. This positive moral judgment may be emotionally grounded, but the neuroimaging method subtracts away this emotional information, because it is present in each scenario, and imaging results of this kind report only contrasts between different conditions. Thus, a major dimension of moral emotions may be systematically concealed by the method. The other study that fails to show an increase in emotional responses during moral judgment is one condition in a series of imagining experiments performed by [Jana Borg et al. \(2006\)](#). But, in that condition, a moral scenario is compared to a scenario about an encroaching fire that threatens one’s property, and it is un-

surprising that moral judgments produce less of an emotional response than a case of personal loss.

Brain science resoundingly links moral judgment to emotion, but the method is correlational. Moral rationalists and externalists could concede that moral judgments excite emotional responses, while denying that these are the basis of moral judgment. Imagine the following view: we use reason to arrive at moral judgments, but morality matters to us, so when we arrive at those judgments emotions normally kick in. By analogy, reason might be used to determine that certain life activities (smoking, high fat diets, sleep deprivation) are harmful, and, upon drawing that reason-based conclusion, we tend to experience corresponding emotions, such as anxiety when contemplating lighting a cigarette. Neuroimaging results showing responses to cigarettes might confirm this, showing emotion areas active when cigarettes are seen, but that wouldn't refute a rationalist theory of how we arrive at the judgment that cigarettes are dangerous.

To adjudicate between the thesis that emotions are constitutive of moral judgments, as opposed to mere consequences, we need behavioral evidence. Numerous studies now establish a causal link between emotion and moral judgment. When emotions are induced, they influence how good or bad things seem. Induction methods have been widely varied: hypnosis, dirt, film clips, autobiographical recall, and smells. In one recent study, Kendal Eskine, Natalie Kacinik, and I induced bitterness by giving people a bitter beverage and found that moral judgments became more severe ([Eskine et al. 2011](#)). In other recent studies Angelika Seidel and I use sound clips to induce specific emotions, and we have shown that different emotions have different moral effects: anger induces more stringent wrongness judgments about crimes against persons; disgust induces greater stringency on crimes against nature (such as cannibalism); and happiness induces stronger judgments that it is both good and compulsory to help the needy ([Seidel & Prinz 2013a, 2013b](#)). There is also evidence that we feel different emotions when judging our own actions

than when judging others. When another person commits a crime against nature, we tend to feel disgust, but when we perform an act deemed by others to be unnatural, the most common response seems to be shame. Conversely, when others commit crimes against persons, we feel angry, but guilt is the natural response when we perform such acts ourselves. To test this hypothesis, I conducted a forced-choice study in which a group of college undergraduates had to pick guilt or shame in response to mildly "unnatural" acts ("Suppose your roommate catches you masturbating"), and mildly harmful acts ("Suppose you take something from someone and never return it"). 80% chose shame for the first case, and over 90% picked guilt for the second.

Such findings demonstrate that different emotions play different roles. I mentioned three distinctions that are currently receiving empirical attention: the split between positive and negative emotions (praise and blame), between two kinds of blame (crimes against nature and crimes against persons), and between self- and other-directed blame. The self/other distinction may be particularly important because it helps us see how moral emotions differ from their non-moral analogues. Anger (or at least irritation) and disgust can both occur in non-moral contexts, but they take on a moral cast, I submit, when paired with dispositions to feel guilt and shame, respectively. If I find eating insects physically revolting, I will experience disgust when I see others eat insects, and disgust when I inadvertently eat them myself. But if I found insect eating immoral, it would not be disgust that I experience in the first-person case, but shame. This feeling of shame would motivate me to make amends for my actions, or to conceal my wrongdoing from others, not simply to repel the unwanted food from my body. The self-directed emotions round out the punitive cast of our moral attitudes. We see morally bad acts as not just worth aggressing against, but as worthy of apology. This need not be a second-order belief. Rather it is implicit in the fact that moralized behaviors carry emotional dispositions toward self

and other that together promote a punitive attitude: a disposition to issue and submit to punishment.

Putting this together, I propose that standing moral values (the values that a given individual has for an extended period of time) consist in dispositions to feel the self- and other-directed emotions that I have been discussing. Such an emotional disposition can be called a sentiment. On any given occasion when a standing value becomes active in thought—i.e., when a moral judgment is made—these dispositions result, all else being equal, in an emotional state. The emotion that is felt depends on who is doing what to whom. For example, if I recall a situation in which I hurt someone's feelings, I will have a feeling of guilt regarding that event, because a person was harmed and I was the culprit. This feeling of guilt toward an event constitutes my judgment that the action was wrong, and I gain introspective access to this judgment by feeling guilt well up inside me. If this is right, then emotions are not merely effects of moral judgments, but essential components of them.

Against this picture, one might object that emotions are merely a heuristic that can be used in certain circumstances, but not strictly necessary for making moral judgment. Following the analogy mentioned before, anxiety might be used as a heuristic when deciding whether to smoke, but the judgment that smoking is dangerous does not depend on fear, and was initially arrived at by the light of reason.

To establish that emotions are not merely helpful heuristics, one must see what happens when emotions are reduced or eliminated. To look into this, [Eskine \(2011\)](#) gave people the bitter taste manipulation and then warned them not to let the feelings caused by that beverage interfere with the moral judgments. In this condition, he found that moral judgments were considerably less severe than a control condition, suggesting that, when we ignore emotions, it is harder to see things as wrong. The finding indicates, in other words, that moral judgments subside when emotions are absent. The study cannot confirm this strong claim, however, because people cannot suppress emo-

tions completely. More powerful evidence comes from the clinical populations who suffer from emotional deficits. For example, psychopaths, who suffer from deficit in guilt and other negative emotions, notoriously fail to appreciate what is wrong with their actions ([Hare 1993](#)). Similarly, people with Huntington's disease, which impairs disgust, show high incidence of paraphelias, suggesting that they cease to see deviant sexual behavior as wrong ([Schmidt & Bonelli 2008](#)). [Kramer \(1993, p. 278\)](#) argues that anti-depressants can flatten affect in a way that results in a "loss of moral sensibility." There is also a positive relationship between alexithymia and Machiavellianism, suggesting that a reduction in emotional competence may act in ways that are more instrumental than moral ([Wastell & Booth 2003](#)). For better or worse, there is no clinical condition in which all emotions are absent and behavioral function remains, but these findings suggest that selective or global dampening of the emotions leads to corresponding deficits in moral judgment. That is, people with diminished emotions seem to be insensitive to corresponding parts of the moral domain, suggesting that they may not be forming moral judgments.

The evidence summarized here suggests that emotions arise when we make moral judgments, that emotions are consulted when reporting such judgments, and that moral judgments are impaired when emotions are unavailable. Some of this evidence is preliminary, but, for present purposes, let's assume that the findings hold up to further and more stringent testing. By inference to the best explanation, such findings suggest that emotions are components of moral judgments. The idea is that, when people say something is morally bad, the thought they are expressing on that occasion consists of a negative emotion directed towards the thing judged bad. Emotions, on this view, function like predicates in thought. That is what traditionally sentimentalists, such as Hume, seem to have maintained. Hume thought ideas—the components of thoughts—were stored copies of impressions, and the idea of moral badness consisted in a stored copy of the impression of disapprobation.

Traditional sentimentalism, which says that emotions (or sentiments) are actually components of moral judgments, differs conspicuously from neo-sentimentalism. Neo-sentimentalists theories say that moral judgments are judgments about the appropriateness of emotions. These theories do not straightforwardly predict that emotions come on line when we make moral judgments, nor that a reduction in emotions should interfere with our ability to moralize. Instead, they predict that people will think about emotions when they make moral judgments. Correlatively, they also predict that people with limited metacognitive abilities will lose their ability to make moral judgments; this is not the case (Nichols 2008). Thus, given the current state of evidence, traditional sentimentalism outperforms neo-sentimentalism empirically. Traditional sentimentalism predicts a robust pattern of empirical findings.

Rationalists and externalist moral realists might balk at this point and say that the empirical evidence lacks the adequate modal strength to support sentimentalism. The evidence shows that emotions are often consulted when making moral judgments, but this leaves open the possibility that we might also make moral judgments dispassionately under circumstances that have not yet been empirically explored. So stated, this objection is just an expression of faith. It suffers from both conceptual and empirical weaknesses. Conceptually, opponents of sentimentalism must say what moral judgments are, such that they can be had dispassionately. What thought is a dispassionate person conveying, when she says, “Killing the innocent is morally bad?” Any attempt to give a reductive answer will be vulnerable to open-question worries. No descriptive substitute for the phrase “morally bad” leaves us with a sentence that is conceptually synonymous with the third.

Arguably, the open-question argument does not threaten sentimentalism. Let’s distinguish two kinds of open questions. First, given a certain attitude towards killing, one can still wonder whether killing really is morally bad. Second, given a certain attitude toward killing, one can wonder whether one is thereby regard-

ing it as morally bad. Reductive theories of value leave both questions open. If I form the attitude that killing cannot be willed as a universal law, I can still wonder both whether killing is bad and whether I am judging that it is bad. Sentimentalism leaves the first question open, but not the second. When experiencing outrage at killing, it seems impossible to wonder I am regarding killing as bad. I can of course wonder whether killing really is as bad as it seems. Such doubts can arise because I may not know the true source of the emotion I am feeling. Perhaps my outrage comes from some extraneous source (such as a bitter beverage), for example. But this open question does not threaten the thesis that moral judgments are constituted by sentiments. The only open question that poses such a threat would be one about what my attitude is, not one about whether my attitude is true. The fact that some sentiments are experienced as condemnatory effectively closes the question about whether someone experiencing those sentiments is adopting a moral stance. By analogy, imagine tasting a wine and wondering whether it really is delicious, while experiencing gustatory pleasure. We can have this thought (a thought about truth), because we can’t be sure where the pleasure came from (was it the wine or the company?). But we can’t experience gustatory pleasure and wonder whether we are, at that moment, finding the experience delicious. Thus, gustatory pleasure is plausible a component of deliciousness judgments.

The foregoing may look like a conceptual argument for sentimentalism. But it can also be construed as an empirical claim. The argument hangs on the premise that people experiencing outrage take themselves to be making moral judgments. This can be empirically tested. Indeed, all the evidence about people consulting their emotions when making moral judgments stands as evidential support. Merely making someone mad results in more negative moral attitudes. This can be interpreted as showing that, when people are angry, there is no question for them about whether they are holding something in negative moral regard. Conversely, it would be easy to show that people do not ne-

cessarily draw this inference when they form the judgment that something cannot be willed as a universal law. Opponents of sentimentalism owe us a positive account of evaluative thoughts that avoids open-question worries as successfully as sentimentalist accounts.

Opponents of sentimentalism might try to bypass this demand by offering a non-reductive account of moral judgments, treating thin moral concepts as primitives. That possibility, which was attractive to Moore, looks unmotivated given the empirical evidence for an emotional foundation. Every study suggests that emotions arise when we make moral judgments. All evidence also suggests that when emotions are eliminated, judgments subside as well. This does not prove that we can make moral judgments without emotions, but, by induction, it provides evidence. Some have argued that extant evidence is ambiguous about whether emotions are essential components of moral judgments or mere accompaniments, but I have suggested here that the former may provide a better explanation (and certainly better predictions) of the total pattern of data (Huebner et al. 2009; Waldmann et al. 2012). Until opponents of sentimentalism can identify some clear cases of moral judgments without emotions, they will be on the losing side of the debate. At the moment, there is no empirical evidence that this ever happens.

Notice too, that it would be relatively uninteresting to show that, under as-yet-unidentified and highly unusual conditions, people can make what look like moral judgments in the absence of emotions. The sentimentalist will reply that the vast majority of ordinary moral judgments are emotionally based. If moral vocabulary is occasionally used dispassionately, sentimentalists can ask whether the thoughts expressed on such occasions are of the same kind that we find, in study after study, in the usual cases. Upon finding a class of dispassionate judgments, one might do best to posit an ambiguity in the category. The sentimentalist can content herself with the project of providing a metaethics for garden-variety moral judgments, while leaving open the possibility that there may be psychological exotica, which conform to

the theories of their opponents. At the moment, there is no empirical evidence for such exotica.

More modestly, the empirically-minded sentimentalist might welcome an attempt to find evidence for opposing views. Little effort has been put into this task, though empirical claims for emotion-free moralizing are occasionally advanced. The most publicized example is Koenigs et al.'s (2007) study, which shows intact consequentialist judgments in patients who suffer from ventromedial prefrontal brain injuries, which are thought to impair emotion. But this description is misleading. As the authors note, ventromedial patients are highly emotional, and their most notorious symptom is that they are insensitive to costs when seeking rewards. Presumably, reward-seeking is an affectively grounded behavior. The fact that these patients make normal consequentialist judgments does not entail that they rely on reason alone, but rather on their positive emotions. Since these emotions cannot be easily regulated by negative feedback in ventromedial patients, they tend to be more consequentialist than healthy populations—that is, they are more willing to push a heavy man in a trolley's path in order to save five.

Will better empirical evidence for rationalism or externalist moral realism be forthcoming? I doubt it. Rationalists hold that we can arrive at moral judgments through reasoning. Unlike some sentimentalists, I think reasoning is important to morality. It is likely that we use reasoning to extrapolate from basic values to novel cases. But it is unlikely that we could use reasoning to derive basic moral values. Philosophers have tried to do this for centuries with no consensus behind any view. This might be described as a strong empirical argument by induction: thousands of smart, trained moral experts have failed to identify a line of reasoning that is widely recognized as providing adequate rational support for basic moral propositions. Moreover, when moral debates arise, there is little evidence that reasoning is efficacious on its own. Instead, societal transformations in values seem to arrive with political upheavals, economic revolutions, and generational change. Attitudes towards slavery changed with the indus-

trial revolution, women's suffrage came with a world war, and increase in support for gay rights correlates with the dissolution of traditional social roles and economic transformations that have made procreation more costly than abstinence. I don't mean to imply that there are no rational arguments for these liberation movements. Rather, I am suggesting that those arguments take hold only when social conditions are right. It is noteworthy, for example, that scientific racism appeared very late in the history of slavery, suggesting that slavery was not simply based on false beliefs about racial inequality. In fact many societies have enslaved their own people, and many proponents of scientific racism have been against slavery. Rather, advocacy of slavery seems to reflect a set of basic moral values that changed in recent history: values that say social standing can be determined by the lottery of birth. With industrialization, models of labor based on the idea of self-determination took hold, and the idea that birth should determine social standing began to wane. Of course, it hasn't disappeared altogether, but it has been tempered by the emergence of a new norm. Before industrialization, the idea that human beings are born equal and free might have seemed manifestly false, and thus it could have played no effective role in any argument against slavery. With industrialization, this premise gained appeal, and became the foundation of compelling arguments. Arguments are not inert, but they are only as good as the premises on which they are based, and the plausibility of those premises may depend on factors other than reasoning. It is possible that reasons have little role in driving basic values. And if so, then the recent broadening moral umbrella is not the result of a rational inference to the conclusion that our basic values cover more cases than we thought, but rather an irrational shift in basic values.

A realist might concede that such considerations threaten rationalism, but vie instead for a kind of intuitionist perspective, according to which basic moral truths are simply obvious. To me, this looks like a magical moral epistemology—one wonders what moral facts could be such that our moral sense could simply lock on to

them. It is also open to a damaging empirical objection. Phenomenologically, it is true that moral intuitions often seem immediate and unbidden, but this can be readily explained on a sentimentalist account. Emotions are conditioned (by training or evolution) to arise automatically and often intensely when certain actions, such as torturing babies, are considered. This gives an impression of immediacy without postulating any special contact with moral reality. Moreover, these intuitions vary from group to group. For example, there is empirical evidence that liberals and conservatives have divergent basic values (Graham et al. 2009). The presence of such foundational intuitions can be explained demographically, and their lack of convergence casts doubt on the existence of a moral faculty that reveals universal moral truths. In other words, intuitionism is vulnerable to a debunking argument. Social science coupled with sentimentalism provides a good explanation of deeply-held intuitions, so there is no need to suppose that these intuitions reflect anything deeper.

This point about moral variation, to which I will return, also counts against some forms of externalist moral realism. Advocates of that position sometimes suggest that objective moral facts can be established by identifying the external factors that best explain human moral behavior or judgments. If moral behavior and judgments vary from group to group, however, it is unlikely that we will find an external common denominator underlying these practices. Such a search also seems unnecessary given that we already have good explanations of moral behavior and judgments in terms of socially-conditioned sentiments.

None of these arguments are the nail in the coffin for externalist realist or rationalist theories. They merely illustrate the relevance of empirical results. The findings mentioned here must be explained. It is my contention that sentimentalism provides the best explanation of the findings I have reviewed, but further arguments and evidence could tip the balance in another direction.

2.2 Cognitivism vs. non-cognitivism

Let's move on to the second question on the metaethics decision tree: Are moral judgments truth-apt? As positioned on the tree, this is a

question that arises for sentimentalists, raised pressingly by the conclusion that moral judgments have a basis in the emotions. It is that conclusion that seems to put truth-aptness in jeopardy, since emotions have not traditionally been regarded as having accuracy conditions in the way regarded as allowing for truth. But, it should be noted that the question of truth-aptness could also be raised independently of sentimentalism. There are non-sentimentalist theories that deny truth-aptness (for example, one might say that moral judgments are imperative, while denying that they need be passionate), and there are non-sentimentalist theories that accept truth-aptness (the vast majority fall in this category). To keep things as neutral as possible, I will begin by asking whether there is any empirical evidence that moral judgments are non-cognitive, whether or not they are affect-laden.

The posing of this question is itself a degree of philosophical progress, because non-cognitivists too rarely reflect on the predictions of their view. Indeed, the most obvious empirical prediction fails resoundingly. If moral judgments do not aim at truth, we might expect them to have a non-declarative syntactic. For example, we might expect them to take the form of imperatives or exclamations. But they do not. In every language that I know of, moral judgments are expressed using declarative sentences, which should stand as a profound embarrassment to the theory. Granted, non-cognitivists sometimes propose elaborate logics to accommodate this fact, but it is surprising that they should have to do so. One would expect the surface grammar to reflect the non-cognitive form.

To push things further, one might look for more subtle linguistic evidence in favor of non-cognitivism. For example, some non-cognitivists assume that moral utterances have the illocutionary force of directives, such as orders, requests, or demands. Directives often occur in speech contexts that contain words that play a role in persuasion, such as “come!”, “let’s”, or “we encourage you...” To empirically test this kind of non-cognitivism, Olasov (2011) ingeniously used this technique for sociolinguistics, called corpus analysis. He used a set of such linguistic elements

that correlate with directive speech, such as those just mentioned, and he searched corpora of spoken and written texts for co-variance between these elements and moral terms. He calls the directive elements “suasion markers,” and the correlations between these and other linguistic items a “suasion score.” Non-cognitivism seems to predict a high suasion score, given the postulated directive function of moral judgments. This prediction fails. Not only is there no positive correlation between moral vocabulary and suasion markers, there is actually a negative correlation, which approaches significance. This negative relationship was observed in seventeen out of nineteen different categories of text that he examined. These results are preliminary—a first foray into empirical ethics—but they provide compelling evidence that moral discourse is not directive in nature.

Non-cognitivism entails that moral discourse does not aim to refer to facts in the world. This carries another linguistic prediction that can be readily tested. Certainly adverbs are used to indicate a focus on how things are in the world. These include “really,” “truly,” and “actually.” These words have other uses (“really” can be a term of emphasis), but they often play a role in emphasizing the factive nature of the modified phrase. Therefore, if non-cognitivism were true one might expect these words to rarely be used as modifiers for moral terms. To test this, I used Google search engine to search for and note the frequency of three phrases: “really immoral,” “truly immoral,” and “actually immoral.” To do this, I needed a baseline, and chose to compare “immoral” to a word widely believed to designate a objective feature of the world. I chose “triangular,” a classic primary quality, on a Lockean scheme. The results are as follows (as of March, 2013):

“really triangular”: 6,500 hits
 “really immoral”: 10,600 hits
 “truly triangular”: 4,920 hits
 “truly immoral”: 32,000 hits
 “actually triangular”: 21,600 hits
 “actually immoral”: 61,600 hits

Clearly, the adverbs that indicate a real-world focus are used more frequently for moral terms

than for terms designating objective physical features—over six times as common in the case of “truly.” I also tried the phrases “in truth,” “truthfully,” and “in actual fact”:

“truthfully triangular”: 6 hits
 “truthfully immoral”: 44 hits
 “in truth triangular”: 46 hits
 “in truth immoral”: 1,350 hits
 “in actual fact triangular”: 2 hits
 “in actual fact immoral”: 133 hits

These truth-tracking phrases modify “immoral” between 7 and 166 times more frequently than they modify “triangular.” Moreover, these differentials are misleadingly small because the base rate for “immoral” is far lower than “triangular” (6,910,000 hits as compared to 11,600,000). This was just an exploratory study, but there is a simple implication. Non-cognitivism makes linguistic predictions, and when those are tested, they do not seem to pan out. Non-cognitivists owe us evidence, or they must deny that their theory makes predictions, in which case it would cease to be falsifiable.

In response, non-cognitivists might claim that there is one crucial line of evidence in favor of the view, and it’s a line of evidence that we have already seen. In the previous section, I surveyed studies suggesting that morality is affect-laden. At the start of this section, I said the non-cognitivism is orthogonal to affect-ladenness, but some non-cognitivists would vehemently disagree with this. They would say that non-cognitivism *follows from* affect-ladenness. Emotions are traditionally regarded as feelings, and feelings are not traditionally believed to be representations of anything. If the thought that killing innocents is wrong is really a bad feeling about killing, then why think this thought has any truth conditions? Does a feeling of indigestion or irritation really refer?

This move might have been compelling in the early part of the twentieth century, but the last fifty years of emotion research have emphasized the intentionality of affect. Some philosophers have adopted cognitive theories of the emotions, according to which emotions are identical to judgments. Elsewhere I have argued

against such theories, in favor of the view that emotions are bodily feelings (Prinz 2004), but contemporary feeling theorists still insist that emotions aim to refer. Feeling sad, for example, can be understood as a downtrodden bodily state that represents loss. To say that the feeling represents loss is to say that it has the function of arising in response to losses, and hence carries the information that there has been a loss to a person who experiences it. In a like manner, pain may indicate tissue damage and fatigue may indicate energy depletion, even though pain and fatigue are bodily feelings. None of these feelings are arbitrary. They prepare an organism to cope with specific conditions or events. Emotions qua feelings are in the business of keeping us abreast about how we are faring. Each emotion has a different significance, and any one of them can misfire. I might be sad when there is no loss, or frightened when there is no threat. Such emotions would qualify as erroneous.

If emotions are in the business of representing, then there is no difficulty supposing that moral judgments are truth-apt. When we sincerely assert that, “Killing innocents is bad,” we express a negative feeling towards killing, and that feeling functions as a kind of visceral predicate. It attributes a property to killing (I will have more to say about this property below). In this sense, moral discourse may be much like other forms of emotional discourse. If we say that some food is icky, we express a feeling, while also attributing a property. For example, the feeling of ickiness might represent the property of noxiousness, or perhaps something more subjective, such as the property of causing nausea in the speaker. Someone who calls something “icky” need not know what property that feeling represents, but most language users probably recognize that in using this term we are attempting to say something about whatever it is that elicits the feeling. By analogy to “icky,” moral assertions can be understood as both expressive and predicative. It is a mistake, based on overly simplistic theories of emotions, to assume that feelings cannot play a semantic function. Once we see that feelings can represent properties and function as predicates,

non-cognitivism no longer looks like a serious option.

2.3 Realism vs. the error theory

It is one thing to say that moral assertions aim to represent and quite another to say that they succeed in doing so. It is possible that when we say that an action is immoral, we aim to ascribe a property to it, but we do not succeed in doing so. This is precisely what defenders of the error theory have claimed. So, even if the forgoing case for cognitivism succeeds, we must now descend the decision tree and ask whether moral judgments are ever true.

The error theory, which states that moral judgments are truth-apt but always false, was first promulgated by [J. L. Mackie \(1977\)](#). Mackie's argument begins with the premise that moral predicates aim to represent properties with two important features. The first is objectivity: moral properties are supposed to be the kinds of things that can obtain independent of our beliefs, desires, inclinations, and preferences. The second is action-guidingness: moral properties are supposed to be the kinds of things that compel us to act when we recognize them. Mackie's second premise is that these two features are difficult to reconcile. Objective properties are usually the kinds of things about which we can be indifferent. Mackie uses the term "queer" to describe properties that are both objective and action-guiding, and he also suggests that such queer properties would require an odd epistemology. For these reasons, he thinks we shouldn't postulate objective action-guiding properties. But, Mackie thinks that moral concepts commit to the existence of such properties, and, thus, that moral judgments posit properties that don't exist. Therefore, moral judgments are systematically false.

In recent years, the error theory has become popular among evolutionary ethicists ([Ruse 1991](#); [Joyce 2006](#)). Mackie's theory leaves us with a puzzle. Why do people make moral judgments if they are incoherent? Evolutionary ethicists purport to have an answer. They say that morality is an illusion that has been naturally selected because it confers a survival ad-

vantage. For example, if we believe that cheating others is objectively bad and that belief is action-guiding, then we will hold others accountable when they cheat, and we will resist cheating even when it might seem advantageous to do so. This reduces the likelihood of free riders and leads to an evolutionarily stable strategy—one that can foster cooperation and collective works. Evolutionary ethicists also typically endorse sentimentalism, suggesting that moral emotions have evolved to motivate such things as punishment and altruism. Mackie himself is not explicit about the role of emotions in his view, which makes it unclear what he means when he says that we perceive the discovery of alleged moral facts to be action-guiding. The link between judgments and emotions, emphasized by evolutionists, provides one answer.

The evolutionary addendum to Mackie's argument may look like an empirical reason for siding with the error theory. Natural selection is a well-confirmed process, emotions have some basis in evolution, and evolutionary models confirm that emotionally-grounded moral instincts would be adaptive. But there are empirical reasons for doubting the evolutionary story, and for doubting the key premises in Mackie's argument. Consequently, I think the case for the error theory fails.

The evidence for an evolved moral sense is underwhelming. A thorough critique cannot be undertaken here, but let me offer two broad reasons for doubt (for more discussion, see [Prinz 2007a](#)). First, there is little evidence for a moral sense in closely related species. Recall that moral judgments are underwritten by emotions such as anger, disgust, guilt, and shame. There is no evidence that the last three of these emotions exist in chimpanzees, and the anger they exhibit might better be described as reactive aggression, because there is little reason to believe chimps form robust tendencies to be angry about third party offences when they are not directly involved. Evolutionists point out that chimps engage in reciprocal altruism, and other forms of prosocial behavior, but these behaviors may not depend on any moral judgments. Indeed, psychopaths engage in reciprocal altruism ([Widom 1976](#)), and chimps often be-

have in ways that seem psychopathic; they can be extremely violent (Wrangham 2004) and indifferent to each others welfare (Silk et al. 2005).

Evolutionary ethicists might concede this and argue that morality evolved in the human species after we split from other primates. But this position is vulnerable to a second objection: there is good reason to think that morality in humans is learned. Moral judgments derive from emotions that originate outside the moral domain, such as disgust, which is first applied to noxious agents and later expended to the social domain, through conditioning (Prinz 2007a). Even guilt and shame may be learned byproducts of non-moral emotions: shame is related to embarrassment and guilt may be a blend of sadness and anxiety brought on by violating a social norm (Prinz 2005). These emotions and their range of application depend on extensive conditioning in childhood. Moral variation across cultures is considerable, as we will see, and shared moral values can be attributed to widespread constraints on building a stable society (for example, stable societies must prohibit wanton murder within the in-group). Moreover, there is no poverty-of-the-stimulus argument for morality; children receive ample “negative data” in the form of punishment, and they directly imitate values in their communities. As I argue in greater detail elsewhere, arguments for innate moral norms have been unconvincing (Prinz 2007a). This suggests that morality is learned, not evolved.

If morality is acquired through learning, then one cannot bolster Mackie’s argument by assuming that morality is the product of evolution. This alone does not undermine the error theory, however. Error theorists might abandon the evolutionary approach and try to explain systematic error by appeal to a learning story. There is some evidence that people tend to treat certain rules as universally binding, regardless of operative conventions. When asked whether it would be okay to hit a classmate if the teacher granted permission, children tend to say “no.” Turiel (1983, Ch. 7) who made this discovery, denies that such objectivist leanings are innate. Rather, he thinks children learn to

distinguish moral and conventional rules. Some subsequent authors have argued that the learning in question involves emotional conditionism (Blair 1995; Nichols 2004). Moral rules are acquired through the inculcation of emotions such as anger, guilt, and shame. There are strong negative feelings associated with hitting that don’t disappear when children imagine the teacher saying it is okay to hit. Violating social conventions may lead to other emotions, such as embarrassment, but these are mitigated when we move from one social setting to another. For example, wearing a hat at the dinner table might be frowned on in some circumstances, but not when wearing a birthday hat at a birthday party. The idea that moral rules are learned by emotional conditioning could also explain their motivational impact; emotions impel us to act, so emotionally grounded rules seem to carry practical demands. This analysis would explain both features emphasized by Mackie—action-guidingness and objectivity—without assuming that moral rules actually are objective. Thus, the error theory could get off the ground without assuming that morality is a product of evolution.

On closer scrutiny, however, this argument is not strong enough to rescue the error theory. It conflates objectivity with authority independence. It is true that children think hitting is wrong even when it is permitted, but that does not mean they think moral truths exist independently of subjective responses. Many of our subjective responses seem independent of what authorities happen to say—our preferences for food and music, for example. But we don’t necessarily infer that these things are objective. So it is a further empirical question whether objectivity is an essential feature of how we understand moral properties.

This brings us to the heart of Mackie’s argument. Should we grant his first premise that moral assertions entail objectivity? Empirically, the answer is a bit messy. When polled, many people assume that morality is objective, but many reject this assumption (Nichols 2004; Goodwin & Darley 2008). In survey studies, there is a nearly even split between objectivists and their opponents. Strikingly, belief in ob-

jectivity correlates with religiosity. Goodwin and Darley report that religious beliefs were the strongest predictor of objectivity that they were able to find. This suggests that belief in objectivity is not an essential part of moral competence, but is, rather, an explicitly learned add-on that most often comes with religious education. The authors also found that belief in objectivity goes down in cases of moral issues about which there is considerable public debate, such as abortion. This might be interpreted as showing, again, that objectivity is not a conceptual truth about the moral domain, but rather a negotiable add on, which can be abandoned in light of counter-evidence. Faith in objectivity goes up with certain religious beliefs (e.g., divine command theory), and goes down when confronted with the fact that decent, intelligent people have very different moral convictions. In Quine's terms, moral objectivism, when it is found, may be collateral information rather than an analytic truth—a belief about morality that we are willing to revise.

To test this hypothesis, I conducted a survey study in which I compared a moral predicate (*immoral*) to two natural kind terms (*beetle* and *tuberculosis*), which paradigmatically aim to designate objective properties, and to two terms that are often said to represent secondary qualities (*red* and *humorous*). If natural kind terms have a presumption of objectivity, then any threat to that presumption should lead people to conclude that those terms don't refer. Things are a little trickier with terms such as *red* and *humorous*: many people believe that they designate objective properties, but are willing to give up this assumption when presented with countervailing evidence. When told that there is no unifying essence to humor, people do not conclude that nothing is funny; they conclude that humorousness is a property that depends on our responses. In other words, objectivity is not analytically entailed by *humorous* or *red*. It is collateral information. My study was designed to see if *immoral* followed this same pattern.

A group of college undergraduates read the following vignette for the *immoral* case, with comparable vignettes for the other terms:

Suppose scientists discover that there are two kinds of things that people call immoral. Would it be better to say: (a) The term “immoral” is misleading, and it might be better to replace it with two terms corresponding to the two kinds of cases.

Or

(b) The fact that there are different cases is interesting, but doesn't affect the word. The fact that we react the same way to these two things is sufficient for saying they are both members of the same category; they are both immoral.

When given these options, 75% chose option (b) for *immoral*, resisting the first option which is tantamount to an error theory. Exactly as many chose option (b) for *red*, and a few more picked (b) for *humorous* (90%). In contrast, (a) was the dominant answer for the natural kind terms, *tuberculosis* and *beetles* (55% and 65% respectively). This suggests that people do not treat moral terms the way that they treat natural kind terms. Even if many people happen to think that morality is objective (as the studies by Nichols 2004, and Goodwin & Darley 2008, suggest), they are willing to give up on this belief without abandoning their moral concepts. They are willing to treat those concepts as response-dependent.

I think these results can be best interpreted as follows. Moral concepts are neutral about moral objectivity. People can acquire these concepts without any beliefs about what kinds of properties they designate. This neutrality begets a kind of resistance to error. If there are no objective moral properties, then it wouldn't follow that moral judgments fail to refer; it would mean only that they refer to response-dependent properties. Thus, it is all but guaranteed that some moral judgments will come out true, and to this extent the evidence favors moral realism (defined as the view that there are truthmakers for some moral judgments). Mackie mistakes a popular but dispensable belief about morality for an analytic truth. His error theory rests on an error. In fact, his argument for the error theory may rest on two

mistakes, the second of which we will come to presently. Of course, this is just one study, and other interpretations may be available, but it provides some evidence against Mackie's conceptual claim and shows how empirical findings might be used to explore whether moralizers are, as he suggests, committed to objectivism. Extant empirical evidence suggests otherwise.

2.4 Sensibility vs. moral sense

The survey study just described suggests that one can possess moral concepts without knowing whether moral judgments refer to properties that are objective. The survey also brings out the possibility that people are willing to accept the conclusion that moral truth depends on our responses. But the survey does not settle whether a response-dependent theory is true. This is the next question on the decision tree. As we have seen, Mackie thinks action-guidingness and objectivity are incompatible. This may suggest that he sees no room for a theory that combines moral objectivity with the view that moral judgments have motivational pull. This, however, is Mackie's second mistake. The hypothesis that morality has an emotional basis reveals a way out of Mackie's argument for incompatibility. Emotions are action-guiding in that they motivate us to act. But some emotions may also represent objective features of the world. Fear, for example, may represent danger, and danger may be an objective property. Emotions can represent objective properties in a motivating way: they simultaneously pick up on information while compelling us to respond adaptively. The fact that fear is action-guiding does not rule out the possibility that it is designed by evolution to track objective threats. Likewise, disgust is action-guiding but it may register real sources of contamination.

This brings us back to "icky." This emotionally-expressive term may refer to something objective, like contamination, or to something subjective, such as the tendency to cause feelings of nausea. We can ask whether ickiness is objective or subjective, even if we grant that the word "icky" is expressive. Expressive terms can have objective referents. Likewise, we can ask

this question about moral terms. This question frames a historical debate between Francis Hutcheson, who may have believed that our moral sentiments track objective moral truths, and David Hume, who suggests that morality depends on human responses. The claim that moral judgments track objective properties is called the moral sense theory. It seems to have been defended by Francis Hutcheson in the eighteenth century. It may even have been Kant's considered view, since he had an objective procedure for arriving at moral truth, but also insisted that every moral judgment is associated with a moral feeling. The moral sense view finds an analogue in contemporary authors who combine external standards of moral truth with motivationally charged moral psychologies (e.g., [Campbell 2007](#); [Copp 2001](#); see also [Railton 2009](#), who makes a modest move in that direction). The alternative view, which says that moral judgments refer to response-dependent properties, has been called the sensibility theory ([McDowell 1985](#); [Wiggins 1987](#)). We can now ask whether there is any way to decide between these options empirically.

I think there is some reason to favor sensibility over moral sense. For the moral sense theory to be true, there would have to be a candidate objective property to which our moral concepts could refer. Unfortunately, I cannot undertake a review of modern moral sense theories here, but I will offer, instead, a more general line of empirically-informed resistance. Moral rules are emotionally conditioned, and communities condition people to avoid a wide range of different behaviors. Within a given society, the range of things that we learn to condemn is remarkably varied. Examples include physical harm, theft, unfair distributions, neglect, disrespect, selfishness, self-destruction, insults, harassment, privacy invasions, indecent exposure, and sex with the wrong partners (children, animals, relatives, people who are married to other people). One might think that all of these wrongs have a common underlying essence. For example, one might propose that each involves a form of harm. But this is simply not true. Empirical evidence shows that people condemn actions that have no victims, such as

consensual sex between adult siblings and eating the bodies of people who die in accidents (Murphy et al. 2000). Furthermore, harm itself is a subjective construct. It cannot be reduced to something like physical injury. Privacy violations are regarded as a kind of harm, even though they don't hurt or threaten health, whereas manual labor is not considered a harm, but it threatens the body more than, say, theft. Similar problems arise if we try to define moral wrongs in terms of autonomy violations. Mandatory education violates autonomy, but it is considered good, and consensual incest is an expression of autonomy, but is considered bad.

Realists would no doubt resist some of these claims, but theirs is an uphill battle. On the face of it, morality lacks a common denominator. Empirical surveys of human values suggest that moral rules are a potpourri, which can be extended and contracted in any number of ways, with no fixed ingredients. Or rather, the common denominator is not a property shared by the things we condemn, but rather by the condemning itself. Moral sense theorists liken morality to perception, and, in so doing, they imply that there is an external feature of the world that our moral sentiments pick up on. But there is little reason to believe this. Unlike perception, there is massive variation in what we moralize, and there is a perfectly good explanation for this: the content of morality is determined by social conditioning rather than by the mind-independent world. Morality is not something we get by simply observing.

The foregoing is offered as an empirical challenge to moral sense theories, not a decisive refutation. Too often philosophers stick with examples of moral norms that clearly concern harm or violations of autonomy. This inflates optimism about a unifying essence. If one uses empirical methods to discover the full range of things that people actually moralize (such as victimless harms), the task of finding a unified essence looks much harder. Moral sense theorists might reply that this diversity is illusory. They might say, for example, that people would stop condemning victimless crimes on reflection. That claim is amenable to empirical testing, and so far the tests provide little support. For

example, Murphy et al. (2000) presented people with cases of incest and cannibalism where it was extremely salient that no one was harmed. They invited people to revise knee jerk moral intuitions and rule that, on reflection, these victimless actions are permissible. A piddling 20% revised accordingly, but 80% stuck to their original view. Moral sense theories seem to place their bets on the 20%. The challenge is to explain why the stubborn and considered opinions of the majority are performance errors of some kind.

Given the diversity of things about which people moralize, I think the sensibility theory is more promising than the moral sense theory. Wrongness is projected, not perceived. The property of being wrong is the property of causing negative sentiments, not a response-independent property that those sentiments are designed to detect. This conclusion follows from an inference to the best explanation. Empirically it looks as if there is no common essence to the things that we find morally wrong—a finding that is difficult to explain on the moral sense model, but easy to explain on the assumption that wrongness is response dependent. By analogy, imagine that we catalogue the things that make people laugh, and find that they lack a shared essence. This would imply that laughter does not pick up on an objective property. The things that we find funny are unified by the very fact that we are amused by them. Likewise for the things we find immoral: disapprobation carves the moral landscape.

2.5 Relativism vs. ideal observers

I have just been arguing that moral truth is response-dependent. Moral judgments can be true, but their truth depends on our sentiments. Something is immoral if it causes anger, disgust, guilt, and shame in us. But now we can ask, who does “us” refer to here? Whose sentiments determine moral truth? This brings us to the final question in the metaethics decision tree. Can divergent responses have equal claim to truth?

Empirical evidence strongly suggests that moral sentiments vary, both within and across

cultures. Within a culture, the clearest divisions are between political orientations. Liberals and conservatives have interminable debates, even when they are exposed to the same science and education. Research suggests that these debates come down to fundamental differences in moral values. Conservatives are much more likely than liberals to emphasize purity, authority, and preservation of the in-group in justifying their moral norms (Haidt 2007). These things are foundational for conservatives and largely irrelevant to liberals.

Across cultures, differences are even greater. Everything that we condemn is accepted somewhere else (such as slavery and torture), and things that have been condemned by other cultures (such as women's suffrage) have been embraced by us. There are cultures whose moral outlooks are dominated by considerations that we tend to downplay in the post-industrial West (sanctity and honor, for example), and ideals that are central to our moral outlook appear to be modern inventions (rights and the idea of human equality).

Descriptively, then, people do not seem to have the same moral values, within or across cultures. There is divergence in our sentiments. Some of this divergence might diminish if we filtered out cases where people were reasoning badly or on poor evidence, but there is ample evidence that disagreements remain among people who reason carefully and draw on the same factual knowledge. Indeed, if we filter for good reasoning, divergence might increase rather than decrease: consider professional normative ethicists, who are experts at reasoning but nevertheless arrive at varied and novel moral perspectives that neither converge with each other nor with the communities to which they belong.

I think such descriptive moral relativism provides support for metaethical moral relativism. This would be a terrible inference on its own, as every metaethics textbook points out, but the inference gains plausibility if bolstered by a premise I argued for above: moral truth is dependent on our responses. If responses vary, even under favorable epistemic conditions, and responses determine truth, then the truth of a

moral judgment can vary depending on whose values are being expressed.

The ethical universalist can resist this conclusion by offering an antidote to moral variation. The most natural strategy would be to defend universality by developing an ideal observer theory, and to argue that, under ideal epistemic conditions (which might include external factors as well as being an epistemically ideal agent), judges would arrive at the same set of moral values. This strikes me as woefully unlikely. Once we grant that sentimentalism is true, and that our sentiments track response-dependent properties, it's not clear how to settle on which observer is ideal. Two people who have the same factual knowledge may have different sentiments as a result of differences in temperament (Lovett et al. 2012), reward sensitivity (Moore et al. 2011), gender (Fumagalli et al. 2010), class (Côté et al. 2013), and age (Truett 1993). Whose sentiments are right? Moreover, the standard traits associated with ideal observation may be problematic in the moral domain. Should we consult someone who is disinterested when we know, empirically, that distance from a situation can lead to moral indifference? Should we consult someone who has not been conditioned by a particular culture when we know that innate sentiments are unlikely to deliver moral attitudes? Should we consult someone who attends to every detail of a case, when we know that framing, vivid description, and concreteness can alter moral judgments? These problems strike me as insuperable. There are no clear criteria for ideal observation and no reason to believe that careful observers would converge.

In posing this challenge, I am inviting ideal observer theorists to look at empirical findings and propose epistemic standards that would overcome the sources of variation mentioned here. Some ideal observer theories try to be empirically responsive in this way. For example, Smith (1994) advances the hypothesis that ideal rational agents would converge, but he also realizes that some readers might be reluctant to share his optimistic outlook. To quell these doubts he makes three empirical observations (p. 188): there is considerable moral con-

vergence already (he cites the existence of thick concepts as evidence: we all think brutality is bad and honesty is good); there has been moral progress (he cites slavery, among other examples); and entrenched disagreements often reflect faulty rationality, such as religious beliefs. Here, I think further empirical scrutiny would weaken Smith's case. Divergence is rampant, and people disagree on the scope of thick concepts (is torture brutal? is espionage dishonest?). Cases of (what we consider to be) moral progress are, I've noted, often driven by economic upheavals and other irrational factors, with reasoning playing a post-hoc role. Finally, disagreements remain after bad reasoning and religiosity are controlled for; the examples mentioned, in formulating the challenge include things such as temperament and framing effects. I think empirical evidence provides little reason to expect that rational and informed observers would deliver consistent verdicts.

In light of such worries, universalists might abandon the ideal observer theory and offer instead a procedural approach to consensus, arguing that people would and should converge if they arrived at their sentiments in the right way. For example, many people might agree that it is good to arrive at decisions democratically, taking multiple sentiments into consideration, and we might sentimentally endorse the outcome of democratically-resolved moral disputes. Though I cannot make the case here, I suspect the problems with such a procedural approach outweigh its prospects. Democratic decision-making does not result in moral consensus; it can even polarize. When such procedures increase consensus it is often through power and prestige rather than sentimental convergence. Our faith in democratic procedures may also be an expression of moral relativism rather than a solution. Democratic procedures are an historical anomaly, which emerged in the modern period with the rise of capitalism, and they have often been used to oppress minorities and to impose the values of the many over the few. Perhaps such procedures are an improvement over totalitarian forms of decision-making, but they do not remedy relativism. Indeed, as societies move towards consensus-building pro-

cedures, they may actually promote variation, leading to an endless proliferation of values and an ever widening gulf between those who cherish diversity and those who reside in more traditional societies. From a social science perspective, the prospects for a universal morality look grim.

Once the case for relativism is established, the question arises: relative to what? Are moral judgments relative to value systems? Are those systems individuated at the scale of cultures and subcultures or do they vary across individuals? Little empirical work has been done to address this question, but let me end with a suggestion about how to proceed. When examining the semantics of natural kind terms, philosophers have sometimes appealed to a linguistic division of labor (Putnam 1975). We defer to experts and thereby license them to adjudicate the boundaries between natural kinds. Now we can ask, is there such a thing as moral expertise? Do we appeal implicitly or explicitly to moral experts? Would we change our moral judgments if the designated members of our community told us we were morally mistaken? We don't know the answers to such questions, because moral expertise has not been intensively studied. I suspect there will be considerable individual differences, with members of more traditional societies showing more willingness to defer. But I also suspect that deference in the moral domain will be less prevalent than for natural kinds; we are more inclined to take ourselves as having morally authoritative insight. What is most clear, however, is whether the scope of the relativity depends ultimately on how we use moral concepts and terms; and this is something that can be investigated empirically. Naturalizing relativism will require the marriage of cultural anthropology and sociolinguistics. From the armchair, it is tempting to think there is a single true morality; introspective reflection tends towards solipsism.

3 Conclusion

Throughout this discussion, we have worked our way down a metaethics decision tree. I have

made a case for a relativist cognitivist sentimentalist sensibility theory. Admittedly, each of my arguments is only a first pass, and much more could be said for and against these positions. Many of the empirical findings that I have described are preliminary. My main goal here is not to make a decisive case for any position in metaethics. Rather, I am pleading for the relevance of empirical methods in doing this traditionally philosophical work. Moral philosophy is undergoing a process of naturalization. This has been felt most strongly in normative theory (e.g., the debate about the status of character in virtue ethics) and moral psychology (e.g., questions about how deontological and consequentialist judgments are made). I hope to have shown that the empirical work also bears directly on metaethical questions—questions about what, if anything, is the source of moral truth.

Empirical work cannot replace philosophical toil. We need philosophy to pose questions and identify possible theories. Experimental design is itself a kind of philosophical reasoning, and it takes considerable argumentation to move from data to theory. Naturalization is supplementation, not usurpation. But it is not just supplementation. The empirical arsenal may just be our best hope for adjudicating philosophical debates. Reflection can delineate the logical space, but we need observation to locate ourselves therein. Philosophers have always relied on observation, in some sense, but scientific methods allow us to observe processes that are unconscious, inchoate, or distant in space and time. Empirical studies can test the content, prevalence, and malleability of intuitions, and they can also tell us where our intuitions come from—a question of central metaethical concern. We should embrace any tools that help us resolve the questions that we are employed to answer. A century ago, there was a linguistic turn, and philosophers began to treat traditional philosophical problems as amenable to semantic analysis. Around the same time, the boundary between philosophy and psychology was still blurred, and journals such as *Mind* published articles that we might now classify as psychological. Such crossovers

fell out of fashion, however, and it has taken a century to get back to this incipient moment. With the linguistic turn, Anglophone philosophers became convinced that we should all learn logic because it would help us make progress. Logic did help, and it did not undermine philosophy. Now, we can encourage all philosophers to learn about methods and results used in the relevant social and physical sciences. The payoff of this naturalistic turn may be vastly greater than the linguistic turn. Science, not formal logic, is positioned to tell us whether morality is a human construction.

Acknowledgments

This discussion has benefited immeasurably from the feedback of anonymous referees and from Ying-Tung Lin, Jessica McCormack, Thomas Metzinger, and Jennifer Windt. I am grateful for their close reading and helpful suggestions.

Conceptualizing Metaethics

A Commentary on Prinz

Yann Wilhelm

In this commentary on Prinz's "Naturalizing Metaethics" I shall first look briefly at his methodological assumptions. I will argue that Prinz's approach is more radical and less conciliatory between analytical and empirical approaches than it seems from his own description. In the second part of my commentary, I shall look at one possible objection to Prinz's sentimentalism: the evidence he presents does not provide the needed modal strength for sentimentalism. I shall present two example of this objection, and argue that Prinz's own depiction doesn't adequately represent it. I shall then use the helpful distinction offered by Jon Tresan between *de dicto*- and *de re*-internalism to analyze underlying problems in the objection. I will present another way of reacting to it, which I think fits nicely with Prinz's naturalized methodology. In the last part, I shall look at his critique of non-cognitivism. Prinz argues that non-cognitivism makes certain linguistic predictions that turn out to be wrong: if non-cognitivism were true we would expect our moral language to reflect this. I will argue that there are many forms of non-cognitivism that predict this surface grammar. The key idea is that non-cognitivism entails a pragmatic theory of moral language. I then offer a speculative explanation about why the moral language has its surface form. This speculation, I argue, has at least the same amount of plausibility as cognitivist theories. Furthermore, this possible explanation is open to empirical investigation. I agree with Prinz that, ultimately, metaethical theories should be tested against empirical evidence. Prinz presents conceptual and empirical work as mutually enhancing enterprises. My commentary is, I hope, a small contribution highlighting the conceptual side of the coin.

1 Metaethics under empirical scrutiny

Prinz proposes to naturalize metaethics. Metaethics is traditionally regarded as a second-order discourse about ethics. Where normative ethics asks what is good and what is bad, what we should or shouldn't do, metaethics asks the question of what morality is itself (DeLapp 2011). Its subject is the ontology of moral properties, the semantics of moral discourse, the epistemic foundation of moral judgments and the psychology of moral opinions. These different aspects are highly interrelated—answers in one area influence questions asked in others.

There are many different ways to tackle the question of what morality itself actually is. Prinz

characterizes metaethics as being concerned with the foundations of moral judgments (Prinz this collection, p. 1). This is his starting point, which shapes his decision tree. He acknowledges that one could arrange the tree in different ways, depending on which aspect one wants to pull into focus.

Prinz's primary goal is to show that every question in the decision tree is empirically tractable (this collection, p. 1). This is his *methodological naturalism* (p. 2).¹ He argues that we

¹ He contrasts this with *metaphysical naturalism* and *semantic naturalism*. The former says that everything there is belongs to the natural world. The latter tries to reduce concepts from various domains in terms that are more likely to be naturalized in the metaphysical sense.

should study the domain of metaethics empirically. He wants to test “[...] theories derived from philosophical reflection against the tribunal of empirical evidence” (Prinz [this collection](#), p. 5).

Metaethics, according to him, is not the sole matter of armchair reflection. This seems natural when we characterize metaethics as the question of what morality itself is. But that goes against the view that metaethics—or philosophy in general—is not concerned with what actually is the case, but with what *must* be the case. What are the *necessary* conditions of morality? On this view, metaethics is concerned with statements that hold *a priori*. Most of the time this means deriving knowledge from reflection upon the meaning of our concepts. This method of *conceptual analysis* had been at the core of philosophy since the *analytic turn* (Prinz [this collection](#), p. 3).

Against this turn Prinz sets the *empirical turn* ([this collection](#), p. 3). He describes this development as an enrichment of the philosopher’s tool box. Where conceptual considerations help us to formulate theories and flesh out the differences between different views, empirical methods confirm the theories derived from this work. The former pose questions and formulates possible answers; the latter test those answers. Prinz emphasizes that empirical and traditional approaches are not opposed to one another ([this collection](#), p. 5). Rather, they complement each other. They’re more like opposing points on a continuum of methods for exploring the world.

It is important to see that this view is not as conciliatory between traditional analytic philosophy and empirical philosophy as it might seem. It does not leave room for *a priori* armchair reflection. In fact, Prinz even regards conceptual analysis as an empirical task: “[A]rmchair conceptual analysis can be characterized as an introspective memory retrieval process. As such, it can be regarded as a form of observation” (2008, p. 191).

When Prinz speaks of “traditional methods”, he does not include conceptual analysis as an *a priori* enterprise. Rather, he is referring to various tools, for example formal semantics or logic, which help us articulate theories. They are tools for exploring the natural world, from

which we gain knowledge only through experience. Prinz is a radical empiricist at heart.

An empirical scientist could ask: “What differentiates this from my own work?” For she, too, reflects upon different theories, how they relate to each other, formulates questions, and so on. This is an important part of scientific, empirical work. I think Prinz would agree. An important upshot of his naturalized philosophy is that there are no clear-cut borders between philosophy and psychology (Prinz 2008, pp. 204–206). They are different disciplines not because of their different subject areas or methods but for pragmatic reasons. They are different *academic* disciplines, shaped by sociological and historical processes. The borders between the different disciplines become blurred in the empirical turn. According to Prinz, this is a good thing.

I think this the real strength of Prinz’s approach. Arguably many disciplines are divided largely by pragmatic differences, like education and academic organization. Instead of demarcating different approaches, instead of drawing sharp lines between them, Prinz proposes that we unite them in the search for explanations of the natural world.

Prinz’s target article is a very good example of this approach. Here I want to make a few remarks in the spirit of Prinz’s own methodology. In the next section I will focus on a specific objection against Prinz’s answers to the first question in the decision tree. I think that it can clarify some consequences of his methodological naturalism for metaethics.

2 Internalism and modal strength

In this section I discuss Prinz’s answer to a potential objection to his sentimentalism, namely, that the evidence lacks *modal strength*. In fact, objections of this kind have already been raised against Prinz’s and other naturalistic metaethical theories already. I shall first argue that his answer doesn’t get to the heart of the objection. Second, I propose a way in which Prinz can and should answer it. To do this I shall present two instances where this objection has been made. A helpful distinction by Jon

Tresan will then show that there are actually two kinds of internalist theses at play here. Only one of these is really relevant for Prinz's naturalized metaethics, I shall argue. The objection then loses its force in light of Prinz's project of a naturalistic methodology. The following reasoning can also be seen as a small case study in recent (naturalized) metaethics.

The first question in Prinz's decision tree is whether moral judgments are essentially affect-laden or not. This is Prinz's take on the internalist-externalist debate.² This debate is a classical debate in metaethics that can be traced back to the British moralists (Darwall 1995). It concerns the question of whether *motivation* is *internal* or *external* to moral judgments. Do moral judgments necessarily involve motivation to act accordingly? Or does the motivation come from a desire external to them (e.g., the desire to be a good person)?³

Prinz advocates a position that he calls sentimentalism:

Sentimentalism =_{DF} Moral Judgments essentially involve affective states, such as emotions, in one of two ways: such states as constituent parts of moral judgments (traditional sentimentalism); or moral judgments are judgments about the appropriateness of such states (neo-sentimentalism). (Prinz this collection, p. 6)

The evidence for a link between moral judgments and emotions is overwhelming (Prinz this collection, p. 10). But is it enough to warrant a stronger relation than mere accompaniment? Even if we grant Prinz the interpretation that affective states are not only mere *consequences* of moral judgments, could we not still question whether they are essential components of moral judgments? The objection is this: the empirical evidence lacks *modal strength* to support senti-

mentalism. Even if all our ordinary moral judgments are based on emotions, it could still be *possible* to judge dispassionately (Prinz this collection, p. 13). Therefore the evidence doesn't support sentimentalism.

Prinz answers that the empirical evidence gives us enough reason to infer that we *cannot* make moral judgments without emotions: "Every study suggests that emotions arise when we make moral judgments. All evidence also suggests that when emotions are eliminated, judgments subside as well" (Prinz this collection, p. 13).

According to Prinz, the theory that emotions are essential components of moral judgments explains the total pattern of data better than its rivals (this collection, p. 14). Furthermore, he argues that the sentimentalist can accept psychologically exotic cases, in which the connection between moral judgments and emotions doesn't occur, which conform rival theories.

This answer, I argue, misses the real core of the objection. Prinz confronts it upfront and just states what it questions. He puts the objection in the following way:

The evidence shows that emotions are often consulted when making moral judgments, but this leaves open the possibility that we might also make moral judgments dispassionately under circumstances that have not yet been empirically explored. (Prinz this collection, p. 13)

But this does not represent the objection adequately. The objection doesn't rest on possible, not-yet-found empirical evidence against sentimentalism. Rather, it rests on opposing ideas about what kind of modal strength claims about the relation between moral judgments and emotions should possess. At the heart of this objection there is no disagreement about the empirical evidence, but an opposition in the underlying methodology.

Adina Roskies, for example, accepts that "[...] those [brain] areas involved in moral judgments normally send their output to areas involved in affect, resulting in motives

² Although he doesn't explicitly put it like this, I think it's safe to frame it in this way. The option that denies affect-ladenness is called "externalist moral realism", and he states in various places that emotions are motivating or action-guiding (Prinz this collection, pp. 8, 11, 21). And one answer to the third question is a position called "internal realism". What I say about internalism in the following therefore applies equally to Prinz's sentimentalism. See also Prinz (2006), where he explicitly states motivational internalism.

³ See Björklund et al. (2012) for a short overview.

that in some instances cause us to act” (2008, p. 192).

But she thinks that this is not enough for internalism to be true.⁴ In her view there is a connection between the cognitive and the affective system, but “this link is causal and thus contingent and not constitutive” (Roskies 2008, p. 192). In this sense the connection, according to her, is not necessary.

Antti Kauppinen sees the difference between internalism and externalism in a similar way. He depicts internalism as saying that there is a link between moral judgments and motivation that holds a priori and with conceptual necessity. externalism, in contrast, is the view that this link is contingent and a posteriori (Kauppinen 2008, p. 3). For Kauppinen, every internalist position then becomes an externalist position if it weakens the modality of the claim. When a metaethical account doesn’t claim that the connection between moral judgments and motivation holds a priori and by necessity, it is an externalist account. No amount of empirical data can refute this criticism.

In Kauppinen’s case the disagreement with Prinz about the underlying methodology is clear. He reacts to the proposal by Roskies, Prinz, and Alfred Mele (among others) that we clarify the debate empirically (Kauppinen 2008, 4). Because of his definitions of internalism and externalism as conceptual necessary claims he argues that “[...] findings in either actual or fictional experimental psychology or neuroscience have little relevance to the debate” (Kauppinen 2008, p. 4).

Kauppinen is opposed to methodological naturalism in philosophical moral psychology (2008, p. 4). That is why he would not be satisfied with Prinz’s answer to this objection. Against him, Prinz would have to defend his metaethical naturalism. Interestingly enough, Roskies, on the other hand, thinks that we *can* clarify metaethical debates empirically.

In what follows I shall show how I think Prinz should meet this objection. Furthermore,

⁴ Her critique is directed at internalism, not sentimentalism. But I regard both positions as similar enough to treat Roskies’s critique as an argument against Prinz’s sentimentalism (see also above). At the core of both positions is the connection between moral judgments and affective (motivational) states.

I will argue that everyone who wants to apply empirical data to metaethical debates, such as, e.g., Adina Roskies, should side with Prinz on his methodological naturalism and accept internalism as a true a posteriori theory about moral judgments.

I will now present an analysis of the internalism–externalism debate offered by Jon Tresan that I think will be very helpful here (2009). He distinguishes different formulations of internalism along various dimensions. He claims that a very important distinction has been overlooked: most philosophers in the debate neglected the difference between the modality of the internalist claim and the stated relation between moral opinions and motivation. According to Tresan, there are two different kinds of necessity that can occur in such claims: wide-scope necessity, which operates over the entire proposition—*de dicto*—and narrow-scope necessity, which operates over the predicate—*de re* (Tresan 2009, p. 54). The first operates on the dimension of *Modality* and the second on the dimension of *Relation* (Tresan 2009, p. 55).

For example, the statement that parents have children can be formulated with both kinds of necessities:

Necessarily, parents have children (*de dicto*).

Parents have, necessarily, children (*de re*).

In the first case the proposition that parents have children is stated as holding necessarily. Parents have children, otherwise they would not be called parents. If someone has a child, she is a parent. But the second statement says that people who are parents have their kids necessarily. But this is obviously false. John and Mary don’t have their children necessarily. They could easily never have had any children at all. True, they would not, then, be parents – but the fact that they are parents may have, initially, been quite accidental. We can easily see that there is a difference between *de dicto*- and *de re*-necessities because these two statements can have different truth-values at the same time.

With this distinction at hand we can distinguish two different internalist theses: a strong Modality/weak Relation or *de dicto*-internalism, and a weak Modality/strong Relation or *de re*-internalism. The former states that, with necessity, there is a connection between moral judgments and motivation. The latter says that there is a necessary connection between these two things.

Tresan uses this distinction to argue that something has gone fundamentally wrong in the internalism–externalism debate. The neglect of the two features has led to the *internalist fallacy*: the strength in Modality of an internalist claim was taken to be strength in Relation, which led to an overestimation of the epistemic value of the claim (Tresan 2009, p. 55). The classical debate stated the connection between moral judgments and motivation in terms of conceptual necessity (a *de dicto*-internalism) (see Roskies’s and Kauppinen’s accounts above). Arguments for this claim were supposed to evoke the intuition that no one can make a moral judgment without being motivated to act. If we have such intuitions, the arguments go, the connection is a conceptual necessity. Likewise, arguments against this internalist claim consisted in thought experiments that were supposed to evoke contrary intuitions.

From Tresan’s distinction follows that claims with *de dicto* necessity are claims about our concepts and not about the subject matter (2009, p. 57). *De dicto*-internalism, then, is a claim about our concept “moral judgment” and *de re*-internalism a claim about the subject matter—the phenomenon of moral judgments.

Returning to Prinz (and to Roskies’s proposal), we can now see that there are really two empirical questions we can ask: First, what is our concept of “moral judgment”? And second, what are moral judgments? Traditionally the first was not regarded as an empirical question. Philosophers probed their intuitions and just assumed that others shared them. Prinz, on the other hand, regards these kinds of questions as empirical in nature and presents his own survey studies that probes *folk intuitions*. He concludes that most people do consider emotions necessary for moral judgments (Prinz this collection,

p. 10; for other studies on this with different results see also Nichols 2002, p. 22; Strandberg & Björklund 2013, p. 325; Björnsson et al. 2014, p. 16).

These studies can answer the first question regarding our concept of moral judgments. But, as Prinz rightly points out, people could be wrong (Prinz this collection, p. 10). These studies do not tell us anything about the subject matter. This is a further point Tresan makes. He argues that even if we have internalist intuitions this is not enough to support internalism. He argues that strength in modality is not interesting for a substantial theory of moral opinions. A claim with strong modality doesn’t tell us more about the subject of the claim than the same claim without it. That, necessarily, bachelors are unmarried (*de dicto*) tells us nothing more than that they need to be unmarried to be called bachelors. It’s a claim about our concept “bachelor”. It tells us simply that the subjects are unmarried—the same as this exact claim without modality tells us. But if bachelors were necessarily unmarried (*de re*) this would be bad news for the subjects and would tell us something substantial about them—that they’re essentially unmarried, that they, the individuals, are unable to be married. He concludes that “[i]f we are interested in the nature of the Subject Matter, we must look to Relation not Modality” (Tresan 2009, p. 57; emphasis in original).

Only an internalist claim with a strong relation is interesting. But Tresan thinks that there are no arguments for a *de re*-internalism, which would tell us something interesting and substantial about the subject matter. A *de re*-internalism that states a strong Relation is wrong. This is because our intuitions regarding moral judgments and motivation can only support a *de dicto* internalism (Tresan 2009, p. 64). And traditional arguments for internalism provoke only such intuitions.

I think it is clear that Tresan misses one important possible source of evidence for a strong relation: empirical evidence. Here lies the connection to Prinz’s work. The empirical findings, which he collected, all point to a strong relation between moral judgment and affective states. I take Prinz to be looking for a strong

Relation when he says that emotions are an “essential component” of moral judgments ([Prinz this collection](#), p. 12).

What I have tried to show here is the following. Prinz raises a potential objection against his own sentimentalism: the relation between moral judgments and emotions lack modal strength. He answers by saying that we have enough evidence to conclude their necessary connection. I argued that this is not a satisfying answer because it misses the core of the objection.

I think the evidence that he has collected points to a strong Relation between moral judgments and affective (motivational) states. Therefore Prinz has an answer to objections that call this strong relation into question. But this is not an answer to an objection that operates with a *de dicto* internalism. Underlying these objections is an opposition to methodological naturalism in general. [Antti Kauppinen](#) is one example of someone holding this position (2008, p. 4). Kauppinen does not think we should ask what moral judgments *actually* are. In his view, metaethics is concerned with what moral judgments *necessarily* are. “This takes us from the realm of the actual to the realm of the metaphysical or conceptually possible, and thus beyond the empirical and the observable” ([Kauppinen 2008](#), p. 22).

The evidence that Prinz presents in the target paper doesn’t suffice to refute this position. But I hope to have shown that this need not be a cause of concern for Prinz, because this kind of necessity takes us away from the subject matter. At the heart of Prinz’s account lies an interest in moral judgments as a natural phenomenon that we should study by empirical means.

Adina Roskies, on the other hand, is sympathetic to empirical philosophy. One of her aims in the internalist–externalist debate was to show that “[...] moral philosophy need not be, and perhaps ought not be, exclusively a priori” ([Roskies 2003](#), p. 2003).

But this is in contrast to her understanding of the required modality of the internalist claim, as I tried to show using Tresan’s analysis. If we want to clarify those kinds of debates em-

pirically, it’s not enough to just take traditional philosophical claims and look for evidence in their favor or evidence that can refute them. We have to formulate them as a posteriori synthetic claims that are part of a bigger explanatory project ([Björnsson 2002](#), p. 329).

I hope that this can shed more light on the implications of naturalistic metaethics for philosophical claims. They shouldn’t be regarded as conceptual a priori claims, but as hypotheses that need empirical confirmation. Naturalistic metaethics is not concerned with a priori conceptual necessities. It requires revising our concepts when they don’t fit into the best theories. In that sense empirical philosophers should be revisionists (see [Francén 2010](#), pp. 137 and 142 for a more detailed account of revisionism).

Before I go on, I want to offer one last thought about this. What might be the motivation for framing these positions as claims about conceptual necessity? [Roskies](#) writes:

I take it that internalist philosophers have intended to offer something stronger than contingent claims about human wiring (...) Only a view involving necessity or intrinsicality can distinguish moral beliefs and judgments from other types by their special content. (2008, p. 193)

But why do we need a priori conceptual necessities to distinguish between different kind of beliefs and judgments? We could start with very simple observations. Apparently people play a game of blaming and blessing: they use words like “good” and “bad” that are somehow different than other terms. The task of defining what morality is could be a descriptive anthropological enterprise. And I think this is in the spirit of naturalistic metaethics.

I have argued that it is enough for Prinz’s sentimentalism (and for internalism) to claim a strong Relation between moral judgments and emotions. But what kind of Relation is strong enough for it? A mere statistical connection is surely not enough. If the important part of the sentimentalist thesis is not the Modality of the whole claim, we have to analyze the terms “ne-

cessary” and “essential” in a non-modal way. One possibility, that harmonizes with naturalized metaethics, is to regard this connection as *functional*.⁵

In the next, and final, section I shall look at Prinz’s critique of non-cognitivism. I shall present a speculative alternative to his view that I hope, again, is in agreement with his proposal for a naturalized metaethics.

3 Defending non-cognitivism as an empirical theory

Here, I want to argue against Prinz’s attack on non-cognitivism. He thinks that there are good empirical reasons to reject non-cognitivism. His first argument is that cognitivism can predict the surface form of moral language better than non-cognitivism. First, I argue against this by pointing to non-cognitivist accounts of moral language that I think can predict this surface form. Second, I provide a speculative non-cognitivist theory of why moral language has the surface form we can observe. Again, I think my proposal is in agreement with Prinz’s naturalized metaethics. I do think, however, that it challenges him to explore the space of possible accounts. My proposal shows, I hope, that the empirical evidence cannot, at this point, decide this question.

The second question in Prinz’s decision tree is whether or not moral judgments are truth-apt. Can they be true or false? Theories that answer yes to this question are cognitivist, while theories that answer negatively are non-cognitivist. *Non-cognitivism* is a collective term that can refer to many different theories (Shafer-Landau 2003, p. 17). It consists of two theses (Roojen 2013, section 1.1): the first says that moral utterances do not express propositions; they’re not truth apt. This is a semantic thesis about moral language. The second thesis says that moral beliefs are not representational. They do not refer to anything in the world. This is a thesis about the mental state of the

moral agent. Here Prinz wants to defend cognitivism by providing empirically-informed reasons to reject non-cognitivism. He defines expressivism in the following way (we can think of Expressivism as one form of the first, semantic thesis of non-cognitivism):

Expressivism =_{Def} Moral assertions express mere feelings or non-assertoric attitudes, and do not purport to convey facts. (Prinz this collection, p. 7)

Prinz denies both of the two theses that make up non-cognitivism. He argues that the most obvious empirical prediction of non-cognitivism fails, as he thinks that if non-cognitivism was true we would expect our moral language to have a non-cognitive form (Prinz this collection, p. 16). But this is not the case. It seems that our moral language mostly has declarative form.

If this is correct, and if I don’t have reasons to disbelieve it, does it mean that non-cognitivism makes wrong predictions? I don’t think this is the case. Much of the work in non-cognitivism is dedicated to explaining this apparent tension. But I don’t think that this involves “elaborate logics”, as Prinz puts it (this collection, p. 16). Rather, most non-cognitivists provide theories about the nature of moral discourse that show that we should expect the surface grammar to be declarative. I don’t think that non-cognitivism has or needs to have these “obvious empirical predictions”.

The starting point is to look at the way language is used. It is not the literal meaning of ethical terms that are of interest but their *function* (Björnsson 2002, p. 328). Expressivism entails a pragmatist theory of moral language:

[T]he pragmatist attempts to describe the function that a word, phrase or concept plays in human life, and once he has satisfied his curiosity there, he does not think that there are any further questions to ask about utterances of that sort. (Smyth 2014, p. 608)

Arguably, such a pragmatist view is easier to naturalize because we have the social sciences,

⁵ For this proposal see Björnsson & Francén Olinder (2013) and Bedke (2009) and Schulte (2012). They detail the idea that we can think of this relation as *teleo-functionalistic*.

which offer large toolboxes for investigating human practices.

Although Prinz's definition of expressivism may be at the heart of non-cognitivism, in most cases this is not the whole story. According to expressivism, moral terms are not only used to express one's attitudes but also to provoke certain attitudes in the hearer. This idea goes back to the early emotivists. The "dynamic use" of language (Stevenson 1937, p. 21) involves the manipulation of others: "[E]thical terms are instruments used in the complicated interplay and readjustment of human interests" (Stevenson 1937, p. 20; emphasis in original).

Stevenson, and many others following him, analyze expressions like "x is good" as meaning "Hooray for x! Do hooray as well!" (Stevenson 1937, p. 25).⁶ It expresses the speaker's attitude and the wish or the prescription that the hearer should adopt this attitude as well.

At this point Prinz could reiterate his point and simply ask: "Why then do we say 'this is good' and not 'I like this, do so as well'?" Here I want to offer a speculative answer: because we don't like to be manipulated. If the function of moral language is, at least in part, to influence the attitudes and the behavior of others, I think we should expect it to take this form. This is because a declarative sentence has more *authority* than a mere expressive one. If I want someone to do something it is arguably more effective to disguise it in non-subjective form, to give it the appeal of a truth-aptness.⁷ I want to disguise it so that it will serve this persuasive purpose.

I don't want to say that these ideas are correct. But they're plausible theories that predict the surface form of moral language, and which are no worse than cognitivist theories. Expressivism focuses on what people do with language. It focuses on the speech act, not the literal meaning. Whether people express, declare, prescribe, describe, recommend, or evaluate is nothing we can easily read from the sur-

face form. But this is what Prinz seems to presuppose when he says the most obvious empirical prediction fails. We have to look at their behavior and the pragmatic context in which the discourse happens.

I argue that this fits even better with Prinz's project of a naturalized metaethics. When Prinz discusses the last step in the decision tree, he writes: "Naturalizing relativism will require the marriage of cultural anthropology and sociolinguistics" (this collection, p. 24). I think this marriage could be more helpful at an earlier stage in the decision tree—to help answer the question of whether or not moral terms aim at truth.

4 Conclusion

In this commentary on Prinz's highly interesting and substantial target paper I welcomed his methodological naturalism, but argued that his project is not as conciliatory between traditional analytical philosophy and naturalized philosophy as he seems to think. The reason is that on closer scrutiny we find opposing views on the methodology and purpose of philosophy. In the second part of my contribution I looked at an objection against Prinz's sentimentalism. I argued, first, that he misses the real core of this kind of objections. Then I used Jon Tresan's distinction between *de dicto*- and *de re*-internalism as a conceptual tool to propose and develop another answer that Prinz could use against this objection. In particular, I claimed that, given Prinz's metaethical naturalism, we should not look for conceptual necessity but for fruitful hypotheses which we can test in *a posteriori*. In the third and last part I argued against Prinz's critique of non-cognitivism. Prinz thinks that the most obvious empirical prediction of non-cognitivism fails. Here, I tried to demonstrate how non-cognitivism, given a pragmatical view of moral language, actually predicts the surface grammar of moral discourse as well as cognitivist alternatives. I proposed a speculative explanation for this interesting fact. This kind of explanation, I believe, fits even better with Prinz's project of a naturalized metaethics.

⁶ Stevenson (1937, p. 25) writes: "I do like this; do so as well!" But the first part looks suspiciously descriptive. Because this doesn't fit with Stevenson's account, I reformulated it in this way.

⁷ Mackie discusses this instrumental use when he discusses why people give their moral judgments the appeal of objectivity (1990, p. 42). But as we saw, Prinz thinks this premise is wrong.

Should Metaethical Naturalists Abandon *de dicto* Internalism and Cognitivism?

A Reply to Yann Wilhelm

Jesse Prinz

Yann Wilhelm pursues three issues in response to my target article. First, he tries to expose my naturalism as more radical than I let on. I concede the point, though I also offer ways in which my radicalism might be mitigated. Second, he exposes a limitation in my argument for internalism, and suggests that naturalists should defend form on internalism that is neutral about conceptual claims (*de re* internalism, rather than *de dicto*). I welcome the suggestion, but also consider how naturalists might defend *de dicto* internalism. Third, Wilhelm challenges my argument against non-cognitivism, by offering a novel explanation of the fact that moral judgments have an assertoric form. I response, I note avenues for cognitivist resistance to Wilhelm's explanation.

1 Introduction

In “Naturalizing Metaethics,” I try to establish that core questions in metaethics lend themselves to empirical investigation. I argue that we can potentially adjudicate long-standing debates by testing predictions made by competing metaethical theories. I also make some conjectures about how such empirical investigations will turn out. Based on a small selection of preliminary findings, I advance a case of a version of sentimentalism—the

view that emotions are essential to moral judgments. I also suggest that sentimentalism commits me to internalism—the view that moral judgments are essentially motivating—and I advance an empirical case for cognitivism—the claim that moral judgments are, like other assertions, capable of being true or false.

In his insightful commentary, Yann Wilhelm offers clarifications and challenges to my

arguments. First, he asks whether my naturalism is compatible with traditional approaches in philosophy. I imply that the two can co-exist in a complementary way, but Wilhelm suggests that my naturalism is more radical than it appears. I am forced to agree, and to clarify the co-existence claim. Wilhelm also challenges my case for internalism, distinguishing two different forms and suggesting I am only in a position to argue for one of them. I am open to that possibility, but I also sketch a strategy for defending both forms. Wilhelm concludes with a challenge to my defense of cognitivism. He provides non-cognitivists with an explanation for findings that I say they cannot explain. I offer a cognitivist response, but grant that this proposal demands empirical attention.

Wilhelm's commentary provides a valuable contribution to empirically oriented metaethics. He offers strategies for avoiding certain kinds of debates with opponents of naturalism, and he identifies empirical issues that can be used to settle debates between card-carrying naturalists. Wilhelm deepens my understanding of these issues and strengthens my optimism about the prospects of naturalistic metaethics.

2 Is naturalism a radical position?

Before moving on to the first order debates that Wilhelm so helpfully pursues, I want to concede an important point that he makes in the opening of his commentary. Wilhelm rightly observes that I overstate the extent to which a thoroughgoing naturalism can preserve traditional approaches to philosophy. Though ostensibly a plea for conciliation, I am, in fact, skeptical about the notion *a prioricity*. Rather, I claim that armchair methods are observational (intuitions are defeasible inner observations informed by prior experience, and open to empirical correction). As Wilhelm makes clear, traditionalists who view conceptual analysis as an *a priori* endeavor will not share my enthusiasm for naturalism.

In another respect, however, my position is conservative. I don't think traditional philosophers must stop working as they currently do. Armchair methods remain the primary source of

philosophical theories and distinctions. They also are the primary source for philosophical thought experiments that can be used to test between theories. Thus, my invitation to interpret armchair methods as observation is intended as a vindication of traditional philosophy, though not a vindication of how some traditional philosophers understand their own endeavors.

Proof of this qualified vindication comes from the fact that empirically oriented philosophers regularly draw on traditional work in devising their studies. For example, experimental philosophers have used trolley problems, twin earth cases, and the thought experiments used to back contextualism in epistemology. In my target paper, I relied on theories that have been identified and articulated within traditional philosophy. Testing between theories requires observation, I believe, but it would be a great loss if every philosopher ran a laboratory. Instead, I envision a future for philosophy in which many researchers do no experimental work, others are primarily experimentalists, and still others do a combination of the two. If we begin to make empirical methods a standard part of philosophical training, then philosophers will be able to read psychological research more responsibly and conduct experiments when they see fit. But it doesn't mean that they will also suddenly stop thinking and blindly collect data. As in the sciences, theoretical work is required in philosophy. We can resist the idea of *a priori* truth without throwing away the armchair.

3 Must naturalist be content with *de re* internalism?

These methodological points bear on Wilhelm's first challenge to my metaethical conclusions. In the target paper I argue for a form of internalism (roughly, the view that moral judgments are essentially motivating). Wilhelm points out that my evidence for this claim will not satisfy many externalists. I primarily rely on evidence that moral judgments always co-occur with emotional states, but for externalists will be impressed; they will say that such findings cannot address questions about whether it is necessar-

ily the case that moral judgments are motivating, even if they always happen to be motivating.

Wilhelm helpfully replies to this objection on my behalf, using Jon Tresan's distinction between *de dicto* and *de re* internalism. The former is a thesis about the concept of moral judgment (viz., it is a conceptual truth that when that concept applies, motivation applies as well). The latter is a claim about moral judgments themselves (viz., moral judgments do in fact carry motivation force). Wilhelm concurs that my evidence can contribute to a defense of the *de re* claim. He suggests that I abandon the case for *de dicto* internalism, since naturalists should not concern themselves with conceptual claims.

I welcome Wilhelm's suggestion, and I am inclined to endorse it. Let me mention, however, a strategy available to the naturalist whose heart is set on defending the *de dicto* claim. Returning to Wilhelm's discussion of methodology, let's imagine that naturalists wage a successful campaign against the *a priori*. Properly pursued, such a campaign might also undermine metaphysical necessity. Metaphysical necessities, unlike nomological necessities, are alleged to be true in virtue of conceptual entailments rather than laws of nature or natural facts. The critique of *a prioricity* threatens metaphysical necessity because it advances the view that truths about concepts are open to empirical revision. Let's suppose that concepts are mental representations garnered through experience with the function of classifying things in the world. So construed, concepts are susceptible to improvement through empirical inquiry. Initial concepts are rough and ready pointers that we use to carve up the observational world, and revised concepts are carvings that remain after observation. Now let us define a "robust conceptual truth" as the conceptual entailments that survive after a concept has been subjected to empirical fine-tuning. Such truths would more or less coincide with how the world is, together with certain pragmatic assumptions that go into theory construction. Thus, they would coincide with truths that emerge from our study of the things themselves (which are also constrained

by pragmatic assumptions). On this picture, *de dicto* collapses into *de re*. A defense of *de re* internalism would indicate that our concept of moral judgment will converge on internalism as well. Rather than bypassing *de re* internalism, we can try to defend it by naturalizing conceptual truth.

Wilhelm might reply that this defense of *de dicto* internalism would not persuade non-naturalists. The defense is based on the assumption that the naturalist critique of *a prioricity* goes through, but that is just what non-naturalists are inclined to deny. Thus, it might appear that the debate over the *de dicto* position is hostage to unresolvable disputes about the nature of philosophy.

Here I'd balk at the claim that such disputes are unresolvable. Those who believe in *a prioricity* may dislike naturalism, but they certainly believe that their views require evidential support. Naturalists offer an account of what concepts are (mental representations) and an explanation of conceptual intuitions (introspection of mental representations). Non-naturalists are obliged to provide an alternative account of both, and the two accounts can then be compared by agreed upon standards. I venture that the naturalist account will find a resounding victory in such a head-to-head match. It is more parsimonious view, since both sides must grant the existence of mental representations, and I suspect it can fully account for our conceptual intuitions.

These are, of course, big debates, which I cannot settle here. My point is simply that we can imagine a two-stage process that begins with broad issues about naturalism, and then moves on to first-order views. On my prognosis, we won't end up abandoning the notion of conceptual truth, but rather revising it. If so, *de dicto* naturalism might turn out true. Wilhelm may be right, however, that until we come to greater consensus on the nature of philosophy, naturalists might be on firmer ground if they try to bypass conceptual questions. He is also right that, from a naturalist perspective *de re* internalism may be the more interesting thesis. Conceptual claims lose their distinctive interest if concepts are revisable and, ultimately, coincident with empirical theories.

4 Can non-cognitivists explain the assertoric form of moral judgments?

Let me turn, finally, to Wilhelm's constructive effort to defend non-cognitivism. Non-cognitivists claim that moral judgments are not like ordinary assertions; they cannot be assessed as true or false, but rather merely express the speakers attitudes and commendations. If so, I ask, why do we express moral judgments as assertions? This is a familiar challenge. In my discussion, I merely point out that can be backed up by empirical data. Wilhelm has a two-part reply. First, he observes that, for non-cognitivists, the primary function of moral discourse is to persuade. C. L. Stevenson, for example, says that "x is bad" does not just mean "boo to x!"; it also means and "say boo to x as well!". Second, Wilhelm makes the original and plausible suggestion that this persuasive function is most effective when it covert. People, he notes, don't like to be manipulated. If I explicitly exhort you to say "boo!" you may resist, because no one likes being told what to do. But if I present my attitude in the form of an assertion, you might causally take it on board, as you would if I were presenting an ordinary statement of fact.

I think Wilhelm's proposal deserves serious exploration. Cognitivists can respond in two ways. First, they can try to show that moral discourse often occurs in contexts that don't aim at persuasion. This might seem implausible. After all, why should we bother engaging in moral discourse if we don't intend to persuade anyone? On closer analysis, however, it does seem that much of our moral discourse involves preaching to the choir. In political debates, for example, left wing pundits and right wing pundits engage in a lot of moral discourse, but they never seem to persuade each other. This raises the intriguing possibility that moral judgments are not primarily in the business of persuasion. An alternative possibility is that we make moral judgments to assert our identity, or express solidarity with like-minded individuals. Empirical tests might be designed to compare the persuasion model and the self-expression model.

Cognitivists might also try to resist Wilhelm's conjecture that people do not like to be manipulated by consulting research on explicit persuasion. In defense of Wilhelm's conjecture, there is a literature suggesting that people sometimes resist explicit persuasion (e.g., [Petty & Cacioppo 1979](#)). On the other hand, resistance does not occur in all contexts. Indeed, in a consumer product context, [Reinhard et al. \(2006\)](#) found that, when a person is regarded as likeable (or attractive!), they become even more persuasive when they make their intent to persuade explicit. Similarly, in studies of college drinking behavior, [Neighbors et al. \(2008\)](#) found that injunctive norms (which explicitly reference attitudes) are effective when and only when they are expressed by members of the students' social groups. Further work could test the effects of explicit injunctions in the moral domain.

I should underscore that I think more testing is required to settle these debates. Wilhelm's explanation for surface discourse remains viable, and we can make progress on these issues by devising new ways to test it. These are manifestly empirical issues. While I wager with the cognitivists, I grant that the case is far from closed.

5 Conclusion

I am indebted to Yann Wilhelm for his generous and probing commentary. It brings welcome clarification and new challenges to the project I set out "Naturalizing Metaethics." I also welcome the spirit of Wilhelm's discussion, which moves beyond ideological debates about metaphilosophy, and offers promising strategies for answering core metaethical questions.

Wilhelm successfully establishes that my preferred form of naturalism is less compatible with traditional philosophy than I let on, but I also pointed out that work by traditionally minded philosophy remains an invaluable font of philosophical theories. Wilhelm then offers a helpful suggestion that naturalists might more easily defend internalism if they bypass conceptual versions of that view. In response, I suggested that the radical implications of naturalism may actually offer a way to defend the concep-

tual version of internalism, by advancing a naturalized account of conceptual truth. Finally, Wilhelm offered a new psychological cum functional account of moral discourse, which inoculates non-cognitivists against grammatical objections. While I hold out hope for cognitivism, Wilhelm has identified a genuine empirical challenge to the cognitivist. This challenge beautifully demonstrates the value of empirical testing in metaethics, and it also reminds us that there is much work to be done.

The Representational Structure of Feelings

Joëlle Proust

The word “feeling” denotes a reactive, subjective experience with a distinctive embodied phenomenal quality. Several types of feelings are usually distinguished, such as bodily, agentive, affective, and metacognitive feelings. The hypothesis developed in this article is that all feelings are represented in a specialized, non-conceptual “expressive” mode, whose function is evaluative and action-guiding. Feelings, it is claimed, are conceptually impenetrable. Against a two-factor theory of feelings, it is argued, in the cases of affective and metacognitive feelings, that background beliefs can circumvent feelings in gaining the control of action, but cannot fully suppress them or their motivational potential.

1 Introduction

“Feeling” denotes a reactive, subjective experience with a distinctive embodied phenomenal quality and a formal object, which may or may not coincide with embodied experience. Feelings typically express affect and valence in sensation. “Reactive” means that feelings are closely associated with an appraisal of a present property or event. The term “reactive” is crucial. The term “feeling” is sometimes used to refer to a non-reactive, perceptual experience. For example, when one perceives an object through touch, it is common to say that “one feels one’s key in one’s pocket”. But “feeling”, in this context, does not refer to a reactive phenomenon.

It rather refers to the feedback of one’s own key-touching activity. This type of perceptual feeling is expected to result from one’s action and, hence, does not belong to the domain of reactive feelings. What is called the “formal object” (see [Kenny 1963](#)) of a feeling is the property in the triggering event that elicits the reactive feeling. For example, the formal object of fear is some threatening property detected in the perceptual field.

Feelings can be pleasant or aversive, strong or weak, short-lived or long-lasting, or have an arousing or depressing character. They motivate distinctive dispositions to act, whose

Glossary

Feeling	“Feeling” denotes a reactive, subjective experience with a distinctive embodied phenomenal quality and a formal object, which may or may not coincide with the embodied experience. Feelings typically express affect and valence in sensation.
Reactive	“Reactive” means that feelings are closely associated with an appraisal of a present property or event.
Formal object	“Formal object” of a feeling is the property in the triggering event that elicits the reactive feeling.
Metacognitive feelings	Metacognitive feeling are experienced while conducting a cognitive task: the agent may find the task easy or difficult, anticipate her ability or inability to conduct it. Once the task is completed, the agent may have the feeling of being right, or have a feeling of uncertainty about the outcome of her endeavour.
Affordance	Affordances are positive or negative opportunities, expressed in feelings: an affordance-sensing swiftly and non-reflectively motivates the agent to act in a particular way.
FS Affordance	FS Affordance _a [Place _a =here], [Time _a =Now/soon], [Valence _a =+], [Intensity _a =.8 (comparatively specified on a scale 0 to 1)], [motivation to act of degreed according to action programa].
Transparency	A mental state is transparent if, when it is activated, its intentional content is accessible to the subject who entertains it.
Incidental and integral feeling	Metacognitive feelings are called “incidental” when they are not based on valid cues about the cognitive task at hand, and hence, have no predictive value. They are called “integral” when they actually carry information about cognitive outcome.

urgency is entailed both by the feeling experience and the context in which it is experienced: feeling an intense pain disposes the person to promptly locate and remove the cause of the pain; except, for example, when it is self-inflicted, or when it is part of a ritual.

Most theorists of feelings agree that they are associated with—or, for those who identify emotions with conscious experiences¹ consist of—specialized, internally generated bodily sensations, such as an increase in heart rate, contractions or relaxations of the facial muscles, visceral impressions, tremors or tears, impulses to run away, etc. As will be seen below, some feelings, however, do not express emotions., i.e.,

¹ From the viewpoint of the somatic feeling theory of emotions, emotions can be explained as a somatic change caused by the perception, real or simulated, of a particular object. See [James \(1884, p. 190\)](#), and [Damasio \(1994, 2003\)](#). Other theorists of emotion, however, consider that the conscious experience of having an emotion includes propositional attitudes, and not only feelings. See sections 4 and 5 below. Moods are long-term affective states, and will not concern us here.

they are not affective. A feeling tends to be more explicitly felt as bodily when it has a body-related function; that is, the phenomenology makes the need to be served salient (feeling tired, feeling a pain in the joints) in order to motivate action. In affective feelings, in contrast, the bodily phenomenology tends to recede to the fringe of consciousness (feeling in love with *A*, feeling angry with *B*).² From this observation, it is easy to infer that types of feelings differ in their respective meanings: they in some sense *express what they are about*. In affective feelings, an experience of “feeling toward” is supposedly present: the emotion is felt as being about an object, a person, or a situation—the objects, rather than bodily sensations, are the focus of one’s emotional attention. Affective feelings also include mixed cases where one seems to both experience a strong bodily feeling at the same time as the intentional content that

² On this concept, see [Mangan \(1993, 2000\)](#) and [Reber et al. \(2002\)](#).

this feeling seems to refer to, as when Marcel Proust's narrator reports experiencing an acute pain in the chest when thinking about his beloved deceased friend, Madame de Guermantes.³ It is unclear whether metacognitive (also called noetic, or epistemic) feelings are affective or non-affective (see section 7 below). They are experienced while conducting a cognitive task: the agent may find the task easy or difficult, and may anticipate her ability or inability to conduct it. Once the task is completed, the agent may have the feeling of being right, or may have a feeling of uncertainty about the outcome of her endeavour. Take the case of a person who feels unable, presently, to remember what she had for dinner last night. Her feeling of not remembering is correlated with activity in a facial muscle, the corrugator supercilii (Stepper & Strack 1993). Her feeling, however, is not about her disposition to contract or relax this or that muscle, of which she is certainly unaware. It is, rather, about her present disposition to remember what she had for dinner. Epistemic feelings seem to be “feeling-toward” experiences, and have cognitive dispositions or contents as their object.

Descriptive phenomenology, however, does not offer in itself an account of the intentional structure of feelings. We need to understand how feelings in general gain their real or supposed aboutness, and how they relate to action-guidance as a function of context; i.e., we need to provide a functional analysis of feelings. Section 2 will begin to provide such an analysis, and will address a preliminary issue—namely, Do the phenomena that are usually called “feelings” share a property that makes them a natural kind? In section 3, the specific informational structure of feelings will be seen to account for their generic characteristics. Section 4 will clarify the account by way of addressing various objections. Section 5 will attempt to show that the proposed account fares better with experimental evidence than a cognitivist account of affective and metacognitive feelings. Section 6 will examine whether or not metacognitive feelings have an affective valence.

2 Are feelings a natural kind?

Paul Griffiths has claimed that *emotions* do not constitute a natural kind, in the sense that they do not form “a category about which we can make inductive scientific discoveries” (2004, pp. 901–911). One can agree with latter claim, however, without concluding that *feelings* do not constitute a natural kind. First, feelings are not only affective ingredients in emotional awareness. Some feelings, such as feeling cold or sick, or feeling that one is acting, have nothing to do with affective episodes. Second, there are evolutionary reasons to distinguish, within emotions, two classes of subjective appraisals. Emotion theorists usually contrast *feelings* expressed in primary emotions—fear, anger, happiness, sadness, surprise, and disgust—with *various appraisals cum conative dispositions* associated with higher cognitive emotions, such as envy, guilt, pride, shame, loyalty, vengefulness, and regret. The first are phylogenetically and ontogenetically prior to cognitions. They belong to the ancient limbic system, which is present in some form in most animals. A quick route from the retinal image to the amygdala through the thalamus allows affective information to control behavior (see LeDoux 1996). Primary feelings are thus triggered independently of concept possession and motivate specific responses. Secondary affective experiences, in contrast, might have evolved on the basis of social constraints in relation to cooperative action among humans. Indeed (with the possible exception of pride and shame) they are not present in nonhuman *primates*.⁴ They activate newer brain structures; they require concept possession, depend on background beliefs, and do not generate characteristic behaviors. Finally, primary feelings are clearly embodied, while secondary emotions seem to have no proprietary somatic markers. An interesting idea, suggested by Jesse Prinz (2004, p. 95), is that the facial or somatic correlate of secondary emotions, *when they have one*, involves a blend of the somatic markers for primary feelings.

³ See the analysis of this example in Goldie (2002), p. 56.

⁴ On this contrast, see Frank (1988), Griffiths (1997), and Prinz (2004, pp. 82–83). On whether they qualify as emotions, see Ekman (1992).

In summary: emotions differ, among other things, because of the unequal role that feelings have in the two classes of emotions just discussed. The wider scope of feelings, when understood as “reactive, subjective experiences with a distinctive embodied phenomenal quality”, seems to be more unified than emotions, and making feelings seem like plausible candidates for a natural kind.

We need, however, to turn this tentative definition into a general functional characterization that presumably holds for all feelings (beyond affective ones) and only for them. Here is a proposal: feelings constitute the sensitive part of predictive and retrospective processes of non-conceptual evaluation of one’s own and others’ well-being and actions. Being essentially evaluative, feelings are always the output of a comparator: in other terms, they are crucial *monitoring* ingredients in self-regulated adaptive control systems. In such systems, the specific function of a feeling consists in detecting how much a current *observed* value of a parameter *deviates from its expected value*, on one or several dimensions relevant to survival (see Carver & Scheier 2001). Their formal object, when they have one,⁵ (such as being afraid of the bear in front of me) cannot be analyzed independently of the monitoring function they serve within a specialized control loop.⁶ Relevance to well-being, however, extends to bodily condition, goal achievement, and availability of preferred goods of all kinds (food, partner, social status). The relevant dimensions of variation that feelings track may accordingly be of a sensory, proprioceptive kind (feeling thirsty, cold, etc.), social-affective (feeling angry), or agentive (goal-related). Goal achievement, however, involves either epistemic or instrumental success, respectively generating epistemic feelings (feeling interested, bored, epistemically uncertain) and agentive feelings (feeling of happiness, of agentive confidence, of ownership of one’s action, etc.). Feelings, in summary, are the outcomes of comparators in a con-

trol loop; they carry non-conceptual information about how much one’s present condition deviates from the expected condition. From a functional viewpoint, they form a natural kind insofar as their function is to indicate a comparative outcome through a dedicated embodied experience.

Note, however, that there are comparators that trigger no feelings at all: these non-sensitive comparators may either work outside consciousness (for example, error signals driving immediate correction⁷, not to mention comparators that work at the cell level), or they can take concepts as their input, rather than reacting to percepts or situations (for example comparators of currency or of educational value).

As far as feelings are concerned, they are directly related to a presently-perceived context (or an imagined or remembered context, but in a “present-like”, indexical mode): one can feel too hot, too cold, or too tired (or feel “OK”, which usually means a tolerable deviation from the expected value). One can feel the fright one has had, even after the frightening event has ended. The outcome of a feeling-based appraisal, from a functional viewpoint, has to consist in some disposition to act that is adaptive, relative to the input to which the feeling is a reaction. Granting that feelings, as sensitive comparators in a control system, form a natural kind, there should be common properties cutting across the various types listed above. In fact we find three types of functional relations between feelings of a given kind and the associated disposition to act. First, feelings, according to their embodied valence, typically determine actions of approach or of avoidance. Some dictate caution, others boldness. Some encourage self-restraint, others self-assertion. Fear promotes a flight tendency, hunger a tendency to approach food. Second, they have a specific orientation in time: some feelings have a *predictive* function, and thus induce a behavior that is based on contingencies to be *further* displayed in the present context. For example, fear, when directed at a possible danger, increases the readiness to flee in case the danger concretizes.

⁵ As observed by Goldie (2009), some feelings, for example, [feeling anxious] or [feeling depressed], seem to lack a formal object, which is typically the case with moods. As indicated above, moods will not be discussed in this article.

⁶ Bechara et al. (2000) make it clear that the somatic marker theory applies to action, whether it engages affects or not.

⁷ see Logan & Crump 2010 and Nieuwenhuis et al. 2001

Others have a *retrospective* function, and induce corrections to the commands one has previously used, or to one's previous preferences. For example, feeling nauseous *after* food ingestion induces food avoidance, i.e., a change in the agent's preferences. In contrast, feeling disgust at the sight of some food may prevent the agent from approaching it. A subset of feelings, such as feeling happy, have both temporal orientations. Third, according to their embodied dynamics and intensity (which is called their "level of arousal"), feelings can provoke an elevation in the energy available to the system: they provoke excitement, agitation, power in the coming response; or, on the contrary, they may have a soothing effect and diminish the tendency to act.

One major functional property of feelings, from the viewpoint of information extraction and use, is that they can very rapidly extract and synthesize multiple cues from perception. This rapidity is a consequence of the automatic and encapsulated character of the control mechanism whose output they express. Feelings are automatically triggered by a specific type of input (which is the definition of informational encapsulation).⁸ Automaticity is associated with feelings being inescapable, at least for those feelings that have been allowed to develop within a culture, granting normal development.⁹ The mechanism that generates somatic, noetic, or affective feelings from inputs (perceptual, imaginative, or memorial) does not require one to have specific beliefs or intentions.¹⁰ Informational encapsulation explains why transitive feelings persist when the agent finds out that the situation is different from what she thought to be the case. Just as an optical illusion such as the Müller-Lyer effect does not immediately dissipate when it turns out that the segments are equal, a feeling of anger does not disappear as soon as the agent realizes that its formal object is not exemplified.

⁸ Automaticity in appraisal is central to Ekman's analysis of primary emotions (1992). See also Griffiths (1997), Prinz (2004), and Zajonc (1980). On informational encapsulation, see Fodor (1983).

⁹ For example, fearlessness in the presence of danger may result from a disturbed childhood.

¹⁰ Some affective feelings, however, can be intentionally controlled in the long run, through cultural learning. See Murata et al. (2013).

Automaticity and informational encapsulation seem also to characterize agentive feelings (see Pacherie 2008). Feelings generated in the course of a physical action come in two varieties: generalized or specialized. Some, such as feelings of agency, of initiation of action, of ownership and of motor control, are indicators monitoring action in progress: they concern "who" is performing the action, and "how" the action is being conducted (see Proust 2000). Others concern the evaluation of an action in one's own repertoire: a professional carpenter or an experienced musician, for example, have feelings telling them if an action sequence (whether their own or another agent's) in this repertoire sounds or looks right, even before they identify why they have this feeling. These feelings are also the outputs of a comparison between motor anticipations and observed properties of the action (a "forward model of action" supposedly stores the expected values of crucial parameters; Wolpert et al. 2001). They can predict the likelihood of completing an action (when the question arises, in difficult or non-routine cases), or evaluate—on-line or in retrospect—how swiftly, effortlessly, or unhesitatingly an action was performed. Agentive feelings thus have an essential role in regulating the fundamental properties of physical actions, such as the quality of the outcome,¹¹ and the ownership of the action.¹²

Noetic feelings, finally, are functionally similar to somatic, affective, and agentive feelings—although their evolutionary pattern seems to be different from the other three kinds. While most organisms have proprioceptive, affective, and motor control, and hence, presumably, somatic, affective, and agentive feelings, few are able to control their cognitive decisions through metacognitive feelings (see Beran et al. 2012 and Proust 2013). The latter are generated when trying to perceive, to remember, or to plan a cognitive task (in particular, when trying to plan how long to study material in order to

¹¹ Non-conscious error signals can also guide corrective steps, without the agent noticing them.

¹² Pat Haggard et al. (2002) have demonstrated the crucial role of the temporal binding between felt initiation of action and output in the sense of being the agent of an action. See, among other articles, Haggard et al. (2002).

master it).¹³ They are also relied upon when trying to reason or to solve a problem; when conversing, feelings of effort, and of informativeness, are monitored by speakers and hearers in order to maintain a common level of relevance. Like other feelings, they have two distinctive temporal orientations. Some have a predictive function. A feeling of knowing (FOK) may arise when trying to remember an item—for example a proper name—that one has not yet retrieved: having a strong FOK reliably predicts that one will finally retrieve the searched content (Koriat & Levy-Sadot 2001). A feeling of having a name on the tip of one's tongue (TOT) both signals the fact that a word is not presently available, and, according to its onset, valence, and intensity, whether it is worth or not worth pursuing one's effort to retrieve it (see Brown 1991 and Schwartz et al. 2000). Feelings of fluency are the sense of ease of processing one may feel or fail to feel when attempting to perceptually discriminate objects with a given property, or to retrieve items from episodic or semantic memory. A feeling of familiarity is particularly salient, in human adults, when no further fact about the target can be retrieved. It offers useful information about the epistemic status of the target: that it is not new, but nevertheless not fully recognized. A feeling of familiarity, then, motivates, among others, an attempt to recognize what or who a target is. Other metacognitive feelings have a retrospective function. When a name is retrieved, a feeling of rightness (FOR) motivates the agent to consider her response the expected one.¹⁴ Various feelings of uncertainty, based on fluency, coherence, plausibility, informativeness, or relevance, also have retrospective functions: their valence and intensity tell the agent whether she should accept or reject a cognitive outcome. These parameters are expressed through specialized somatic markers, such as increased activity in the facial muscle involved in smiling, the zygomaticus major—for positive valence—or the corrugator supercilli (involved in frowning)—for negative valence (Winkielman & Cacioppo 2001).

Taken together, these considerations are compatible with the view that somatic, agentive, metacognitive, and “primary” affective feelings, even if they differ in their formal objects, form a natural kind. Our attempt above at a functional characterization focused on the general relations of feelings to inputs, outputs, and mediating evaluative mechanisms. From this characterization, it emerges that feelings are gradients in comparators that are felt subjectively, rather than being propositional states describable in analytic, objective terms. These observations, however, suggest that, in order to express a specialized and fine-tuned reactivity to one or several formal objects, and to motivate adapted behaviors, in order to be remembered and conveyed to others feelings must have their own representational format. We now turn to the following question: What is the structure of the information that is extracted and expressed in a feeling?

3 What kind of information do feelings express?

The above question is important for clarifying the relation of feelings both to their formal object, when they have one, and to the action that they motivate. In the case of metacognitive feelings (M-feelings), the difficulty is particularly pregnant: it stems from the fact that, if we grant that M-feelings do not require concept possession to be felt, then it is unclear how their formal object should be construed: What are they about? Let us take a feeling of uncertainty, felt while trying to remember a proper name. Is this feeling about a memory *state*, or about a *disposition* to retrieve a proper name? If a feeling is about a memorial state or a disposition, its intentional content needs to include concepts of memory, of correctness, and of uncertainty. Empirical evidence, however, demonstrates that animals with no mindreading ability, and hence that are deprived of concepts of perception or of memory, are able to monitor their perception and memory as reliably as humans do.¹⁵ Furthermore, human children, from

¹³ This prediction involves judgments of learning (JOL). See Koriat & Ackerman (2010).

¹⁴ On FORs, see Thompson et al. (2011).

¹⁵ Rhesus monkeys have been found to opt out of more or less challenging perceptual or memory trials as a result of trial difficulty. For a

early on, are sensitive to the contrast between familiar and unfamiliar faces and environments. This supports our claim above: one can feel cold or anxious or uncertain without having the corresponding concepts of those feelings. A propositional format does not seem to apply to feelings in general.¹⁶

How do feelings fulfill their particular embodied, subjective way of representing—a mode we will call the “expressive mode”? The broadly functional characterization given above provides useful clues. Expressive representations comprise exclusively non-conceptual, perceptual, and evaluative (gradient- and valence-based) elements, which taken together express a subjective relation to the environment (internal or external) and a given tendency to act. It should be emphasized, however, that adult humans can obviously entertain *simultaneously* expressive and conceptual representations. The present hypothesis, in conformity with the literature on dual-processing, is that the expressive system processes information and influences decisions on the basis of its own narrow range of associations and norms; while the conceptual system takes advantage of background beliefs and inferential reasoning to make decisions in light of a broader set of norms. Let us take the case of an agent feeling joy after having won the lottery. A human adult normally has [lottery] in her conceptual repertoire, along with some of the inferences that can be made on its basis. However, the agent’s reactivity to the winning event falls under the expressive mode of representation, because this is the mode in which evaluation of the opportunities is conducted. This feeling representation presumably enlightens and orients the concept-based reasoning that can be conducted concerning the same event, such as wondering how to spend the money, or whether quitting her job is a good idea. We propose to call “affordance-sensing” the information that a feeling expresses. Affordances are positive or negative opportunities, expressed in feelings: an affordance-sensing swiftly and non-reflectively

motivates the agent to act in a particular way. Departing somewhat from Gibson’s use of this term within his ecological theory of perception, “affordance” is used here to refer to a non-conceptual and entirely subjective appraisal of the environment by the agent: an affordance is a perceived utility, which can be positive (something to approach and grasp) or negative (something to avoid and from which to flee).¹⁷

The corresponding representation has an indexical structure, because it has an essential relation to an occurrent represented property. Indexicality, however, has to be understood here in a non-referential sense. What is indexed is an *occurrent* (relational) affordance, rather than an individual event or object. Here is our proposal for what a given feeling structure (FS) looks like:

- FS Affordance_a [Place_a=here], [Time_a=now/soon], [Valence_a=+], [Intensity_a=s (comparatively specified on a scale 0 to 1)], [motivation to act of degree_a according to action program_a].

The subscript “_a” is meant to indicate that all the elements that have this subscript are representational cues, i.e., ingredients, in present affordance-sensing *a*. Note that the strength (or degree) of the motivation to act does not depend only on the fitness significance, i.e., on the valence and intensity of the affordance. Other factors, such as the physical condition of the agent and her prior arousal level (her mood) also modulate her motivational level (Schwarz & Clore 2007). The specification of the location of the affordance may vary, depending on the way the feeling was generated, but indexicality and reactivity suggest that the relevant affordance is often sensed to occur where the feeling is experienced. As will be seen later, however, M-feelings do not involve a specification of place.

The feeling structure proposed above includes somatic markers, even if they are not

summary of the results and a methodological discussion of their significance, see Beran et al. (2012), Chapter 1, and Proust (2013), Chapter 5.

¹⁶ For a defense of emotional representations as nonconceptual and action oriented, see Griffiths & Scarantino (2009).

¹⁷ See Proust (2009, 2013). Prinz (2004) briefly discusses this idea in connection with the intentional content of emotions (p. 228). See also Griffiths & Scarantino (2009): in emotion, “the environment is represented in terms of what it affords to the emoter in the way of skillful engagement with it.”

made explicit: these markers are the substrates for the information of valence and intensity. This information is carried by neural activations and associated bodily changes, such as a sudden sensation of pleasant muscle relaxation, or of unpleasant muscle contraction, or of visceral contractions associated with fear. Intensity of affordance, i.e., the arousal produced by a feeling, is also felt through the comparative amount of bodily reactivity to the affordance. These somatic markers, as emphasized above, are themselves part of a monitoring system designed to predict and assess one's relations to the environment along the relevant dimensions listed above (agency, individual and social well-being, preferences, and metacognition).

Let us consider further how to read the feeling structure given above. It is meant to reflect not only what is presently felt, but also what is stored in memory when a feeling is experienced, what can be imagined, and what can be conveyed to others in expressive behavior. The central idea is that feelings sensitively express *a subjective, embodied relation to an opportunity* in an input from the environment (understood in a broad sense as including external and bodily properties relevant to well-being). This primitive intentional relation is best captured by the term *affordance-sensing*. Feelings express this affordance as their focus (or formal object), along with its graded valence—ranging from very unpleasant to very pleasant—and with its intensity gradient, which ranges from small to large.¹⁸

As often emphasized, reactivity to an affordance occurs very rapidly in a processing sequence—even before the perceptual processing has been completed—and well before a concept-based judgment can be made (see Dolan 2002, p. 1191; Griffiths 1997, pp. 77; LeDoux 1996, pp. 174; Prinz 2004, pp. 60, and Zajonc 1980, pp. 153). This suggests that an alternative,

evaluative informational system screens the input with its own independent memorial structures.¹⁹

An affordance does not need to have an objective counterpart to be sensed, i.e., for a feeling to arise: it is enough that the agent anticipates it (even wrongly), imagines it, or remembers it, for the corresponding feeling to be expressed. A feeling, thus, does not presuppose a conceptual appraisal of the context, but rather it indexes in an embodied way a direct evaluative registration. Given that an affordance does not aim at characterizing the world, one cannot say, when the expressed affordance has no objective counterpart, that a feeling “misrepresents” the world as having a given affordance, or reciprocally that an existing affordance was “missed” by the agent when the latter failed to detect it. For misrepresentation to occur, a system must be equipped to attribute properties to individual objects, that is, it must be able to apply concepts. The expressive system, however, does not refer to objects as independent entities. Hence, affordance is not literally what a feeling is about, because aboutness presupposes that what is represented is independent from the representational system. Being relational, affordances cannot be grasped independently of the experience of a sensitive agent. When saying that a feeling “expresses” an affordance, we mean that it “resonates” to it (or that it monitors it). Resonance is a neural-somatic reactivity: it carries indexical and evaluative information, but it does not refer to the world or attempt to describe it.

It is possible, however, to objectively characterize what a feeling functionally refers to, and to pinpoint cases of misrepresentation, by re-describing the feeling structure above in non-subjective, non-evaluative propositional terms. Taking advantage of her perceptual and background beliefs, the agent can claim to have mistaken a piece of wood for a snake, for example,

¹⁸ For a review of the theories of valence, see Prinz (2004), Ch. 7. Prinz takes valence to be a different determinate experience in each feeling. On valence as determined by overall value, from a consumer semantics viewpoint, rather than as an experience of pleasure/displeasure, see Carruthers (2011), pp. 127–130. This view, however, does not build on the nonconceptual information being felt, but rather on its being represented “in an abstract and amodal way”, which, nevertheless, is motivating.

¹⁹ These expressive representations do not require a system to have the capacity to form propositional representations. They are close to what Strawson called “a featural representational system”, allowing an animal to navigate with no propositional thinking (1959). On the comparison between the two representational modes, see Proust (2013). The question of the penetrability of feelings by propositional thought is explored below, in section 5.

and to make explicit that there is no reason to be afraid of a piece of wood.

Our analysis of FS helps us to clarify why “feeling one’s keys in one’s pocket” does not belong to reactive feelings. Recognizing through touch the object in one’s pocket as being one’s keys, or merely having a proprioceptive experience in fact caused by one’s keys, are two ways of perceiving one’s keys, involving respectively cognitive and sensory proprioception. But neither needs as such to involve an affordance of a given intensity and valence. In contrast, let us suppose that the perceiver believes wrongly that she has forgotten her home keys, which are in some distant location, and will not be able to get back home. Feeling her keys in her pocket immediately triggers a positive affordance, opening up the field of possible actions.

4 Questions and objections

The present proposal raises a number of additional questions and objections. Let us start with the most radical objection.

4.1 Are feelings representations?

Granting that feelings, affective or not, can be pure “physical effects of objects on the nerves”, in [William James’](#) terms (1890, vol. 2, p. 458), they do not need to have any genuine representational value. James invites us to take the case either of purely somatic feelings or of objectless emotions when they are generated by a pathological condition—such as the precordial catch syndrome (PCS) which is a feeling of pain in the chest that usually goes away without treatment, but can lead the victim to think he or she is suffering a heart attack. In this case, the emotional experience of dread, [James](#) says, is “nothing but the feeling of a bodily state, and it has a purely bodily cause” (1890, vol. 2, p. 459). From this, one might conclude that a feeling is a merely peripheral phenomenon: it does not have a function to represent, nor does it express anything in particular. What can be said, in response, is, first, that feelings have a crucial evaluative function, which they perform thanks to their expressive structure. In PCS, the pa-

tient’s experience of dread has valence and intensity, expressed through sudden breathlessness, chest constriction, blurred vision, tingling sensations in the skin, an elevated heart beat, and a disposition to crouch. These feelings are not only a matter of sensory “peripheral” experience: they are also used by the patient to collect her existing Bayesian correlations, and to monitor with their help the present affordance expressed. A second illustration of the representational nature of feelings is that they can arise in the absence of the sensory basis they seem to have. For example, illusory feelings of being touched—a reactive somatosensory feeling about a change occurring on one’s body surface—can be created by manipulating the coherence of the intermodal inputs from vision, touch, and proprioception. In the so-called “rubber-hand illusion”, participants feel that their hand is being touched with a paint brush, when in fact it is an artificial hand, not theirs, that they see being touched. They also, after a while, “feel as if their (real) hand is turning ‘rubbery’” (see [Botvinick & Cohen 1998](#)). This experiment is evidence that feelings are informational states, which monitor inputs, and, in extreme cases like this, cause the brain to try to reconcile contradictory multimodal input. In the proposed interpretation, however, seeing one’s hand being touched is a reactive feeling, while actively touching an object generates a percept—which plays quite a different role in cognition.

4.2 What does “resonating to an affordance” mean?

Second, speaking of “subjective resonance” to an affordance (see the discussion of how a feeling “resonates” to an affordance in section 3 above) may look improperly metaphorical.²⁰ This is meant, however, to mark the difference between feeling and perceiving. While percepts allow recognition and identification of external objects and properties, feelings express specific affordances in a perceived, imagined, or remembered situation. For example, one can feel cold right now, or simulate being cold when

²⁰ In a similar vein, [William James](#) writes that, in emotions, “the whole organism is a sounding board” (1890, vol. 2, p. 450).

planning a polar trip; one can remember how angry, or bored one was in a given episode and context. Feelings give agents prompt access to the relevant features of a new situation through sensed changes in their experience. Importantly, resonance is also an apt term for empathy, i.e., for the propagation of feelings from an agent to an onlooker, based on expressive behavior (Decety & Meyer 2008; Dezechache et al. 2013). Brain imagery suggests that the perception of pain in another individual largely overlaps with the regions activated when experiencing pain oneself (Jackson et al. 2005). Such empathy, in the present proposal, exemplifies how a feeling structure can be communicated through a set of congruent behavioral cues associated with a given affordance (here a painful stimulus), with a valence and intensity that are bodily conveyed.

4.3 Non-conceptual content as a common feature of feelings and percepts

Third, one might object that a common feature of feelings and percepts is that they include non-conceptual contents. This is true; but notice the difference between the two types of non-conceptual content: while non-conceptual ingredients in perception are related to objective, external contrastive cues such as shapes, edges, colors, volumes, and auditory patterns, which can be static or dynamic, but are always purely descriptive, non-conceptual contents in feelings only include evaluative states, which combine the general type of the affordance, its valence, its intensity, the proper action program, where all constituents are “bodily marked”, i.e., expressed through somatic markers. Therefore we cannot say that feelings “perceive” affordances, for this would suppose either that feelings have direct sensory access to the world—which they don’t, for they extract their inputs from sensory perception—or that they have direct sensory access to the body, which they don’t have either—feelings are the subjective counterpart of bodily changes. Therefore we cannot say that agents “perceive affordances” when they experience a feeling, for this would suppose either that feelings have a direct sens-

ory access to the world, which they don’t, for they extract their inputs from sensory perception, or that they have direct sensory access to the body, which they don’t have either. Feelings are the subjective counterpart of bodily changes.

Neuroscientific research about the role of emotion in perception offers evidence in favor of this view. An affordance is made immediately salient by the system’s ability to sensitively react to a (half-)perceived element in a given known context.²¹ We speak of “half-perception” on the basis of what is known about the timing of object perception. Affordance predictions are made only milliseconds after visual sensations register on the retina, i.e., before the categorisation of perceived objects is completed (Barrett & Bar 2009). The orbitofrontal cortex (OFC; involved in emotion and reward in decision making, thanks to projections from the thalamus) is able to extract an affordance in the first 80ms of the visual process, merely on the basis of low spatial frequency and magnocellular visual input (Lamme & Roelfsema 2000). What happens to perceptual access when a perceiver cannot extract affordances? Barrett & Bar (2009) have shown that the lack of emotional reactivity in early perception impairs object categorization. A patient who accidentally lost his visual ability when three years old received in adulthood a corneal transplant. In spite of his recovered ability to extract visual information from the world, this perceiver had trouble categorizing what he saw. The authors’ suggestion is that reconstituting the internal affective context associated with past exposures to an object (which was lacking in this particular case) is “one component of the prediction that helps a person see the object in the first place” (Barrett & Bar 2009, p. 1325).

In summary: the medial OFC uses early low-level visual output to match the affordance associated with it in past experience of the object: somatic markers are thereby activated, and the appropriate action is prepared. A FS enables an object to be more swiftly categorized

²¹ For a defence of this view in terms of situated cognition, see Griffiths & Scarantino (2009). The authors emphasise the environmental scaffolding that makes possible affordance detection in emoters.

at higher perceptual levels. This evidence suggests that affordances are extracted from perception, but that feelings are not themselves perceived.²² On the contrary, they offer a separate kind of feedback to cognitive perceptual processes.

4.4 Respective role of somatic markers and formal content

Let us turn now to one of the most central questions that our proposal raises. How does it explain the respective roles, in expressive intentional content, of somatic markers, on the one hand, and of the represented formal objects on the other? Cognitive theorists take emotions to represent both salient aspects of the agents' own bodily changes and an evaluative belief about an external fact, with, possibly, a causal relation between this fact and the experienced bodily change (see [Gordon 1987](#); [Tye 2008](#) and [Solomon 2007](#)). For example, when perceiving a bear in the near vicinity, one's experience is taken to be about a complex of subjective bodily impressions (a pounding heart, trembling legs, etc.) and about the perception of a bear as being the cause of these changes. Such a construal of the intentional content of feelings only makes sense within a propositional mode of thought. Can our expressive mode reflect or approximate the information contained in this complex causal structure?

Clearly, FS does not *explicitly* convey a causal relation between situation, somatic markers and subjective feeling. It carries this causal relation implicitly, however, as a consequence of the control architecture that produces feelings. In an emotional control loop, a perceived affordance causes (rather than being represented as causing) its expressive evaluation through its specialized sensory feedback. Emotional awareness expresses this functional relation. An external event (made accessible through a perceived affordance, as detailed above) is immediately followed by subjectively experienced somatic cues of a given intensity and valence. In functional terms, this sequence makes sense in

the following way. When an associated forward model has been selected (often automatically, on the basis of an environmental, somatic, or cognitive affordance), the associated sensory cues (the somatic markers in this particular episode) are automatically activated in order to monitor how this affordance is to be processed and reacted to. As has been shown elsewhere, monitoring implicitly carries information about the command (or the affordance) that is being monitored (see [Proust 2013](#)). This explanation is particularly detailed and convincing in the case of motor representations of action; the feelings of agency that result from the comparators associated with a given feedforward model express (among others) whether the emoter is, or is not, the author of the action currently attended to (see [Wolpert et al. 2001](#) and [Pacherie 2008](#)). The present proposal generalizes the functional significance of feelings throughout their diverse types (reviewed in section 2). As the outcome of sensory comparators, feelings always carry a structured information set about the type of affordance they contribute to regulating, about its amount, and about which actions are appropriate. This information, in its own expressive mode, functionally approximates a causal relation that is, when propositionally expressed, represented as a relation between an internal state, an external cause, and a disposition to act.

In summary: Feelings do not gain their aboutness through a propositional thought where the contrast between object and property is semantically marked; they gain their functional (rather than propositional) aboutness (f-aboutness) through the respective roles, in adaptive control, of the selection of an affordance-dependent control model and of the markers that allow comparisons of valence and intensity to be expressed.

4.5 The attribution problem

This account, however, fails to explain observed variability in the production of feelings and the interpretation of what feelings are “about”. There are cases where agents misattribute their sadness, their anger, or their happiness to an

²² When we say that a feeling is felt, “felt” is not intended to mean “perceived”, but, rather, “entertained”.

event that is either not real, or that actually played no role in feeling production. How can such a misattribution be explained on the present proposal? Our first attempt to address this question is based on the subjective grounding of affordances. “Feeling *f*” normally means that an affordance is sensed, expressed, and subjectively represented as present. This does not mean that the affordance has an objective counterpart. Thus a thirsty traveller can be delighted or relieved when subjected to a water mirage. It is no problem for this view, then, if an event does not have the action potential for a given affordance it is expressed as having.

A trickier problem for the proposal is that a person might feel an *f*-feeling while she thinks that she has a *g*-feeling. Is such a situation even possible? To deal with this question, we must first clarify what “transparency” means when applied to feelings. A mental state is transparent if, when it is activated, its intentional content is accessible to the subject who entertains it, while its vehicle properties are not. On the view defended above, feelings are transparent, because their somatic markers are felt in connection with a certain affordance, and because their valence and intensity directly influence the emoter’s motivation to act in a given way. Such transparency, however, does not need to entail the subject’s ability to verbally report the content of her feeling. First, as seen above, a feeling can be felt by a nonhuman or by a child, both of whom lack the requisite verbal and conceptual capacities. Second, even an agent endowed with language can express through somatic markers a feeling with a distinctive FS content while failing to accurately report, in conceptual terms, what her feeling is “about”. We saw that [aboutness], i.e., reference to an independent event or object, is not a concept that belongs to FS. When subjects try to infer [aboutness] from their experience, their propositional system of representation (PS) is solicited. Because the latter has an analytic rather than an evaluative function, additional constraints step in. While nonconceptual, intensive (analog) and value considerations and norms regulate FS, conceptual, digital, and in-

strumental considerations and norms regulate PS.²³

Hence, when having to report about her feelings, a subject needs to translate one mode of representation into another, with no guarantee that this translation will not enrich or modify FS intentional content. First, she may no longer have access to the rich diversity of her FS experience, because her attention is no longer directed toward the relevant contextually-activated affordance. Second, she has to monitor other goals and their corresponding (social, instrumental, or epistemic) norms. For example, she needs to present her feelings to herself and to others in a socially acceptable way, and to try to justify them rationally. This in turn will depend on her existing background beliefs, on her self-concept, on her capacity for making self-attributions of this particular kind, and on her willingness to perform this kind of introspective report. A number of experiments and novels have documented the wide gap between people’s feeling experiences and the verbal report they provide, or the reasons they offer, for having this or that feeling. These considerations suggest, then, that the issue of transparency cannot be adjudicated independently of one’s viewpoint about mental architecture.²⁴ According to the present proposal, an affordance is *first* subjectively recognized through the resonance it produces—through its specific feeling, rather than through a concept-based interpretation.

Let us now return to our earlier question. Can a person actually feel an *f*-like feeling, and mistake this *f*-feeling for a *g*-feeling? According

²³ About the nature and role of nonconceptual norms, see Proust (2013).

²⁴ An alternative proposal by Carruthers (2011) sees as a condition of transparency of an affective feeling, rather, that the corresponding appraisal include the detection of the details of the associated non-conceptual somatic markers, which makes the recognition of a specific emotion possible, as well as its subsequent global broadcast—hence making this information available to the mindreading system. This analytic view of feelings, however, makes it utterly mysterious how a given pattern of autonomic measures is ever recognized, among thousands of similar patterns, as distinctive of an emotion. On the present view, a feeling is produced within a given forward model, which automatically activates the comparator for this affordance. Transparency, then, is effective only when a given forward model is activated, and does not need to transfer to a verbal modality. This seems to be recognized in part by Peter Carruthers, when he concludes that “we can have transparent access to the strength of only our occurrent *context-bound* affective attitudes” (2011, p. 146).

to the present account, this situation would presuppose that an *f*-feeling, as it occurs in the expressive mode, is misdescribed in a verbal report as a *g*-feeling, to finally be genuinely felt to be *g*. On this view, a change in representational form would not only make it possible to reinterpret the initial experience in terms of a different one, but also to feel differently. To see whether this case is plausible, it is worth discussing Schachter and Singer's (1962) adrenaline experiment.

5 Do beliefs influence affective report?

Schachter and Singer's famous adrenaline study aimed to collect evidence in favor of a two-factor theory of emotion, according to which a changed state of arousal leads agents to form feelings with a given valence that depends only on the epistemic/motivational context. Participants' arousal was manipulated by injecting them, under pretext, with adrenaline or a placebo. Only a subgroup of the adrenaline participants were informed that they had received a drug that would modify their arousal level. Participants were subsequently invited to stay in a waiting room where a confederate was either pretending to be euphoric or angry. Participants' emotional responses, observed in their behavior and subsequent self-report, differed in the various conditions: those unaware of having been injected with adrenaline, and placed in the anger condition, felt angriest, followed by the placebo + anger subjects. The least angry were the adrenaline informed participants. In the euphoria condition, misinformed adrenaline participants were "somewhat" happier, adrenaline informed ones somewhat less happy (in the euphoria condition, the results failed to reach significance both for behavior and self-report).

Were Schachter and Singer successful in making the point that valence of a feeling is a matter of attribution of the source of an experienced arousal? Several powerful objections have been raised against this claim. Recall that subjects were asked to what degree they would describe themselves as happy or angry. A first problem is that the questionnaire *suggested* the relevant target categories of emotions, which is

disturbingly close to influencing participants' responses (see [Plutchik & Ax 1967](#) and [Gordon 1987](#), p. 100). Furthermore, as noted above, ex post-facto reflective labeling of one's emotion does not need to express one's original feelings. As shown by [Nisbett & Wilson \(1977\)](#), self-reporting is highly sensitive to rationalizations from context. A second problem, mentioned by the authors in the discussion, is that the subjects' verbal reports and emotional behavior failed to confirm expectations in the euphoric condition. A third methodological problem, also recognized by the authors, is that the student participants had their own independent reasons for feeling anger in passing this longish test, which predisposed them to feel anger. There are, however, more theoretical objections.

On Schachter and Singer's view, the core feeling of an emotion is an arousal change, which can be artificially induced by drugs. Valence is supposedly gained through contextual beliefs and motives. If this view is accepted, why should we expect that contextually relevant beliefs specify the feeling itself (e.g., the anger experience)? Participants may indeed have been led to believe that they were angry when they were actually merely aroused. This does not show, however, that they ever felt anything else than an arousal change ([Gordon 1987](#), pp. 100–101). Schachter and Singer may have only biased self-attributions and self-report toward target emotions. The behavioral changes that were observed and attributed to felt emotion, in addition, can be imputed to social influence, rather than to intrinsic changes.

A final worry is that inducing in a participant a somatic marker normally associated with a given feeling (e. g., increased heart rate), *and* providing the person with a context rationalizing this somatic change, does not amount to an ecological way of producing a feeling. A cognitivist theorist of emotion will insist that the mere association between a physiological cue of the feeling *f* and a context does not amount to the realization, by a participant, that she feels *f* *because* she is in such and such a context ([Gordon 1987](#), pp. 98–99).²⁵ As discussed in section

²⁵ As Gordon observes, "one will not experience fear unless one connects up that cognition with the arousal one feels. To do this re-

4, the expressive mode has a nonconceptual representation of this causal connection. The architectural relation between feelings and affordances explains why subjects experience a systematic connection between their feeling and what it is “about”, much in the same way that an agent experiences a systematic connection between an intention to move and the goal that is aimed at—that is, without needing to represent conceptually the causal connection between the two. Nothing prevents the emoter, however, from forming a secondary conceptual representation of the emotional experience she has had, and reappraising the context on the basis of her background beliefs. As a consequence of this concept-based reappraisal, the agent may either discount the relevance of her initial feeling (as in the fear-of-snake case), or redescribe it in the richer terms that she now has available (as was done, presumably, by the Schachter and Singer participants).

Taken together, these objections have led most theorists to reject Schachter and Singer’s two-factor theory of emotion, and to look for alternative accounts of the role of inferences in self-attribution of feelings. It is interesting to see, however, that a two-factor theory has also been applied to the case of M-feelings.

6 Are metacognitive feelings sensitive to beliefs and inferences?

What are metacognitive (also called *noetic*, or *epistemic*) feelings? Juxtaposing [being metacognitive] and [being a feeling] sounds, at least prima facie, dangerously close to an oxymoron. When Descartes, Locke, and other 17th-century philosophers explored the properties of ideas as being “clear”, “distinct”, “evident”, and “certain” they certainly never took them to be feelings. These notions were taken, rather, to be objective representational properties that the mind, unaided by imagination, is able to detect. David Hume, in contrast, observed in his *Treat-*

ise that “the vivacity of the idea gives pleasure”, and that “its certainty prevents uneasiness by fixing one particular idea in the mind, and keeping it from wavering in the mind of its objects” (Hume 1739/40, 2007, p. 289). Thus Hume was glad to accept that epistemic feelings exist, and that they vary in their vivacity and in their pleasantness, i.e., in their intensity and in their valence. Following Hume’s lead, let us test how our analysis of FS above fares with the case of noetic feelings. Here, again, is our proposal about the general structure of feelings.

- FS Affordance_a [Place_a=here],
[Time_a=now/soon], [Valence_a=+/-], [Intensity_{a=n}(comparatively specified on a scale 0 to 1)], [motivation to act_a of degree_d according to action program_a].

What is specific to noetic feelings is that the affordances to which the system resonates are “informational” or “metacognitive” rather than environmental. Hence, the affordance does not relate to the external environment (the “here” slot is often irrelevant, except for perceptual affordances, or place-dependent metacognitive affordances, such as concentrating in a noisy spot). Although a cognitive action does not, in general, consist in physical moves towards or away from an affordance, similar decisions are motivated or inhibited in the domain of mental agency: a high retrieval affordance motivates pursuing the memory search, a low one to quit, etc. Hence our FS analysis also applies to noetic feelings.

As already emphasized, the affordances expressed in feelings do not need to be construed conceptually in order to be detected and assessed through their associated somatic markers. A conceptual construal, however, is suggested by the names given, in the literature and in ordinary language, to M-feelings. The term “feeling of knowing” (in response, for example, to the question: “what is the capital of Australia?”) implicitly presupposes that the emoter has access to the concept of knowledge. Expressing her feeling verbally, indeed, an emoter might say: “I feel that I know the response to this question”. In this sentence, she indeed refers

quires, according to him, a second cognition: a recognition or belief that is one’s being (or taking oneself to be) in a situation of danger that is causing the arousal one feels. This “cognitivist” objection is correct when targeting S and S’s theory, who also defend a cognitivist view of feelings. The present view, however, proposes a non-doxastic account of feelings, and is thus immune to this objection.”

to her disposition to retrieve knowledge and, hence, metarepresents her knowledge disposition.²⁶ The affordance theory of noetic feelings suggests a different picture. When trying to remember a proper name, a *feeling of knowing* is a specific experience of having the ability to detect the target, and of predicting its imminent recall. It can be associated with a feeling of tension (Koriat & Levy-Sadot 1999, p. 486). This experience is associated, then, with a graded, intuitive, and affect-like appraisal of a [remembering] affordance. Rhesus monkeys working in experimental labs in comparative psychology show that they can assess their memory affordances (see Beran et al. 2012, Chapter 1).²⁷ What kind of feedback, then, do monkeys use? A surprising and substantive fact about metacognitive control, first revealed through the pioneering research of Asher Koriat, is that the comparator generating metacognitive feelings (such as a feeling of knowing in a memory task, or a feeling of clearly discriminating in a discrimination task) has no access to the semantic contents stored in memory or made available through perception. In Koriat's words, M-feelings "are mediated by the implicit application of non-analytic heuristics, relying on a variety of cues." These cues "pertain to global, structural aspects of the processing of information", such as ease of processing, time devoted to a task, familiarity, and accessibility (Koriat 2000; Koriat & Levy-Sadot 1999).²⁸ Therefore, contrary to what epistemologists have always believed, the most common type of epistemic appraisal is not directly based on the content of the thoughts to be evaluated, but on the properties of the underlying informational process.

Neuroscientific research confirms Koriat's claim. Implicit, associative cues are extracted by the working brain to select, in a cost-efficient

way, what there is to learn, to retrieve from memory, to extract from perception, or what is worth storing in memory. These are all to do with the dynamics of information processing: with its onset, with the comparative amount of activity in incompatible neural responses, and with the time needed to converge on a threshold value. Indeed, the neural activity recorded in rats' OFC when attempting to categorize olfactory stimuli was found to correlate with their predictive behavior (consisting in accepting or rejecting a task trial); similar patterns have been found in other species.²⁹

On the FS model, somatic markers have the function of expressing the intensity and valence of the noetic predictions generated from feedback at the neural level. As indicated in section 2, psychophysiological measures (electromyography) provide evidence for the existence of facial markers associated with feelings of fluency and of disfluency (Winkielman & Cacioppo 2001). Increased activity in the smile muscle, the zygomaticus major, produces feelings with a positive valence. A reduction of fluency is correlated with activity in the corrugator supercilii (involved in frowning), which suggests that this additional effort is felt as unpleasant. Intensity of positive or negative confidence, computed implicitly, is expressed by the corresponding intensity of the noetic feeling. A different somatic marker of memory appraisal is the TOT phenomenon. This often occurs when a search in memory for a specific word fails to retrieve that word within the usual time interval. The informational ingredients of FS are conveyed by the intensity of the activity in the tongue muscle, and by the affective quality of TOT. Taken together, these predict the likeli-

²⁹ See Kepecs et al. (2008). An interesting account of the predictive activity reflected in noetic feelings is that the dynamic activity in the neurons activated by a given task correlates with the so-called "accumulation of evidence" that is diagnostic of success or failure in that task. For example, in a perceptual discrimination task, where a target might be categorized as an *X* or as a *Y*, evidence for each alternative is accumulated in parallel, until the difference exceeds a threshold, which triggers the perceptual decision. The information that will generate a feeling consists, first, in the differential rate of accumulation of evidence for the two (or more) possible responses, and second, in stored information about the threshold value, computed from prior trials, which the rate of accumulation should reach in order to make a cognitive decision likely to be correct. For a discussion and review of the literature, see Fleming & Dolan (2012), and Proust (2013, pp. 99).

²⁶ Arango-Muñoz (2012) claims that feelings of forgetting and feelings of knowing are cases of "conceptual experiences". According to the present view, following the lead of Koriat and colleagues, M-feelings can overlap with judgments, and be redescribed in conceptual terms; they pertain, however, to different representational levels. There are no "conceptual experiences", except in the sense of experiencing the comparative fluency of concepts.

²⁷ As indicated above, rhesus monkeys are able, in a perceptual or memory task, to opt out of more or less challenging trials as a result of trial difficulty.

²⁸ As will transpire below, all these cues are, as far as we know, dimensions or effects of fluency, i.e., of ease of processing.

hood of successful retrieval. An implicit cue-based heuristic might thus explain why TOTs have the valid predictive value they do (Schwartz et al. 2000).

6.1 Two-factor theories of M-feelings

In our FS single-factor model, M-feelings have an intrinsic intensity and an intrinsic valence. Two-factor theories make a different claim, in ways analogous to Schachter and Singer's theory of aboutness in affects: M-feelings have an intrinsic arousal level, but their valence depends on the environment. Jacoby and his colleagues were the first to embrace a two-factor view about feelings of fluency. They manipulated participant's exposure to an item in order to show that enhanced fluency generates an illusory feeling of familiarity. Under conditions of divided attention, reading a list containing both famous and not famous names raised participants' disposition to wrongly judge as famous some names presented in a second list, merely because these names had already been read in the first list. Schachter and Singer's idea was that fluency is a generic feeling, that needs to be interpreted on the basis of goals and current cues, in order to deliver a qualitatively different specific feeling:

Inherent in the idea that the subjective experience of familiarity arises from an interpretation of cues is the notion that cues can be interpreted in a variety of ways. As noted above, if ease of identifying an item is obviously being manipulated by the experimenter, the resulting perceptual fluency does not give rise to a feeling of familiarity. Attributions are also affected by one's goals. In the context of attempts to remember, people may be more likely to interpret ease of generating an item or perceiving it as familiarity. In the context of other tasks, the same cues may be interpreted in other ways. (Kelley & Jacoby 1998, p. 129)

From their viewpoint, the fluency generated by a given name can, according to the task and the

information made consciously available to a participant, be experienced as a feeling of familiarity, or as a feeling of recognition of that name as "old" (i.e., presented in a former list). They conclude that a feeling of fluency (generated by a perceived name) will be experienced as a function of the alternative ways of interpreting this feeling, on the basis of the agent's goals and the additional cues available.³⁰

A similar two-factor theory has been defended in the (Whittlesea & Williams 2000; Whittlesea & Williams 2001) model of M-feelings. According to this model, feelings of familiarity result from the perception of a *nonspecific* discrepancy between the expected and the observed rate of processing of elements in a given context. Valence and the associated action guidance, on the other hand, are based on a conceptual interpretation of what this discrepancy means. For example, you find yourself waiting for the bus next to people you expect to be total strangers. Suddenly, you have an unexpectedly high fluency experience when looking at the face of someone you have already encountered several times—a clerk from the local grocery shop. This unexpectedly high rate of discrepancy-reduction determines an intense feeling of familiarity with a strong motivation to identify the familiar face (see Whittlesea & Williams 2001). Had you seen the clerk in the local grocery store instead, you would have merely had a feeling of recognition when seeing the clerk.

To summarize: the core idea in two-factor accounts is that participants have a primary feeling of fluency, which they interpret in more specific terms as a function of their goals and of the context as they consciously represent it to be. Thus, on this view, a feeling partly relies on background knowledge, and partly on a naïve theory concerning the relation between feelings and mental activity (Schwarz & Clore 2007). The naïve theory is as follows: feelings are about what one is doing, so this feeling must be about this event of trying to perceive, or this attempt at retrieving, etc.

³⁰ Jacoby & Whitehouse (1989) similarly argue that a feeling of fluency can be experienced as familiarity in a memory task, and as confidence in a problem-solving task.

As already observed above, a naïve-theory view is incompatible with monkeys' and young children's epistemic evaluations based on fluency. Our FS structure offers an alternative account: cues (associative heuristics) dictate how an affordance is detected, assessed, and exploited in a context, but these cues are not consciously available, and hence do not depend on a naïve theory of the task. The Jacoby and Whitehouse evidence is compatible with a procedural view of engagement in a task through automatic memory processes, and of the feelings of familiarity they generate. A comparator is always activated as a function of a subject having been highly trained in the corresponding first-level cognitive task. Monkeys and humans feel that a memorial or perceptual affordance is present because, if they need to assess whether, for example, an item was seen earlier, the associated comparator produces a feeling of a given intensity and valence indexing the remembering affordance. Thus, it is uncontroversial that a context-dependent factor determines both the task to be performed and the reactive metacognitive feeling about this task.

It does not follow from the context-dependence of a cognitive task, however, that a concept-based interpretation will affect the experienced feeling itself, as maintained by the two-factor theorist. A cue-based, non-analytic heuristic is not inferential in the interpretive, first-person sense. Regrettably, the word "inference" has been loosely used in affective and in metacognitive studies, to refer both to "automatic, non-analytic, largely unconscious and fast associative processes" (Nussinson & Koriat 2008) and to conscious reasoning and theory-building (Schwarz & Clore 2007). These two types of processes (respectively called "automatic" and "controlled"), are now held by many authors to operate independently.³¹ While unconscious heuristics rely on implicit associations between cues, inferences comprise deductions from premises to conclusions. Looking back at Jacoby and Kelley's point above, we see that

the authors are referring to unconscious cues being recruited for a task: they are thus referring to unconscious associative heuristics rather than to explicit concept-based reasoning. The memory interactions they are exploring, however, typically involve both automatic and controlled processes, which is a source of confusion. As Jacoby and Kelley are eager to show, implicit associations and explicit reasoning lead to different, incompatible predictions. As a result, the evidence they present shows how automatically-generated feelings can be theorized about in controlled processes. It does not demonstrate, however, that feelings depend upon theorization. A theory of the task, in contrast with automatically generated feelings, offers reasons to attribute to oneself beliefs and motivations to act, and, possibly, to reject the relevance of feelings for any particular task.

Our proposal, then, has several advantages over inferential or theory-based accounts of fluency. First, it explains why a feeling of fluency can be experienced, and why it can motivate agents' metacognitive responses in species or individuals with no concept-based attributive capacity (i.e., with no capacity for mindreading). Second, our proposal accounts for the difference between a type of M-feeling (a feeling of fluency) and the various ways in which it is experienced across cognitive tasks. Granting that comparative ease of processing can *always* be computed, and can be used as a reliable indicator of the likelihood of success across a wide range of cognitive activities, it is not surprising that there is a type of feeling based upon it. Fluency can be perceptual, memorial ("retrieval fluency"), or conceptual. It can be used in predictive or retrospective evaluations. If agents are asked to determine which statements are likely to be true or false (presumably a question that only—but not all—humans can understand), felt perceptual fluency will induce a "truth effect". Agents will evaluate a statement as more likely to be true than another merely because it is easier to read.³² If agents are asked

³¹ For a defence of the distinction see Jacoby & Brooks (1984), Koriat & Levy-Sadot (1999), Recanati (2002) and Smith & DeCoster (1999). Koriat & Levy-Sadot (1999) both emphasize the distinction and use the term "inference" in both cases.

³² There is abundant evidence, however, that M-feelings uncritically guide epistemic decision (i.e., are unopposed by concept-based processes) mostly when the cognitive task is unimportant, when cognitive resources are limited (under time pressure or divided attention), and when agents are in a good mood (Nussinson & Koriat 2008; Schwarz 2004).

to detect faces of known people (or of stimuli previously shown), felt fluency will generate a sense of familiarity, which motivates agents to try to identify the target. If people are asked to assess the frequency of a given phenomenon, felt retrieval fluency—that is, what comes immediately to mind—will be used to judge what is more frequent. Felt fluency will also have effects outside of metacognition: if agents are asked which particular face, landscape, or picture they prefer, felt fluency will influence their decision. Several affordances, then, may be associated with the same globally expressive *type* of feeling (constructed as the set of feelings with the same type of facial markers for ease of processing, for example). The notion of type of feeling is a technical term, which is useful to distinguish the diverse ways in which fluency is used by the brain. But a type of feeling is never experienced; only tokens of the type are. Tokens of feelings of the same type will differ in the specific affordances that are detected, and in the tendencies to act that the feeling motivates. As a consequence, one cannot say that feelings of fluency “feel the same” to an emoter: fluency experienced in an FOK and in an FOR, for example, apply to different segments of processing, assess different things, and motivate a different action program. You may first have an FOK after a question is addressed to you, and then fail to have the associated FOR after having come up with a response. These differences have nothing to do with an interpretation: they are constitutive of what sensitivity to a given affordance amounts to. Take the case of feelings of familiarity. As summarized [above](#), Whittlesea and Williams claim that fluency is the core of the experience, while familiarity is a conceptual interpretation of this core feeling. It is more economical, however, to suppose that familiarity is a different feeling within the general fluency type, and that it is associated with a different affordance.

In summary: engaging in a particular cognitive task (e.g., trying to remember, evaluating retrieval, assessing frequency) does not need, per se, to involve a naïve theory of the task. It only requires having a salient affordance, and an implicit heuristic for metacognitive predictions in that task.

6.2 Incidental versus integral feelings

Our proposal also allows us to address in affective terms the issue of incidental versus integral feelings, which, in the literature, is invariably framed in inferential terms (with all the ambiguity relating to this expression). Metacognitive feelings are called “incidental” when they are not based on valid cues for the cognitive task at hand, and hence, have no predictive value. They are called “integral” when they actually carry information about cognitive outcome. Granting the universal role of fluency in metacognition, how do people know when a feeling of fluency is relevant to a given task, and which sequence of their cognitive activity needs to be monitored? A frequent answer, in the literature, is that agents believe that fluency applies by default to the present domain of judgment. When, however, agents are led to believe that a feeling of fluency is purely incidental to the task at hand, they will discount it in their decision, on the basis of a theory of the domain of interest (see [Schwarz & Clore 2007](#) and [Whittlesea & Williams 2000, 2001](#)). Let us suppose, in what we shall call case (a), that an agent is explicitly told that a given cue, such as the ease of reading a given sentence, is irrelevant to a given task—such as assessing the truth value of the written statement. Or, alternatively, let us suppose—case (b)—that the agent discovers by himself that there is a connection, but with reverse relevance. Perhaps he finds that badly written sentences, involving added processing effort—in a given context—are likely to be true (see [Unkelbach 2007](#) and [Unkelbach & Greifeneder 2013](#)). A popular account of these cases is that people will infer respectively, for (a): that the feeling of fluent reading they have had *is not about* the target task, which entails that reading fluency does not predict truth, or, for (b): that what predicts the truth of a written utterance, in this particular context, is disfluent reading (see [Schwarz & Clore 2007](#), p. 394).

According to this two-factor account, M-feelings are cognitively penetrable. They can be suppressed at will, on the basis of a reinterpretation of their being experienced, or can even be

used to predict falsity instead of truth.³³ On the account proposed here, in contrast, M-feelings are never cognitively penetrable. Why, then, do subjects stop trusting their feeling of fluency? Our answer is the following. In the first type of case, subjects do not allow their feelings of fluency to guide their decision because they have received verbal instructions to this effect. In the second type of case, subjects no longer use their feelings of fluency to form an epistemic decision in the proposed task, because they have learned, over time, that these feelings do not predict truth in this task.

In case (a), then, subjects are confronted with a different task. They are no longer asked to express their confidence in the truth of a given sentence (an intuitive, associative task); they are asked to assess the truth of sentences by taking into account the fact that their feelings of fluency are irrelevant. This new task requires the participants to form appraisals based on analytic reasoning. Feelings no longer drive their evaluation and epistemic decision.

In case (b), where bad writing is associated with likely truth, no “theory of the task” needs to be formed, on top of the first-order task, which consists in judging whether a written statement is true or not. A mere change in cue validity can produce, over time, a change in associative heuristics, and, hence, in feelings and in decisions to act. For example, just as our thirsty traveller will eventually learn not to trust an apparent “drinking affordance”, an agent will learn, in certain recurrent contexts, not to trust an apparent “fluency affordance”. Obviously, cue validity can, in humans, be conveyed verbally; this will considerably abridge the revision process of the associated program of action. We then return to case (a): participants will be able to immediately discount an apparently valid cue, to turn to analytic appraisals, and to refrain from acting on their fluent feeling (which, however, is still there). Cue validity, however, can be learnt implicitly as

well, which weakens the case for a theory-laden view of feelings.

These observations suggest that feeling-based and analytic appraisal, as hypothesized in this proposal, “tap separate databases representing knowledge in different formats.”³⁴ A feeling of fluency, as a result, can survive being discounted in decision-making. Another finding points in the same direction. There is evidence that, even when an M-feeling has been explicitly discounted (i.e., shown to agents to unduly bias their epistemic assessment), the initial feeling remains unaffected, and is able to promote further epistemic decisions. In Nussinson & Koriat’s (2008) study, agents exposed to unsolved anagrams and to anagrams accompanied by their solution, were asked to rate the difficulty of these anagrams for naïve participants with no prior access to the solution. The participants’ ratings were influenced by the differential fluency that the anagrams presented for them: the higher fluency of solved anagrams biased their attributions of difficulty. After being informed of the contaminating effect of knowing the solutions, the participants were invited to correct their attributions by re-rating the difficulty of the anagrams, which they did. However, the participants were subjected to a subsequent test, where, under time pressure, they had to predict which of two anagrams would be harder for others to solve. These other-attributions of difficulty presented, again, the same bias for known anagrams. Being under pressure allowed participants’ M-feelings to guide decision. The verbal instruction could shift their controlled responses when re-rating the anagrams, but did not lead the participants to recompute them, as should have been the case if feelings are cognitively penetrable.

In summary: what participants learned (that solved anagrams only *look* easier to process) did not influence what they felt later (higher fluency is diagnostic of ease of solving).

7 Are all feelings affective?

It is often noticed that a phenomenological contrast seems to exist between feelings—that is, they are not equally emotional. Are not M-feel-

³³ This two-factor account is endorsed by Unkelbach (2007): “the feeling resulting from the discrepancy is non specific, and the discrepancy triggers a search for an explanation [...]. The experienced variations are not attributed to prior exposure, resulting in a feeling of familiarity, but to some other quality of the statement, namely, that a statement is true.”

³⁴ A quote from Smith & DeCoster (1999), p. 329, who offer a strong defence of this view.

ings in general as “cold” as the proprioceptive feeling that my right arm is being extended? Or can they also be “hot”—that is, involve valence, i.e., be pleasant or unpleasant? Our proposal of a common expressive evaluative format suggests that all the feelings vary in affect in roughly the same way, because they all include valence in their informational structure. [Stepper & Strack \(1993\)](#), however, have emphasized that epistemic feelings are “cold”. Feelings like effort, familiarity, surprise, or feeling of knowing “have no fixed valence”, in the sense that they don’t feel particularly good or bad. Linguistic research on the emotional lexicon is invoked as congruent evidence: for words referring to readiness, success, and a desire to deal with new information (like “alert” “confused”), i.e., terms expressing metacognition, affects are not “focal”, which implies that they are not centrally emotional ([Ortony et al. 1987](#)).

There is abundant evidence, however, that feelings of fluency increase perceivers’ liking of the objects perceived. Familiar items (other things being equal) are found to be more pleasant than new ones. An initially neutral stimulus is felt to be pleasant after repeated exposure. This “exposure effect”, first demonstrated by Zajonc, has been attributed to increased perceptual fluency ([Zajonc 1968](#)). This affective effect of fluency has since been found to apply to any dimension of a perceptual input. The sense of beauty in a symmetrical face or in a landscape, or the pleasure felt in contemplating a picture seem to be inherent to the feeling of fluency generated in the perception. As noted above, psychophysiological measures in the facial muscles provide additional evidence for the affective character of the feeling of fluency ([Reber et al. 2004](#); [Winkielman & Cacioppo 2001](#); for a review see [Oppenheimer 2008](#)).

An interesting, untested, speculation intended to explain the presence of cold and hot versions of feelings is that valence, although never fully absent from monitoring, is modulated by dynamic aspects of the task under evaluation ([Carver & Scheier 1990](#); [Carver & Scheier 2001](#)). On this view, affective feelings can appear in physical and cognitive action, and probably also in somatosensory experience,

when certain dynamic conditions for affective reactions are present. But what are these conditions?

Let us first examine an area where these dynamic conditions seem to have a minimal role. This is the area of first-order motor control (including the initiation of an action, the monitoring of its development, and of goal completion). As with any other form of control, motor control involves specialized feelings, in the above sense of subjective experiences with a distinctive embodied phenomenal quality (see [Pacherie 2008](#)). At first glance, these feelings do not typically seem to be affective.³⁵ Why is this so? According to Carver and Scheier, this can be explained by the dynamics of a monitored activity that generates feelings. Affective feelings are part of a second-order type of feedback, having, in their terms, “the meta-monitoring function” of “checking on how well the action loop is doing at reducing the behavioral discrepancy that the action loop is monitoring”. This meta-loop, then, monitors a particular aspect of one’s progress in relation to one’s distal goal: it represents “*the rate of discrepancy reduction in the behavioral (monitoring) system over time*”. This dynamic representation is what a feeling is equipped to offer: the intensity and quality of a positive, or a negative, feeling express how far above, or how far below, the observed *rate* of discrepancy reduction is, with respect to some reference value. One consequence of this view, if it turns out to be experimentally validated, is fascinating and deep: affect in action does not depend merely on the amount of discrepancy being reduced. An agent may be an inexperienced performer in a task; if the velocity of her progress to the goal is higher than expected, she will feel more confident, and have retrospectively more positive feelings when reaching her goal than a competent performer whose progress to the goal is as steady as predicted.

There is a second type of affect, according to Carver and Scheier, that the dynamics of prediction can generate. Acceleration is the rate of change of velocity. Feelings express such acceleration when the rate of discrepancy reduc-

³⁵ Even in this domain, however, an error signal, when conscious, is associated with an unpleasant feeling.

tion *increases* beyond expectancy—a sense of exhilaration then occurs. Lucky athletes, who break several records within days, experience this. Symmetrical feelings of sinking, or despair, arise when the rate of discrepancy reduction *decelerates* unexpectedly and falls below the expected threshold more quickly than anticipated. In summary, cold motor feelings are generated when one is routinely acting on the world, when things develop as expected, except for small motor adjustments. Hot action feelings are generated when action monitoring involves unexpected dynamics of reduction or increment of likely success or failure.

How does this theory apply to M-feelings? A similar contrast may exist in M-feelings. Carver and Scheier's model allows us to predict that M-feelings can have colder and warmer varieties, depending on the dynamics of the discrepancy reduction that they express. As seen above, there are two varieties of M-feelings, distinguished by their function. Some, like FOKs, have a predictive function. Others, like FORs, perform retrospective evaluation. Neuroscientists explain these feelings through the rate of the accumulation of evidence, measured through the comparative activity of the neural assemblies involved in cognitive decision. (This rate of accumulation has to be compared with a stored standard in order to produce a reliable feeling of confidence.) From this widely accepted model, it follows that the rate of reduction of discrepancy toward a confidence threshold is automatically computed, and plausibly expressed through somatic markers that themselves have a varying intensity.

If this reasoning is correct, then although all M-feelings do not often have a definite “hot” quality comparable to fear and love, they always have a valence, according to whether they predict an agent's progress towards or away from her cognitive goal. To find more intense M-feelings, however, one needs to look at the dynamics of *meta-monitoring*, which is when an agent expects a given rate of reduction of the discrepancies toward her cognitive goal, and either observes a rate that is well above the expected rate or well below it. In these cases, the sense of confidence that the positively surprised agent

experiences is modulated by an intense, highly motivating affect of joy and renewed passion for the associated cognitive activity; while the uncertainty of the negatively surprised agent is associated with an intense, highly demotivating affect of discouragement, or loss of interest. Note how crucial an intense feeling of this kind can be, especially with regard to future motivation. It can precipitate in children a passion for learning; or it can lead them to reject an activity, or even a whole group of similar activities, because of the threatening affect associated with the activity, often combined with a still more threatening social affect (the sense of being an inferior, incompetent performer, or of being stupid). This kind of meta-monitoring cognitive affect, important as it is in predicting and fuelling epistemic motivation, is not easily observable in experimental settings, because it is elicited in middle or long-term forms of cognitive tasks, such as studying at school in a given grade, learning algebra, etc. This may in part explain why Stepper and Strack have failed to encounter it.

To summarize: noetic feelings, like all feelings, have an evaluative function. They are the output of a monitoring process, which expresses how likely it is that an agent's cognitive preferences or goals will be (or have been) fulfilled in a given task and context. They all have a valence, but their affective tonality is more intensely felt in special cases that arise when meta-monitoring makes “intensively new” affordances salient. The rate or the acceleration with which an observed initial discrepancy differs from a predicted standard value may either exceed the expected value, thereby producing positive feelings of confidence or feelings of knowing, or be insufficient to reach this value, producing negative feelings of uncertainty. The intensity of positive or negative affect in M-feelings thus depends on particularly unexpected properties of the underlying cognitive activity.

8 Conclusion

On the present proposal, “feelings” are not isolated sensory events. They are, rather, the

ingredients of a nonlinguistic expressive mode that allows organisms to evaluate and predict environmental changes and affordances. This expressive mode is of a relational, intensive kind that is not suitable for a predicative, concept-based representation of the world. As a consequence, feelings are not themselves judgments about the world or about one's own thoughts. They are not "about" anything in the objective, referring sense of the term. Feelings are able to approximate (in their own mode) the guidance offered by full-blown judgments, and hence can be re-described in conceptual terms when the latter are available to the emoter.

The importance of the duality between an expressive and a propositional system of representation has generally been overlooked. Even dual-processing theorists rarely appreciate that the two systems involved in cognitive evaluation and in reasoning have their own independent, although asymmetrical, role to play. A purely automatic, reactive type of evaluation is possible, and is present in nonhumans and young children. It is prone, however, to generating throughout life illusions of competence and reasoning errors. A conceptually-controlled type of evaluation, on the other hand, can partially inhibit the influence of the expressive system, but it still depends on the latter to weigh the impact of context on ability, and to assess the trade-off between ease of processing and informativeness—that is, relevance—that is crucial in communication and in problem solving.

A major practical consequence of the duality between the two target representational modes concerns pedagogy. Children cannot learn what they are *not* motivated to learn. Their motivation heavily depends on their subjective experience of what a school context affords them. Their feelings of confidence, i.e., the feedback from the cognitive tasks they engage in, have to be sufficiently positive and appropriately calibrated in order for them to form their own realistic and motivating cognitive goals. No amount of analytic reasoning can replace a positive experience when learning.

Acknowledgement

I am grateful to Dick Carter, Laurence Conty, Terry Eskenazy, Martin Fortier, Jonathan Frome, Thomas Metzinger and Jennifer Windt for their critical comments. Special thanks to Dick Carter for his linguistic advice, to Tony Marcel, whose critical questions about the commonality between M-feelings and affective feelings inspired the present article, and to Robert Gordon, for giving me access to some of his unpublished writings. The Extension of the Indicator-Function of Feelings

A Commentary on Joëlle Proust

Iuliia Pliushch

In the following commentary I will first briefly review the target article, then voice some critical points, and last offer a positive proposal according to which tension in self-deception is a kind of a metacognitive feeling. Proust offers a novel, inspiring view that feelings possess an indexical (non-conceptual) format, are transparent (that is, they may be re-described in propositional terms, but not thereby changed), and acquire valence if the rate of change towards fulfilling the given affordance is greater or less than expected. In my critique I will first point to difficulties in disentangling feelings from emotions, then try to provide a more precise description of the formal object of feelings, along with some examples, and offer a definition of “directness” that is consistent with predictive coding—as well as argue that feelings might be influenced by concepts even if they themselves are non-conceptual. Last, I propose that tension in self-deception is a metacognitive feeling.

1 The expressive mode of feelings

First, I would like to repeat, in short, the main claims of the target paper that will serve as a basis for my subsequent comments and extensions in the following sections. Joëlle Proust’s article is concerned with the functional and informational characterisation of feelings. She argues that the concept of “feeling” consists of the following components:

1. Reactive (associated with appraisal)
2. Subjective experience

3. With distinctive embodied phenomenal quality (somatic markers have the function of expressing intensity and valence of feelings, [Proust this collection](#), p. 8)
4. Possessing a formal object (not always, e.g., feeling depressed; absence of a formal object is typical of moods, footnote 5)

The formal object of feelings is argued to be affordance-sensing, a “non-conceptual and entirely subjective appraisal of the environment by the

agent” (Proust [this collection](#), p. 7) or a “*subjective, embodied relation* to an opportunity in an input from the environment” (p. 8). Assuming the non-referential indexicality of feelings, or that feelings signal a *relational* affordance (p. 7) that depends on the representational system (p. 8), Proust argues that feelings can misrepresent only if they are re-described in propositional terms. She argues that feelings are *transparent*, because of the experienced connection between their somatic markers and affordances, as well as because of the direct influence of their valence and intensity on an agent’s motivation (p. 12). Though subjects feel directly, in order to report their feelings they have to “translate one mode of representation into another, with no guarantee that this translation will not enrich or modify FS intentional content” (p. 12). Subjects might reinterpret and mis-describe their feelings, but they cannot thereby change the nature of those feelings (feelings being *cognitively impenetrable*; p. 19).

Feelings are argued to be a plausible candidate for a natural kind on the basis of the comparison between feelings and emotions—which she considers not to constitute a natural kind (Proust [this collection](#), p. 3). Two kinds of subjective appraisal might be part of an emotion: *primary feelings* on the one hand and *appraisals cum conative dispositions* on the other. While the first kind corresponds to an earlier time in our evolutionary development, is independent of concepts, induces specific responses, and possesses distinct somatic markers, the second kind is not and might be a blend of different instances of the first kind. Apart from primary affective feelings, somatic, agentic, and metacognitive feelings are argued to form a natural kind.

The function of feelings is to non-conceptually evaluate and signal the result of a comparison process between prediction and outcome through embodied experience (Proust [this collection](#), p. 4). Due to their non-conceptual monitoring nature, feelings do not convey, but merely approximate a causal relation between internal states, external states, and actions (p. 11). There are three kinds of functional relations between feelings and actions (pp. 4–5):

1. Determination of a kind of action in response: approach vs. avoidance
2. Specific orientation in time: predictive vs. retrospective
3. Level of arousal: elevation in energy vs. soothing effect

Feelings are argued to be the result of a *comparator* or control mechanism that is *automatic* and *encapsulated*. The latter requirements are imposed in order to explain the independence of feelings of beliefs and intentions (p. 5) such that, e.g., one could still feel the adrenalin rush even though the hypothesized venomous snake turned out to be a twig.

Metacognitive feelings (M-feelings) are held to express informational, instead of environmental affordances, arise in mental acts, and trigger similar actions of approach or avoidance. M-feelings involve appraisal of the properties of the informational processes underlying contents of thought, but not those content themselves. Against Schachter & Singer’s (1962) two-factor theory of emotions (interpreted as feelings possessing intrinsic arousal but extrinsic valence), Proust argues that feelings have *intrinsic intensity and valence*. Cues on which those feelings are based can be conveyed verbally though, and thus, the heuristics (implicitly or explicitly) might change in the long run. The main claim is thus that *context-dependency is not concept-dependency* (Proust [this collection](#), p. 17). Experience of tokens of feelings differs with respect to the kind of affordance they express (several affordances might be linked to the same type of feeling) and actions they trigger.

An especially interesting claim for me is that affective feeling in general, and metacognitive feelings in particular, have a meta-monitoring function of signalling “the rate of reduction of discrepancy toward a confidence threshold” (Proust [this collection](#), p. 21). If the rate of discrepancy reduction is above expected, the valence of a feeling is experienced as more positive, and, if below expected, as more negative. “Cold” feelings without valence are those for which the expectation has been correct. This claim is interesting for two reasons. On the one hand, to the reader familiar with the self-decep-

tion literature the key-concept “confidence threshold” will stand out. It plays an important role in accounts of self-deception that regard it as a kind of hypothesis testing (one prominent proponent of this view is [Mele 2012](#)). In short, according to this type of account, gathering of evidence in favour of a certain hypothesis is pursued up to a certain point: up until the amount of evidence has reached a confidence threshold that is enough to push an acceptance or rejection of the hypothesis (for more see [Pliushch & Metzinger 2015](#)). On the other hand, “prediction error”, or difference between prediction and sensory input, is the key-term in the model of mental representation that has lately gained a large amount of acceptance—predictive coding (for a short introduction to the free-energy principle of which predictive coding is a particular implementation see [Friston 2009](#); see also [Clark, Hohwy, Seth this collection](#)). Predictive coding provides a unifying explanation for perception, cognition, and action as a result of hierarchical Bayesian inference: at different levels, predictions are compared to propagated precision-weighted prediction error that, under different conditions, leads either to changes in the model of causes of sensory input or to action directed at testing the current model ([Clark 2013](#)).

The idea that feelings signal the rate of reduction of prediction error might be worth elaborating in the predictive coding framework, particularly given the recent study by [Furl et al. \(2010\)](#) who argue that facial expressions are represented as anticipated *trajectories* of the change of those expressions: pictures of neutral and fearful faces were morphed to different degrees such that participants got to see trajectories from a neutral to a fearful face and vice versa. After seeing such a sequences of pictures, participants had to rate another picture for fearfulness. The results indicated that predictable sequences in which the degree of being morphed rose or fell monotonously, thus forming a trajectory, biased perception ([Furl et al. 2010](#), p. 696). Combining Proust’s idea with the results of Furl et al.’s study: feelings might also be represented as anticipated trajectories of change, particularly given the possibly bi-direc-

tional causal influence between feelings and facial expressions (see section 2.2).

2 Critique: Affect and implicit heuristics in feelings

2.1 Use of the term “affect”

The aim of this section is threefold: 1) show difficulties in disentangling feelings from emotions; 2) attempt to give a more precise characterisation of the formal object of feelings, along with some examples; 3) criticize the use of the term “direct” and offer another definition that is consistent with predictive coding. The first problematic point that I see is Proust’s use of the term “affective”, which is ambiguous. She employs at least two different definitions of “affective”:

1. Feelings that possess valence (p. 20). Yet *all* kinds of feelings, according to Proust, possess affect *and* valence¹ (p. 1). Given her distinction between “hot” (emotional) feelings and those that have valence² (p. 21), emotional feelings might differ from mere feelings with valence due to the differently-experienced valence, maybe if emotional valence were a richer experience. Thus, the question is about the minimal requirements on valence and intensity in feelings.
2. Feelings that express emotions.
3. *Difference between feelings and emotions*: if agentive and metacognitive feelings can be affective, then the categorization of feelings into bodily, agentive, metacognitive, *and* affective (p. 5) might be better restricted to the first three, with the fourth being a dimension along which they vary. If affective in this categorization means emotional (p. 2), then there is an ambiguity of terms—affect-

1 The following quotations might help to elucidate the matter: “[f]eelings typically express affect and valence in sensation (25-26), all the feelings vary in affect in roughly the same way, because they all include valence in their informational structure” (p. 20).

2 In Proust’s words, the difference between “hot” feelings and feelings with valence, on the example of M-feelings, is that “although all M-feelings do not often have a definite ‘hot’ quality comparable with fear and love, they always have a valence, according to whether they predict the agent’s progress toward or away from her cognitive goal” (p. 21).

ive = having valence and affective = being part of an emotional experience—because the latter seems to be more complex.

4. *Difference between formal objects of feelings and emotions*: if “feelings are affective ingredients in emotional awareness” (p. 3), then there is a circularity in understanding affectivity here: feelings are affective in virtue of being part of an emotion, while at the same time they themselves are the affective component in the emotion of which they are part. The first part of this claim can be followed from that defended by Proust, namely that feelings that do not express emotions are not affective (p. 2). The second part of the claim follows from Proust’s claim that feelings are affective ingredients of emotions (p. 3). As elaborated in the previous section, emotions are said by Proust to contain one of two kinds of subjective appraisals: feelings or appraisals cum conative dispositions. Further, if feelings are components of emotions, but both can have a formal object, then those objects might diverge. The consequence is that an emotion and a feeling that is part of it might be directed at different objects. Thus, Proust on the one hand distinguishes feelings from emotions and yet on the other hand claims that not only emotional feelings, but also agentive and metacognitive feelings might be “feeling toward” experiences (p. 3, pp. 20–21). The latter claim that both feelings and emotions are directed at intentional objects has been used as an argument to identify both (see [de Sousa 2014](#) section 2 for a discussion of this question). Given Proust’s claim that there are somatic, affective, agentive, and metacognitive feelings, and given the claim that at least in metacognitive feelings the formal object is not the cognitive disposition itself but the rate of change of its execution above or below discrepancy, an interesting question focuses on the formal object of emotional feelings.³ For example, can it be

³ To be more precise, the question is about the functional description of the formal object of feelings. Proust ([this collection](#)) says that “[f]eelings express [...] affordance as their focus (for formal object), along with its graded valence, ranging from very unpleasant to very pleasant, and with its intensity gradient, which ranges from small to large” (p. 8). Affordance is defined as “perceived utility”, and can be

that while the formal object of the emotion of fear is some dangerous object, the object of a feeling is a rate of change in the assessment of the situation before and after the change of the formal object of an emotion? This might explain why, e.g., the first bite of a bar of chocolate makes one happier than the following bites.

5. *Bodily phenomenology of feelings as their formal object*: Proust argues that while somatic feelings are about bodily sensations (or, more consistently, about the rate of their change), in affective (emotional) and possibly metacognitive feelings “the bodily phenomenology tends to recede to the fringe of consciousness” ([this collection](#), p. 2). The example that Proust gives with respect to metacognitive feelings is that feelings of remembering are correlated with but not about facial muscle activity (p. 3). Proust acknowledges that there might be mixed cases (experience of bodily feeling + intentional content, pp. 2–3), but I want to argue that in some emotional feelings bodily phenomenology is, to borrow a metaphor, in the *foreground*. There might be emotional feelings whose objects are bodily sensations, e.g., the anxiety that arises during a panic attack: when I concentrate on my accelerated heartbeat, then if I come to associate the heartbeat with some threatening aspects of a situation, such an experience might lead to anxiety, and thus the initial anxiety leads to even more anxiety, leading to a vicious cycle of panic (for a discussion of heartbeat perception in panic disorder see [Ehlers & Breuer 1996](#)). This might be a case of an emotion whose formal object is the rate of change of bodily sensations, or maybe a meta-feeling (for a discussion of meta-emotions see [Mendonça 2013](#)).

In the given panic example it might have seemed as if I had embraced the analogy between feelings and perception that Proust

positive or negative (*ibid.*, p. 7). Positivity and negativity are dimensions along which valence changes, and valence has been characterised as the rate of change of discrepancy towards the (cognitive) goal. For more on why the latter characterisation is interesting see section 3.

denies, so I will explain why it may be more beneficial to use the term “direct” in another sense to that used by Proust. Proust makes a sharp distinction between feeling and perceiving: “[w]hile percepts allow recognition and identification of external objects and properties, feelings express specific affordances in a perceived, imagined, or remembered situation” (this collection, p. 10). Non-conceptual parts of perceptions are said to relate to “objective, external contrastive cues” (Proust this collection, p. 10), while in feelings they relate to evaluative states. Perception is said to involve “direct sensory access to the world” (p. 10), while the access of feelings to the world and the body is claimed to be indirect. Proust’s evidence for a disanalogy between feeling and perception is based on the neuroscientific research of Barrett & Bar, who say that absence of “internal affective context” impairs the categorization of objects (2009, p. 12).⁴ Their evidence for this hypothesis is based on reviewing the anatomic connections involved in affective processing and that of object perception. One critique of this might be that the time of activation of certain regions responsible for emotional processing and perception might justify the claim that emotional processing comes before perception, but not how direct such processing is. Moreover, in light of predictive coding, perception, emotion, and cognition might all be indirect (Hohwy 2014; for more technical elaboration Friston et al. 2014). In other words, predictive coding provides the term “direct” with a meaning other than that used by Proust. In predictive coding directness is an absence of the evidentiary boundary, where the evidentiary boundary is the inferential isolation between the model of the world and the hidden causes of sensory input (Hohwy 2014). This means that causes beyond the boundary have to be inferred on the basis of independent evidence (ibid., p. 6), or, in Hohwy’s words, “[t]he brain doing the inference is secluded at least in the sense that certain

kinds of doubt about the occurrence of the evidence are unanswerable without further, independent evidence” (p. 7). Relating this observation to Proust, on the premise of accepting predictive coding, there might not be a sharp distinction between feeling and perceiving such as Proust postulates, or at least not in the form presented in the target article. If interoception as perception involves inferences about circumstances *beyond* the (same) evidentiary boundary, as suggested by Hohwy (2014), then feeling and perceiving would both be indirect (to the same degree).⁵ If interoception does not go beyond the evidentiary boundary, feelings might be direct, even if perception is not.

2.2 Concept-based feelings?

In this part of the review I will point out the dangers of interpreting the relation between feelings and concepts too simplistically and argue that it is possible that at least some kinds of feelings are influenced by concepts, even if they themselves are non-conceptual. Proust argues that for metacognitive feelings to arise an important affordance, as well as an implicit heuristic, has to be present (this collection, p. 18). This heuristic is based on cues about the dynamics of information processing, but not its contents (p. 15). The dichotomies that Proust uses in the description—implicit–explicit, unconscious–conscious, evolutionarily-old–evolutionarily-new, associative–rule-based (pp. 3–4, p. 17)—have often been mapped onto two different kinds of processes in dual processing theory (e.g., Frankish & Evans 2009). Dual processing theory states that there are two kinds of processing that possess the dichotomous characteristics mentioned above. A minimal description provided by Evans (2009) for type 1 is “fast, automatic, high processing capacity, low effort”, and for type 2 “slow, controlled, limited capacity, high effort” (p. 33). Along these lines, “implicit”, “unconscious”, “evolutionarily old”, “associative” have been also used as descriptors for type 1 and “explicit”, “conscious”, “evolutionar-

⁴ Barrett & Bar (2009) define affect as an influence on bodily states that is either unconscious or, if conscious, experienced as pleasurable or unpleasurable to varying degrees (pp. 1327–1328). Barrett & Bar’s (2009) basic claim is that the orbitofrontal cortex (OFC) integrates into a unified multimodal representation sensory information from both world and body in a dynamic way.

⁵ One could also ask whether the *same* evidentiary boundaries would be involved in feeling and perceiving, since there could be many of them (Friston 2013).

ily new”, “rule-based” as descriptors for type 2. A belief bias (accepting more believable than unbelievable conclusions) might serve as an example for type 1 (*ibid.*, p. 41), and the conscious correction thereof for type 2. The worry I have is adding to those dichotomies another one: non-conceptual (meaning in this case non-propositional; Proust *this collection*, p. 7)–conceptual (propositional, belief-like). Proust holds that “cues (associative heuristics) dictate how an affordance is detected, assessed and exploited in a context, but these cues are not consciously available, and hence do not depend on a naïve theory of the task” (p. 17). This inference is not valid in the given form. I agree with Proust that “[a] cue-based, non-analytic heuristic is not inferential in the interpretive, first-person sense” (p. 17), but I hold that there is at least one step to consider in between non-conceptual⁶ affordances and consciously evaluated affordances. And this is automatic *concept-based* activation (the existence of automatic appraisal is acknowledged by Proust; footnote 7).

Evans (2009) distinguishes between different kinds of dual processing theories, among which are the sequential (first automatic processing, then controlled) and the parallel theory. Proust seems to embrace a sequential kind of dual processing theory, given the functional role she ascribes to metacognitive feelings (evaluation of mental actions before and after their execution; Proust 2013). Yet how far implicit heuristics are independent of concepts is in question. Proust (*this collection*) denies that “a concept-based interpretation will affect the experienced feeling itself” (p. 17). As mentioned in section 1, she also denies that feelings have a conceptual format. Thus, she seems to deny both that concepts play a causal role in the emergence of feelings and that feelings themselves possess a conceptual format. I will briefly demonstrate that the term “implicit heuristic” does not preclude automatic concept activation, if it implies the activation of knowledge or goal representations. Thompson (2009) argues that

heuristic processes are contaminated by background knowledge, as well as by beliefs and expectations (p. 172, p. 174). Frankish (2009) notes that “the concepts of belief and desire correspond to the psychologist’s concepts of knowledge (or memory) and goal structure” (p. 91). Hence, activation of knowledge that may provide the context for feelings could also be conceptual. Goal representations might also be activated in the course of context creation, provided that unconscious goal pursuit is flexible and context-sensitive (Aarts & Custers 2012). Further, unconsciously activated goals not only depend on context, but also *create* context by influencing the accessibility of knowledge, evaluations, and emotions (Fishbach & Ferguson 2007, p. 496). It follows that if goal representations are activated, then they might lead to the activation of conceptual knowledge. Another interesting point is that if there is a continuous interplay between goal representations and affordances (opportunities in the environment; Huang & Bargh 2014, p. 125) and if goal representations can change the experience of the world (*ibid.*, p. 124), then goal representations might change sensing of affordances and, hence, the feelings associated with it. Further, there has been a proposal to distinguish between associative and rule-based processes by the kind of architecture they operate upon: namely connectionist vs. classical computational (for a short discussion see Samuels 2009, pp. 141–142). Thus, implicit heuristics might be understood as certain connected representations in a network being activated by some cues, where the question is about the representational format of such knowledge, or a more precise description of the relational nature of the feeling affordance. Last, a general note about the similarity between feelings and other kinds of representations: if Bliss-Moreau & Williams (2014) are correct in defending the claim that all kinds of representations possess an affective component (valence + arousal in their definition), then affect is something that expressive and conceptual representations share.

Of course, Proust’s claim that in the case of feelings those cues relate to the dynamics, but not to the contents of processes, indicates a

⁶ Among those who agree with Proust that the content of epistemic feelings is non-conceptual and non-metarepresentational are, for example, Michaelian & Arango-Muñoz (2014). But the *content* of a metacognitive feeling being non-conceptual does not preclude that concepts play a causal role in its emergence.

more specific understanding of the kind of implicit heuristic in question. My point, though, is that if humans can “enrich their noetic feelings through concepts, and thereby revise their reliance on fluency where it is not justified” (Proust 2013, p. 144), then in humans implicit heuristics may also be influenced by concepts (in an automatic way) and in such a way influence feelings. Needless to say, the independent existence of such a schema (be it cognitive or emotional) is hard to prove (Eysenck & Keane 2010, p. 597). According to Koriat & Levy-Sadot (1999), as cited by Proust (this collection, p. 15), metacognitive feelings arise as a result of nonanalytic inferential processes (described as the implicit or unconscious application of heuristics), in distinction to the direct memory trace hypothesis, according to which feelings have direct access to memory traces (Koriat & Levy-Sadot 1999, p. 487). Koriat & Levy-Sadot (1999) argue that the presence of dissociations between knowing and the feeling of knowing speaks against the second hypothesis. Even if heuristics in feelings are non-conceptual, the fact that through feelings emotion gets its valence necessitates that we consider how concepts and memory traces influence feelings, given that they play a role in emotions. Lane et al. (forthcoming), for example, argue that psychotherapeutic change is made possible by updating prior emotional experiences, for which memory traces of those experiences have to be reactivated and reconsolidated. Thus, even if feelings are non-propositional (Proust this collection, p. 20), activation of concepts and their expression in propositional terms are to be distinguished. The point is not that metacognitive feelings themselves cannot have indexical formats,⁷ or that an agent could not possess expressive and conceptual representations at the

same time, but that in humans the generation of (at least) metacognitive and emotional feelings might be preceded by an automatic concept activation that influences them. If this is the case, then one could ask again whether feelings are transparent (see section 1).

Further, instead of describing cognitive processes as serial, their *dynamic* (continuous) nature might be more worthy of emphasis. In the target article, Proust mentions that “[i]ncreased activity in the smile muscle, the zygomaticus major, produces feelings with a positive valence” (this collection, p. 15). This suggests that facial expression influences emotions. She also argues for the transparency (impenetrable nature) of feelings and the against two-factor theory, thus against the possibility that appraisal influences the valence of feelings (see section 1). I want to offer for clarification purposes a short review of the recent literature on which factors are supposed to influence feelings and factors feelings influence themselves. Rogers et al. (2014) emphasize the dynamic nature of emotions insofar as they depend on the social appraisal of a situation. Brosch (2013) also emphasizes the dynamic nature of appraisal that plays a causal role in eliciting emotions. The definition of appraisal that Brosch (2013) accepts also encompasses low-level appraisal based on learned schemata (p. 370). Brosch (2013) argues that first an initial low-level appraisal affects the physiology (1), action tendency (2), expression (3), and feeling (4) of an emotional experience, and then those changes in turn affect an on-going (low- and high-level) appraisal, establishing an appraisal loop. Here, the direction of influence is still in question, e.g., whether feelings influence expressions or the other way around. Laird & Lacasse (2014) defend the James-Lange theory of emotion, namely that facial expressions (e.g., BOTOX patients being less responsive to mild positive emotional stimuli; for the reference see *ibid.*, p. 29), expressive behaviour (e.g., romantic attraction as a result of shared, mutual gaze; *ibid.*, p. 29), and visceral responses that are interpreted according to situational cues (e.g., misattribution of emotion) are *causes* of emotions (for a critique of their evidence see Reisenzein &

⁷ A better understanding of the indexical mode of feelings might be provided by the following quotation: “Feelings can be seen as pre-specified states of a comparator, which predict ultimate success or failure in the actions that they monitor. Given that the information they carry is immediately used in controlling and monitoring current effort, it is misleading to present them as ‘reporting’ the epistemic properties of a mental state or referring to it (even *de re*). They are, rather, signals in a control mechanism, which work somewhat as traffic lights do: allowing traffic, stopping it, rechanneling it; no report or reference need be involved” (Proust 2013, p. 76). In another place Proust (2013) notes that feelings “do not properly ‘refer’, because they do not engage propositional thinking” (p. 77).

Stephan 2014). As such, they may influence emotional feelings too, which Proust acknowledges by pointing out the causal connection between measures in facial muscles and affective character of feelings (this collection, p. 25). Yet the direction of influence may also go the other way around (from feelings to facial expressions). Thus, the nature of feelings may also be dynamic, as are the nature of the underlying cognitive processes. Interestingly, Thagard & Schröder (2014) argue for a neurocomputational theory of emotions as semantic pointers (term introduced by Chris Eliasmith). They argue that physiological, appraisal, social, and psychological components of emotions can be integrated into one unified account: emotion tokens can possess both shallow and deep meanings. The compressed (shallow) form of emotions is reportable, while at the same time pointing to the uncompressed deep form that binds together situational, physiological, and appraisal components.

In the preceding paragraph I considered literature supporting the claim that feelings are embedded in *continuous* cognitive processes. The purpose of this was to show that how appraisal might influence feelings in some form is complex and might even be circular. In this paragraph I offer some additional evidence against a discontinuous interpretation of the connection between feelings and propositional descriptions thereof. The existence of *affective blindsight* (ability to discern emotional stimuli despite inability to consciously perceive them; Eysenck & Keane 2010, p. 581) would stand in line with the assumption that emotional and cognitive processing is based on different kinds of information. This is because affective blindsight demonstrates the dissociation between two different kinds of processing and, thus, a dissociation between the information needed for the one kind and for the other. Further, Scott et al.'s (2014) experiment demonstrating *blind insight* (accurate metacognitive accuracy in the absence of discriminative accuracy) on the one hand supports Proust's hypothesis that metacognition and first-order cognition are not based on the same kind of information, yet on the other it speaks against a serial interpretation

according to which feelings arise out of automatic processes and are then re-described in propositional terms and used in first-person inferential reasoning. Liu & Wang (2014), for example, argue that motivational intensity influences the effect of positive affect on cognitive control: low-approach motivated positive affect enhances cognitive flexibility and distractibility, while high-approach motivated positive affect (associated with goal pursuit) enhances cognitive stability. Thus, the role of feelings might be broader than just the indicators that may or may not be used in conscious reasoning.

3 Proposals: Tension in self-deception is a kind of metacognitive feeling

Proust (this collection, as well as 2013) argues that mental actions are preceded and followed by metacognitive feelings indicating the appropriateness of the cognitive process in question. I want to argue that tension in self-deception fits the characterisation of a metacognitive feeling. Tension is described as a feeling of uneasiness and distress, and as such I think that it is precisely this tension that is said to indicate to the self-deceiver that her belief-forming process is faulty.

Self-deception (SD) is a motivated (1) kind of typically subpersonal hypothesis-testing (2) that results in an evidence-incompatible mental representation of reality (3) which fulfils a belief-like role (4) (Pliushch & Metzinger 2015). Self-deception is usually discussed in the context of biased belief-forming processes and it is argued that phenomenological tension arises as a result of the execution of such processes (e.g., Lynch 2012). Thus, the same function has been ascribed to tension in self-deception as the one ascribed by Proust to metacognitive feelings, namely a comparison of the cognitive process to certain criteria. In self-deception, rationality criteria are typically emphasised.

I want to argue that metacognitive feelings apply to self-deception, insofar as they might also monitor *unconscious* cognitive processes and arise not only before or after a cognitive process, but also *during* it. In case of self-deception these cognitive processes are belief-forming

processes. Proust (this collection, 2013) considers conscious mental actions: her argument is that unconscious comparison processes that give rise to metacognitive feelings precede and follow conscious mental actions. She argues that the “attentional-supervisory system” emerges from “distributed metacognitive abilities” (Proust 2013, p. 263). Ignorance of epistemic norms such as relevance, coherence, fluency, and informativeness lead to (pathological) errors in belief acquisition (Proust 2013, pp. 260–261). My argument in favour of the extension of metacognitive feelings to monitor unconscious cognitive processes is of a phenomenological nature. I agree with Proust (this collection) that the term “inference” has been used loosely in the literature and does not always indicate a first-person inference (p. 21). Yet the more basic problem might be that there is no sequential first-person inference as such in the first place. If the shift between mind wandering (task-unrelated cognitive activity) and task-directed cognitive activity goes unnoticed (Metzinger 2013), then there might be other shifts that we do not notice, e.g., the shift from unconscious to conscious cognitive processes, or some changes in the given process. Thus, the phenomenology of a cognitive process might be more complicated than a unified sequence with a starting point and an end. Further, given, for example, mood-state dependent cognition (Eysenck & Keane 2010, pp. 584), I doubt the plausibility of the assumption that only in breaks between conscious cognitive processes do subjects experience affective feelings.

In the previous paragraphs I argued that the functional role of metacognitive feelings fits that of tension in self-deception, and that metacognitive feelings arise not only before and after mental actions, but also before, after, and during unconscious (possibly self-deceptive) cognitive processes. In this paragraph I want to link Proust’s idea that feelings possess valence only if the rate of change of progress is unexpected to predictive coding, in order to provide a functional description of metacognitive feelings. Proust (this collection) argues that the affective quality of feelings arises only if the cognitive process violates expectations: if it progresses

quicker towards the goal, positive feelings arise, if slower, negative feelings arise⁸ (p. 21). Given that the terms “expectation” and “prediction error” have gained popularity in virtue of being key terms in predictive coding, which is a modelling strategy explaining perception, cognition, and action (Clark 2013), I will shortly discuss Proust’s claim about affect in metacognitive feelings in the context of predictive coding. According to predictive coding, prediction errors (deviation between expectation and outcome) are precision-weighted. Precision is the property of prediction errors (errors between the top-down prediction and the bottom-up signal one receives) that can be described as the weight of a prediction error that plays the role of selection: the more precise the prediction error, the more it will change the hypothesis about causes of input. Switching between perception and action depends on the precision of prediction errors: precise prediction errors change hypotheses, while imprecise ones lead to action (Brown et al. 2013). Precision⁹ is also argued to play a dual biasing role: biasing perception toward goal states and enhancing confidence in action choices (Friston et al. 2013). Low precision of prediction errors has been argued to cause anxiety (Mathys et al. 2011, p. 17).¹⁰ I argue that Proust’s proposal that violations of expectations of “a given rate of reduction of the discrepancies toward her [agent’s] cognitive goal” (this collection, p. 26) produce affective feelings might be described in predictive coding terms as violations of *transition probabilities* of reaching the goal state:¹¹ if a state conducive to the goal state or a goal state itself has been reached, despite a low probability of changing

8 Note the analogy to the “dark room problem” in predictive coding: if an agent wants to minimize surprise or prediction error, then she should stay in a dark room, given that there will be no surprise in it (e.g., Clark 2013). If there were no prediction error, this would cause uncertainty (e.g., Friston et al. 2012). Proust’s argument is similar: if there were no violations of expectations, then metacognitive feelings would not have any valence, because they only have valence if the rate of change is quicker or slower than expected.

9 Attention is precision optimization according to predictive coding (Hohwy 2013).

10 Mathys et al. (2011) are also interesting for the given topic insofar as Proust argues that the heuristics upon which metacognitive feelings are based might be changed via associative learning; Mathys et al. (2011) provide a predictive coding model of reinforcement learning.

11 For a predictive-coding model of a goal-directed action see Friston et al. (2013).

into that state from the current state, then positive affective feelings might arise.¹²

The first step in the categorisation of tension as a metacognitive feeling has been an extension of the application of metacognitive feelings to unconscious belief-forming processes. The second is to clarify the representational content of tension. To do the latter, it might be beneficial to consider which other kinds of metacognitive feelings arise out of belief-forming processes. Those are intuitivity, counter-intuitivity, and anxiety, if one classifies them according to the phenomenology and not according to the norm that they control. Intuitivity indicates the appropriateness of a given belief-forming process.¹³ The reason for the ascription of the given functional role to intuitivity is that intuitivity signals 1) a good fit with respect to the network of our explicit background beliefs and 2) a good fit with respect to our conscious and unconscious model of reality (Metzinger & Windt 2014). An appropriate belief-forming process provides a good fit with respect to 1) and highly likely also with respect to 2). I further argue that counter-intuitivity represents that a certain cognitive process violates the chosen criterion of appropriateness, but is neutral with respect to the system's goal representations, while tension or anxiety represents that the cognitive process violates at least some important goal representations. The reason for this distinction is to account for the effect of motivation on belief-forming processes.

Thus, if feelings accompany our belief-forming processes, then readers might have experienced some while reading this commentary: hence the title. To conclude, I think that Proust has offered interesting ideas on the nature of feelings that will greatly contribute to the clari-

fication of the matter: the indexical (affordance-sensing and non-conceptual) format of feelings, their transparency, the taxonomy of feelings into sensory, emotional, agentive, and epistemic, the predictive and retrospective function of feelings signalling the appropriateness of the cognitive process they monitor, and the degree of change of expectation as the origin of valence of feelings. In this review I have tried to extend Proust's account. To do this, I attempted to provide some conceptual clarifications on the distinction between feelings and emotions, the formal object of feelings, and the conceptual influences to which they might be subject. Last, I argued that tension in self-deception is a kind of metacognitive feeling.

Acknowledgements

I am very grateful to the Barbara-Wengeler foundation for generously supporting my PhD project and all the reviewers of this commentary for their helpful improvements.

¹² Emotional valence has been also argued to be modelled as the rate of change of free energy: Instead of estimating volatility or “slow and continuous changes in states of the world” the rate of change of free energy is argued to take that role of estimating (known) uncertainty (Joffily & Coricelli 2013, p. 1). Here Joffily & Coricelli (2013) accept Yu & Dayan's (2005) distinction between expected and unexpected uncertainty: Expected uncertainty is the one about known unreliability of predicting relationships *within* a context and unexpected uncertainty is the one about the appropriateness of the context itself such that when unexpected uncertainty is high, it is a signal that a *context switch* should be made.

¹³ For an elaboration on the phenomenal signature of knowing in intuitions of certainty, see Metzinger & Windt (2014).

Feelings as Evaluative Indicators

A Reply to Iuliia Pliushch

Joëlle Proust

These responses aim at clarifying various aspects and implications of my proposal that feelings are affordance sensings. Affective quality, in the present proposal, extends beyond the domain of primary and secondary emotions to all feelings, because it results from specific features in the dynamics of valence. Feelings do not convey an explicit causal information about the world. Causal relations are, rather, implicitly represented in a felt affordance through the dynamic relations between the associated, embodied cues for location, valence and intensity and type of the affordance. Affordances are neither perceived nor inferred; they are “sensed”, which is an ability distinct from belief, whose informational input is derived from features of a perceived or interpreted situation or cognitive task. The input for an affordance sensing can well be conceptual; it is claimed, however, that even when a task is represented through concepts, the affordance-sensings elicited during the task are nonconceptual and evaluative. The relevant properties in affordance-sensings being dynamic, an interpretation of the view under discussion as being serial is resisted. Finally, Pliushch’s proposal for extending this theory to an interpretation of the feelings involved in self-deception is discussed.

1 Use of the term “affect”

One of the aims of this article is to try to define feelings according to their functional characteristics, when seen as all-purpose comparators. Iuliia Pliushch claims that my use of “affective feelings” is ambiguous, because they seem to be *defined* either as “feelings that possess valence”, or as “feelings that express emotions”. I am happy to accept the blame for not rephrasing in my own terms the subcategory of “affective feelings” discussed in emotion theory.

A similar discrepancy, however, may seem to be present between two passages of my chapter where I do express my own view:

As will be seen below, some feelings, however, do not express emotions, i.e., are not affective. ([Proust this collection](#), p. 2)

All the feelings vary in affect in roughly the same way, because they all include valence in their informational structure. ([Proust this collection](#) p. 20)

The discrepancy is only apparent, however, and should disappear when the issue of valence in its relation to affect is properly addressed. In emotion theory, the relations between valence and affect, and even the existence of valence,

are highly debated. With rare exceptions,¹ the question is ignored by theorists of somatic, agentive, or noetic feelings.² The proposal summarized in (2), however, posits that affect will result from valence (not the other way round). Section 7 aims to explain why affect depends on the dynamics of valence throughout the domain of feelings. These relations are modulated by the dynamic conditions that prevail in the contrast between expectancy and observation in a given domain. When observation and expectancy coincide with a predicted temporal pattern - with a small stake involved-, the corresponding feelings should not involve affect on top of valence. This is the case for the feelings of agentive success that are generated in routine actions. Hence (1) holds. When you predictably overcome a minor obstacle, you don't feel particularly thrilled. When special dynamic conditions obtain, however, (acceleration or deceleration in the rate of observed change, as compared with the expected rate of change), valence will be intensely felt, in terms of vividly positive or negative experiences. Scoring an ace in a tennis game, especially if it is a rare achievement for this player, elicits in him/her an intensive positive affect. Dynamic variations of this kind also apply to metacognition, where Archimedes' "Eureka" is affect-laden, while the felt ability to respond to a memory question in a laboratory is not.

Hence there may be affect-laden feelings beyond the domain of what is traditionally called "emotional" or "affective feelings". Reciprocally, one might suspect that in the latter domain, too, affect only appears beyond thresholds of positive or negative valence, with colder kinds of feelings occupying the lower end of the continuum.

2 Causal information: Explicit versus implicit

Iuliia Pliushch presents my view on the role of causal relations in feeling representations as fol-

lows: "Due to their non-conceptual monitoring nature, feelings do not convey, but merely approximate a causal relation between internal states and actions" ([this collection](#), p. 2). It may be useful to briefly comment on this summary, in order to clarify the aim of the passage where this question is discussed as follows:

Clearly, FS does not explicitly convey a causal relation between situation, somatic markers and subjective feeling. It carries this causal relation implicitly, however, as a consequence of the control architecture that produces feelings. In an emotional control loop, a perceived affordance causes (not: is represented as causing) its expressive evaluation through its specialized sensory feedback. Emotional awareness expresses this functional relation. ([Proust this collection](#), p. 11)

What is at stake is not the causal relation between internal states and actions, but rather the nature of the causal relation between, on the one hand, the agent's perceptual belief about an external situation ("there is a bear in front of me") and his/her own bodily changes (pounding heart, trembling legs, etc.). According to cognitivists, this causal relation is not only generating a specific emotion, or in my terms, a given feeling, as most theories would accept. It also constitutes in part the intentional content of the experience of fear, or more generally, of an emotional experience. What I object to here is that the *representational* structure of feelings is not *constituted* by a conceptual representation of the causal link between an external fact and observed bodily changes. The causal relations are, rather, implicitly represented in a felt affordance through the dynamic relations between the associated, embodied cues for location, valence and intensity and the type of affordance perceived. Perceiving a bear elicits a bear-affordance (i.e., a feeling of fear of this bear). Even though, from an external viewpoint, one might say that identifying an object as dangerous has caused a disposition to act in the agent, from the viewpoint of the engaged agent, no such judgment needs to be

¹ In particular Carver & Scheier (1990, 2001) for feelings of agentive success or failure, and Stepper & Strack (1993) for noetic feelings.

² For an interesting philosophical discussion of the nature of valence, see Prinz (2010), against Solomon's skeptical stance (2003).

formed because the representation of a given affordance includes the relevant “causal” information in its associative dynamic structure. As suggested by Pliushch, being evaluative, feelings predispose to act adaptively. A disposition to act, then, is associated with an affordance, and with the bodily markers for valence and intensity constituting this affordance.

3 Phenomenology of feelings: Background or foreground?

Should we construe the phenomenology of feelings – the presence of a bodily change – as being in the foreground or in the background of consciousness? The article under review briefly discusses this issue (Pliushch [this collection](#), pp. 2-3): A feeling tends to be more explicitly felt as bodily when making a bodily need salient (feeling tired, feeling a pain in the joints), plausibly because its function is to motivate bodily-directed action. Although in so-called “affective feelings” ¹ the bodily phenomenology tends to recede to the fringe of consciousness, there are cases, as Iuliia Pliushch notes correctly, where it occupies center stage – think of Proust’s report about his chest pain when learning that Madame de Guermantes just died.

It is debatable, however, that in such cases, the formal object of the feeling consists merely in the bodily changes, say, in heartbeat rate. For such states are part of an intensifying negative affordance: the loss of a friend. The notions of “meta-emotion” and “meta-feeling”, which are used by Pliushch to discuss the amplification of a feeling might be captured either in purely dynamic terms, or in a conceptual reconstruction of the situation at hand. This interesting issue, discussed in section 2.2 of Iuliia Pliushch’s comments, has connections with the notion of how concepts and feelings interact, and will be addressed in section 4.

4 Directedness

Iuliia Pliushch objects to my distinction between perceptions and feelings. The claim that “feelings do not have a direct sensory access to the world”, she says, relies on a meaning

of “direct” that is not compatible with the view defended by predictive coding theorists, where “directness is an absence of the evidentiary boundary” (Pliushch [this collection](#), p. 5). Being direct, then, if I understand this sentence correctly, means to lack independent evidence about the world of the kind that perception could bring. Although predictive coding offers a stimulating scheme for understanding mental function, it is open to interpretation and controversy. The functional hypothesis that perceiving and feeling are both indirect will appear highly counter-intuitive to many psychologists and philosophers.

As far as my article is concerned, I have defended the view that feelings are directly related to an opportunity, in the sense that they represent it in an immediate way, a view that has been defended by most affordance theorists. This is compatible with the claim that their informational pathway is derived from perception or memory. What may appear puzzling in my proposal is that an affordance is neither directly *perceived* nor *inferred*. It is directly *sensed*, which requires a different kind of ability. In section 5.1, I have proposed to distinguish associations from inferences, which is relevant to the present discussion. The kind of trigger for feelings are cues elicited in a currently active context, not inferences. These cues are delivered by sensory perception or by memory, but dealt with in a separate subsystem.

5 What are the relations between feelings and conceptual representations?

The comments in section 2.2 of my reviewer’s contribution are presented as an alternative approach to my own view, but I find myself in agreement with most of the claims, in particular with the remarks on p. 6 concerning the relations between feelings and conceptual representations. The main point concerns how one’s own goal, when acting, may influence the production of particular feelings. I discuss this issue at length in sections 5 and 6 of the article under review (Proust [this collection](#)), as well as in a recent publication devoted to action representa-

tions (Proust 2014). My position is captured by two claims. 1) Feelings – affordance sensings – can be, and indeed are usually triggered while performing a task that has been defined in conceptual terms. Cognitive affordances, in particular, are important relational properties that an agent needs to use when attempting to solve highly complex problems, for example when playing chess or looking for a mathematical proof. 2) The feeling episode, however, has an exclusively evaluative, non-conceptual content. I am aware that these two claims may easily be misunderstood. To disentangle the two, think of what agents mean to do: they mean to play chess according to the rules, or to prove a theorem. These goals, indeed, are conceptually represented, and depend on background beliefs and a sensitivity to epistemic norms such as truth and coherence, which presupposes in these particular cases an ability to represent beliefs as beliefs. Feelings of knowing, feelings of being right, and other affordance sensings are generated while the agents are conducting these higher-level forms of reasoning. They are dependent on the mental and neural activity which is thereby elicited. In other words, these feelings do not result from *a consideration* of the concepts involved, but from the dynamic features of the underlying processes. Hence, I would go farther than my reviewer, when she claims that noetic feelings are often elicited when concepts are automatically activated when forming a cognitive goal: they are also elicited when concepts are activated in a controlled way, e.g., in the process of planning what to do.

Should we conclude from this claim that heuristic processes are “contaminated by background knowledge” (Pliushch this collection, p. 6)? No. One should rather conclude that while the goal of a mental action is conceptually defined, the feelings entertained while acting are generated not by the concepts themselves, but by the dynamic characteristics of the processes underlying concept use. It is thus perfectly coherent to conclude that feelings have their own representational format that is not itself “infected” by concepts. A “theory of the task” is not a constituent of an affordance sensing, it is only a precondition for evaluating one’s ability in solving a task.

6 Serial versus dynamic properties of cognitive processes

My reviewer attributes to me a serial view of cognitive processes because I distinguish predictive from retrodictive evaluations of mental actions (Pliushch this collection, pp. 7-8). I do not think that this distinction commits me to serialism however. In my 2013 book, I propose that “a mind should primarily be seen as consisting of a hierarchy of control-and-monitoring loops, and their essentially dynamic interaction with the world, rather than as constituted by the successive states that emerge from this interaction”. Examples of how the dynamics at lower levels of representation can influence higher levels, and the converse, are discussed in chapters 11 and 12, where the case of schizophrenic delusions is analyzed. Hence, I have no problem with the view that low-level appraisal affects higher-level appraisals: these types of influences are part of what it is to have a hierarchy of control. This does not mean, however, that predictive appraisal and retrodictive appraisal should be conflated: they have a different evaluative function, and are based on different dynamic cues. This does not mean, either, that a concept-based judgment can easily influence an affordance-based appraisal. The difficulty of having a prolonged *strategic control* over one’s feelings (based on what one knows, as in the anagram experiment), originates in the different roles of associative cues and inferential relations between concepts in mental activity.³

Iuliia Pliushch is right, however, when observing that I stick to the distinction between feelings and their propositional re-description. From the viewpoint of action theory, this distinction corresponds to the contrast between reacting and acting strategically. I subscribe also to her remarks on p. 6, according to which goal representations might change affordance-sensings. The point is: how sustained is this change? A conceptual re-description tends to modify one’s representation of the context, and hence of one’s goals, which might either favor or re-

³ This point is developed in Proust (2014). A third form of action, habitual or routine action, is claimed to pertain to a second affordance-based system with its own agentic feelings of opportunity.

duce *further elicitation of feelings* (for example, by being ashamed of having felt anger), and even inhibit the influence of feelings on action. This is the case for the participants' epistemic decisions in phase 2 of the Anagram Experiment discussed in the section 5.2 of the article. Their ability to control their feelings, however, cannot resist time pressure and/or divided attention in phase 3.

On the view that I propose, feelings can only be sustainably modulated by having other feelings replace them. There are both automatic and strategic ways of enhancing one's feelings through other feelings (see [Proust 2014](#)). Feelings can easily be enhanced by enriching the associative representations constituting an affordance. Deliberately suppressing them, or reorienting them to new targets, however, is very difficult (as rejected lovers know all too well). The Confucian moral practices offer a very good example of a strategic attempt to train new moral feelings in followers (see [Reber 2013](#)). As Rolf Reber shows in his fascinating analysis of what he calls critical feelings, strategically redirecting one's feelings to new targets can only be performed by manipulating the fluency of one's own re-descriptions and conceptual rules for acting morally. In other terms, the agents need to be trained until they entertain feelings of ease of processing (i.e., feelings of fluency) when activating target concepts and inferences, rather than merely trying to immediately subsume their own initial feelings under critical concepts.

7 Self-deception and metacognition

Iuliia Pliushch finally makes an interesting suggestion: when self-deception occurs, the believer senses a metacognitive feeling of uneasiness, indicating that her underlying belief-forming process is faulty. This suggestion offers an account of the tension that arises while forming a belief on the basis of motivational, rather than evidential grounds. It would be wrong to interpret her proposal as the claim that finding faulty a belief, or a belief-forming process, involves an appraisal of the content of the belief, or of the kind of process that has been used to form it. As I understand her, Pliushch is rather claim-

ing, as psychologists and neuroscientists of metacognition do, that the mind is able to detect fault in the dynamical properties of the underlying processes. Pliushch argues further that, in contrast (she claims) with my own proposal, monitoring not only occurs "before or after a cognitive process, but also *during it*". There is no real conflict, however, about this claim. Presence of intermediate monitoring depends on the temporal extension of the mental action considered. When confronted with perceptual or memorial uncertainty, there is only control-based, mainly unconscious, intermediate monitoring; intermediate becomes prominent, however, in prolonged, effortful actions, such as problem solving ([Ackerman 2013](#)). I agree with Pliushch, however, that representing a mental action merely in terms of a starting and end points misrepresents the facts: it is based on a serial view that does not fit the dynamic character of metacognition (as already discussed in section 7 above). The evidence presented in [Proust \(2013\)](#) suggests that retrospective evaluation is based on the underlying dynamic of the *whole* action (the rate of accumulation in favor of a dominant response, as well as the dispersion of the neural responses), while predictive evaluation is based on the dynamics elicited by the command for this action, as compared with a stored standard (the complexity of the feedback used is addressed in [Koriat et al. 2006](#)). An epistemic evaluation, however, has two functions: stop the action, and encourage its continued performance, hence the role of polar valence in motivating action, which is reflected in the bi-partition of evaluations in two classes. This is in close agreement with how predictive coding, as any other theory of emotion and action, describes the facts.

Does predictive coding offer *new* insights on metacognition? The concept of "transition probabilities" mentioned by Pliushch, is shared by all theorists working on neural dynamics, as well by theorists of recurrent feedback; the concept of free-energy minimization, related to the minimization of surprise, seems *prima facie* to be consonant with [Rescorla & Wagner's \(1972\)](#) well established model of reinforcement learning. There is an internal connection

between free energy minimization and the evaluation of one's own uncertainty, because it is adaptive to predict one's chances of being incorrect, and hence avoid surprising failures. The concept of free energy, however, is no more equipped to provide any mechanistic account of brain function as any other evolutionary theory. "It is nothing more than the principle of least action applied to information theory", Friston recognizes (Friston et al. 2012). Indeed a prominent problem remains to be solved, concerning how priors vary as a function of task demands and of environmental statistics. Unpacking the principle across adaptive time-scales and survival contexts is indeed a complex future goal. Ways in which predictive coding might enrich the analysis of metacognition with new descriptive, operational tools or new functional explanations remain, then, to be specified.

Pliushch claims further that a first step in the proposed metacognitive theory of self-deception consists in recognizing that metacognitive feelings must be "extended to unconscious belief forming processes". If what is meant is that the dynamic properties that elicit feelings belong to such processes, there is universal agreement on this claim (see the so-called "cross-over principle" between unconscious heuristics and representations (including beliefs) and conscious feelings in Koriat 2000). What is meant, then, by the suggested "extension" is unclear. If what is meant, rather, is that the feelings themselves might be unconscious, this is a possibility that is taken seriously in studies of metaperception in blindsight patients (Reder & Schunn 1996). The very existence of such feelings complicates the phenomenologist's task. A second step is claimed to consist in "clarifying the representational content of tension". Although more detailed work needs to be done in order to better understand the contrast between perceptual and conceptual fluency, intuitivity is generally identified as a variety of what experimental psychologists call "feelings of fluency". One suggestion is that what creates feelings of tension or dysfluency in self-deception is not merely the representation that "the cognitive process violates some important goal representation", but rather, that it violates an implicit heuristic of

self-consistency, as discussed in Koriat (2012). Another suggestion is that tension has to do with the realization that the effort initially planned for a current task needs to be upgraded, which is a source of anxiety (Ackerman 2013). In summary: belief-forming processes are known to elicit metacognitive feelings. It remains to be shown how a metacognitive analysis of self-deception might enlighten philosophical and epistemological views about it. Self-deception is a good test case for making the point that conceptual-inferential processing also conveys non-conceptual information.

8 Serial versus dynamic properties of cognitive processes

As noted in the title of an article by Koriat et al. (2006), the relations between control and monitoring in the production of metacognitive feelings are very "intricate". Iuliia Pliushch's insightful comments have initiated what I hope to be a useful clarification of another aspect of feelings (whether metacognitive or not): their relations with propositional thoughts. Feelings elicited by tasks that are conceptually characterized do not become *ipso facto* conceptually penetrable: this difficult, unintuitive claim is often misunderstood and resisted for wrong reasons, which does not mean that it would resist any reason! The objection related to serialism was odd, given my own interest in the dynamic properties of the mental processes as offering a source of information that stable propositional properties of mental contents cannot provide. Once prediction and post-evaluation are identified as two major functions in metacognition, it is indeed important to emphasize that metacognitive processes of each kind are dynamic, and rely on various types of re-afferent feedback. Epistemic decisions, however, once made, are discontinuous by design, which turns the pre-decisional confidence level into a final evaluation that triggers or inhibits the corresponding action. Hence, a contrast must be maintained between how to select a goal and determine the level of effort needed to achieve it (i.e., a control command), on the one hand, and monitoring progress toward the goal, on the other hand.

Each form of metacognition elicits feelings. This does not mean that the two functions need to be serially executed: for long, effortful tasks, agents need to frequently revise their level of effort and of success expectancy, by monitoring over time their progress through associated heuristics and feelings.

The Avatars in the Machine

Dreaming as a Simulation of Social Reality

Antti Revonsuo, Jarno Tuominen & Katja Valli

The idea that dreaming is a simulation of the waking world is currently becoming a far more widely shared and accepted view among dream researchers. Several philosophers, psychologists, and neuroscientists have recently characterized dreaming in terms of virtual reality, immersive spatiotemporal simulation, or realistic and useful world simulation. Thus, the conception of dreaming as a simulated world now unifies definitions of the basic nature of dreaming within dream and consciousness research. This novel concept of dreaming has consequently led to the idea that social interactions in dreams, known to be a universal and abundant feature of human dream content, can best be characterized as a simulation of human social reality, simulating the social skills, bonds, interactions, and networks that we engage in during our waking lives. Yet this tempting idea has never before been formulated into a clear and empirically testable theory of dreaming. Here we show that a testable Social Simulation Theory (SST) of dreaming can be formulated, from which empirical predictions can be derived. Some of the predictions can gain initial support by relying on already existing data in the literature, but many more remain to be tested by further research. We argue that the SST should be tested by directly contrasting its predictions with the major competing theories on the nature and function of dreaming, such as the Continuity Hypothesis (CH) and the Threat Simulation Theory (TST). These three major theories of dreaming make differing predictions as to the quality and the quantity of social simulations in dreams. We will outline the first steps towards a theory-and-hypothesis-driven research program in dream research that treats dreaming as a simulated world in general and as a social simulation in particular. By following this research program it will be possible to find out whether dreaming is a relatively unselective and thus probably non-functional simulation of the waking world (CH), a simulation primarily specialized in the simulation of dangerous and threatening events that present important challenges for our survival and prosperity (TST), or whether it is a simulation primarily specialized in training the social skills and bonds most important for us humans as a social species (SST). Whatever the evidence for or against the specific theories turn out to be, in any case the conception of dreaming as a simulated world has already proved to be a fruitful theoretical approach to understanding the nature of dreaming and consciousness.

1 Introduction

There may be no Cartesian ghosts residing within the machinery of the brain, but still, something rather peculiar is going on in there, especially during the darkest hours of the night. As we sleep and our bodies cease to interact behaviourally with the surrounding physical world, our conscious experiences do not entirely disappear. On the contrary, during sleep we often find ourselves embodied and immersed in an experiential reality, an altered state of consciousness called dreaming. The Dream Self—the character with which we identify ourselves in the dream world, and from whose embodied perspective the dream world is experienced—is who *I* am in the dream world (Revonsuo 2005).

But we are not alone in this alternative reality—there are other apparently living, intelligent beings present, who seem to share this reality with us. We see and interact with realistic human characters in our dreams. Their behaviour and their very existence in the dream world seem to be autonomous. The dream people who I encounter within the dream seem to go about their own business: I cannot predict or control what they will say or do. Yet, they, too, are somehow produced by my own dreaming brain.

On the one hand, dreaming is a solipsistic experience: when we dream, we dream alone, and outsiders have no way of participating in our dream. Yet on the other hand, dreaming is an intensely *social* experience, even if the social contacts and interactions in the dream world are merely virtual. In this paper, we will explore the idea that dreaming is a *simulated* world, but not only a simulation of the *physical* world. It is equally or perhaps even more importantly a simulation of the *social* world. We will proceed in the following way:

First, we will argue that a remarkable convergence has gradually emerged in theories about the nature of dreaming. The field used to be a disunified battleground of directly opposing views on what dreams are, how exactly the concept of “dreaming” should be defined, and on the proper level of description and explanation for dreaming. Recently, the field has con-

verged towards a more unified understanding of the basic nature of dreams. A widely shared conceptualization of dreaming now depicts it as the *simulation* of waking reality. We will briefly describe how this theoretical shift has taken place and where we currently are in the theoretical definition of dreaming. This theoretical development has paved the way for understanding the *social* nature of dreams in terms of social simulation.

Second, we will explore the nature of social dream simulation in more detail. In what sense can dreaming be taken as a simulation of our human *social* reality? How much and what types of social perception and interaction occur in dreams? This question can be broken down into a number of more detailed questions. We will try to answer some of these questions based on the already existing knowledge and empirical evidence about the social nature of dreams. Furthermore, we will try to formulate more clearly the questions that cannot yet be answered empirically due to the lack of appropriate data.

Third, we will review hypotheses that already address the question of the social nature of dreams or assign a social simulation function for dreams. Finally, we will outline some basic ideas of a Social Simulation Theory (SST) of dreaming that might offer some explanations for the social nature of dreams, or at least might produce well-defined, testable research questions concerning the possible *functions* of social dream simulations.

To describe and explain the social nature of dreams as social simulation, concepts borrowed from virtual reality technology may be applied, in this case to the social aspects of dreaming. One of these concepts is the notion of “avatar”: *A simulated virtual human character* who plays the role of a corresponding real human within a virtual reality. If dreams are virtual realities in the brain (Revonsuo 1995), then we ourselves within the dream world are avatars, and we interact with other avatars inside the simulated reality. Somehow, the dreaming brain is capable of creating credible, autonomous human simulations out of neural

activities in the sleeping brain. A theory of dreaming as a social simulation should predict what kind of avatars are represented in our dreams, what types of interactions we engage in with them, and in particular, *why* it would be useful to simulate such avatars and interactions in our dreams—what functions, if any, do they serve for us.

2 Consciousness as reality-modeling and world-simulation

Dreaming is the most universal and most regularly occurring, as well as a perfectly natural and physiological (as opposed to pathological), altered state of consciousness. Thus, any plausible (empirical or philosophical) theory of consciousness should also describe and explain dreaming as a major state of consciousness. Most theories of consciousness, however, do not consider dreaming at all or at least do not discuss the results of dream research in any detail (Revonsuo 2006).

Dreaming presents a particularly difficult challenge for externalist, embodied, and enactive types of theories of consciousness.¹ They all anchor the existence and nature of consciousness to something in the world external to the brain, or to some kind of brain-world relations that, at least partly, reside outside the brain. By contrast, the empirical evidence from dream research shows that full-blown, complex subjective experiences similar with or identical to experiences during wakefulness (e.g., Rechtschaffen & Buchignani 1992), regularly and universally happen during rapid eye movement (REM) sleep. The conscious experiences we have during dreaming are isolated from behavioural and perceptual interactions with the environment, which refutes any theory that states that organism-environment interaction or other external relationships are constitutive of the existence of consciousness (Revonsuo 2006).

A few theories of consciousness have, however, taken dreaming as a central starting point in their conceptualization and explanation of

consciousness. When dreaming is taken seriously, ideas about the nature of consciousness tend to converge on internalist theories of consciousness that take consciousness and dreaming to be varieties of the same internal phenomenon, whose main function is to simulate reality.

One of the earliest attempts to conceptualize both waking consciousness and dreaming as the expressions of the same internally-activated neural mechanism, only differently stimulated, was put forward by Llinás & Paré in 1991:

[C]onsciousness is an intrinsic property arising from the expression of existing dispositions of the brain to be active in certain ways. It is a close kin to dreaming, where sensory input by constraining the intrinsic functional states specifies, rather than informs, the brain of those properties of external reality that are important for survival. [...] That consciousness is generated intrinsically is not difficult to understand when one considers the completeness of the sensory representations in our dreams. (1991, p. 531)

The argument by Llinás & Paré (1991) was mostly based on considerations of the shared neurophysiological mechanisms (in the thalamo-cortical system) that could act as the final common path for both dreaming and waking consciousness. Binding information together within this system intrinsically generates consciousness (“It binds, therefore I am”, Llinás 2001, p. 261); but only during wakefulness is consciousness modulated by sensory-perceptual information—in this model, wakefulness can be seen as a dream-like state (Llinás & Ribary 1994).

Although the idea that dreaming *simulates* waking consciousness was implicit in this neuroscientific theory, Llinás & Paré (1991) did not consider the phenomenology of dreaming and consciousness in any detail. Theoretical approaches characterizing the nature of dreaming as simulation, based on a combination of philosophical arguments and empirical facts about dreaming, started to emerge during the 1990s. In Revonsuo (1995) the idea was put forward

¹ The same criticism may to some extent also apply to representationalist theories of consciousness and dreaming, depending on which externalist or internalist version of representationalism the theory is committed to.

that consciousness in general and dreaming in particular may best be characterized as a virtual reality in the brain, or a model of the world that places a (virtual) self in the centre of a (virtual) world. All experiences are virtual in the sense that they are world-models rather than the external physical world somehow directly apprehended. While the causal chains that modulate the virtual reality are different during wakefulness and dreaming, the virtual world is ontologically the same biological phenomenon: the *phenomenal level of organization* in the brain (Revonsuo 1995). All experiences are, according to this view, in their intrinsic phenomenal character, no different from dreams.

Metzinger (2003) took this line of thought further and analysed dreams as complex, multimodal, sequentially organized models of the world that satisfy several important constraints of consciousness. Dreams activate a *global* model of the world (globality), they integrate this model into a *window of presence* (presentationality), and this model is *transparent* to the experiencing subject, who takes it to be a real world and not a mere model of the world (transparency) (see also Windt & Metzinger 2007).

In *Inner Presence* Revonsuo (2006) presented a lengthy analysis and defence of the idea that dreams are internal virtual realities, or *world-simulations*, and argued that consciousness in general would be best described and explained by treating dreaming as a paradigmatic model system for consciousness. The world-simulation contains the *virtual self* and its *sense of presence* in the centre of the simulation. The virtual self is perceptually surrounded by the *virtual place*; the virtual place in turn contains multiple perceptual contents in the form of animate and inanimate *virtual objects*, including human characters. The virtual objects are bound together from phenomenal features like color, shape, and motion, but this binding in dreams does not always work coherently, thereby resulting in bizarre feature combinations and incongruous or discontinuous objects and persons in dreams (Revonsuo 2006).

Recently, Windt (2010) has formulated a definition of dreams that stems from similar ba-

sic ideas. Windt's definition aims to capture the minimal set of phenomenological features that an experience during sleep should have in order to count as a "dream" (as opposed to other types of sleep mentation). This definition, although not explicitly applying the concept of "simulation", is consistent with the world-simulation model of dreaming. According to Windt, dreams are Immersive Spatiotemporal Hallucinations (ISTH): there is a sense of spatial and temporal presence in dreams; there is a hallucinatory scene organized around a first-person perspective, and there is a sense of "now", along with temporal duration. The core feature of a dream experience is, in Windt's ISTH, *the sense of immersion or presence in a spatiotemporal frame of reference*. Thus, Windt's ISTH, as well as Metzinger and Revonsuo's earlier definitions, all involve similar ideas of dreams as involving an immersive presence of a virtual self in a virtual, spatiotemporally organized world-model or simulation.

3 Dreaming as simulation: Converging definitions from dream research

Within empirical dream research, definitions of dreaming have been highly variable and often motivated by underlying theoretical background assumptions held by the theorist. Thus, the pure description of the *explanandum*, which should come first in any scientific inquiry, has perhaps been biased by a pre-existing theory as to what might count as the *explanans*—the entities, processes, and concepts that are supposed to explain the phenomenon. We will only briefly mention three approaches to defining (and explaining) dreams in the recent history of dream research, where the definition and description of the data seem to have been theoretically motivated.

The field of dream research was, in the 1970–1990s, a theoretically disunified field. The deep disagreements over finding a definition of "dreaming" that would be acceptable across the field were noted by Nielsen (2000, p. 853)

[T]here is currently no widely accepted or standardized definition of dreaming.

as well as by Hobson et al. (2000, p. 1019):

[...T]here is no clearly agreed upon definition of what a dream is [...] and we are not even close to agreement.

Hobson's (1988, 1997, 2001) own definition of dreaming is (or at least was in his earlier writings) a list of some features of dream experience. According to him, a dream is mentation during sleep that has most of the following features: *hallucination, delusion, narrative structure, hyperemotionality, and bizarreness*. This definition may be (and was) criticized as including only paradigmatic late-night REM dreams that are spontaneously remembered and on which our everyday stereotype of what dreams are like is based. This bias in the definition towards REM dreams might be seen to reflect the underlying theoretical idea or commitment, obvious in Hobson's earlier theories, that dream phenomenology should be (reductively) explained by referring to the features of REM neurophysiology.

The opposing, cognitive-psychological view of the 1980s and 1990s conceptualized dreaming as a cognitive process that should be explained at the cognitive-psychological level (Foulkes 1985). References to the neurophysiological level were unnecessary. In that time and in the spirit of functionalism and classical cognitive science, the cognitive levels of description and explanation were in general seen to be completely independent of implementation levels, such as neurophysiology. Furthermore, dreaming was thought to occur in every stage of sleep, not only REM sleep, and rather than being full of bizarreness was mostly a credible replica of the waking world. Thus, according to the cognitive approach, an explanation of dreaming cannot be based on neurophysiological mechanisms in general, or for REM sleep on neurophysiology in particular. The explanation should be given at cognitive levels rather than neurobiological ones. Interestingly, it was probably Foulkes (1985) who first characterized dreams in terms of the idea and the concept of simulation. In 1985 he described dreams as *credible world analogs*, an organized form of

consciousness that *simulates* what life is like in a nearly perfect manner.

A third theoretical definition of dreaming came from clinical dream research, and reflected the long and widespread idea in clinical psychology that dreams restore our emotional balance and have a psychotherapeutic function. Hartmann formulated this definition of dreaming most clearly, when he said that "Dreaming, like therapy, is the making of connections in a safe place" (1996, p. 13).

During recent years in dream research, the concept of simulation has become a widely accepted way of characterizing and defining dreaming, as well as a way of formulating theoretical ideas about the potential functions of dreaming. Thus, the idea that *dreaming is a multimodal, complex, dynamic world-simulation in consciousness during sleep*, may be a type of conception and definition of dreaming that many if not most dream researchers are ready to accept (Nielsen 2010). The various contents of dreams—their events and objects and characters—can be taken to be simulations of their real-world counterparts.

Taking Foulkes's idea of dreams as credible world analogs and as the simulation of what life is like as a starting point for defining dreaming, Revonsuo (1995) formulated the Virtual Reality metaphor and later the TST (Threat Simulation Theory) of the evolutionary function of dreaming. This theory is built on two background assumptions, the first of which is precisely the definition of dreaming as "an organized simulation of the perceptual world" (Revonsuo 2000, p. 883). An additional, more specific assumption of this theory is that dream experience is *specialized* in particular in the simulation of *threatening* events: it tends to select and include various types of dangerous enemies and events and then simulates what it is like to perceive and recognize them (simulation of threat perception) as well as how to react and behaviourally respond to them (simulation of threat avoidance behaviours and strategies). Threat simulations appear in a paradigmatic and powerful form especially in nightmares, bad dreams, and post-traumatic dreams, but are also abundant in many other types of dreams

such as everyday dreams, recurrent dreams, and in various parasomnias such as RBD (REM-Sleep Behaviour Disorder).

Domhoff (2007), who represents a similar psychological and content-analysis approach to dream research as Foulkes (1985), also characterizes dreams as mostly realistic and reasonable *simulations* of waking life. By emphasizing that, according to convincing empirical data from content-analysis studies of dreams, dream simulations are mostly *realistic* rather than overly bizarre and hyperemotional, Domhoff argues against the Hobsonian definition of dreaming as being full of bizarre contents.

Still, despite their disagreements, both camps now seem to accept the notion of *simulation* as a valid description of the core nature of dreaming. Hobson, in his new *protoconsciousness* theory of dreaming and REM sleep (2009), uses the concept of simulation to characterize the root phenomenon, protoconsciousness, from which both our waking and dreaming consciousness arise. According to Hobson, protoconsciousness is the simulated experiential reality or a virtual reality model of the world that the developing brain turns on during REM sleep even before birth, to prepare the conscious brain to simulate the external reality that it will encounter through the senses after birth. This model of the world is genetic, innate, and a human universal. Protoconsciousness acts as the template on which both waking and dreaming consciousness are built after birth. Thus, according to this theory, protoconscious dream consciousness—a very basic form of an internally simulated world—comes into being prior to waking consciousness, and is causally necessary for waking consciousness. As Hobson (2011, p. 30) puts it: “I REM, therefore I will be”. According to Hobson & Friston (2012), *predictive coding* is an underlying mechanism in the brain that produces predictive simulations of the world. Therefore, dreaming may also function as a preparatory simulation of the waking world; thus their idea is closely related to the other simulation-theories of dreaming (Hobson & Friston 2012).

In conclusion, while there still are disagreements about many details of dream con-

tent and function, there seems to be relatively widespread agreement that the definition of dreaming includes the idea of “simulation” of the waking world. The use of the concept of “simulation” to characterize dreaming has recently gained wide acceptance in the field. The simulation is variously characterized as the simulation of waking life, of waking reality, or of waking consciousness, and variously called by different authors a realistic world-simulation, a virtual reality, an immersive spatiotemporal model of the world, and so on—but despite the somewhat varying terminology, the different terms seem to describe the same basic idea. This conceptual unification is a significant step forward in the theoretical description and explanation of dreams. It paves the way for a more unified theory of dreaming.

4 The simulation of social reality in dreams

Dreaming not only places us into an immersive (virtual) physical reality, but also immerses us into a (virtual) *social* reality: in dreams we are surrounded by close friends and family members, schoolmates, teachers and students, spouses, romantic partners, old crushes, colleagues and bosses, celebrities, politicians, acquaintances, strangers, and mobs as well as monsters and other fictitious characters from movies and video games. All are there in dream simulation with us as simulated characters—avatars—and we interact with these avatars in multiple ways: we perceive, recognize, and semantically classify them, we communicate and talk with them, we collaborate with them, help them, criticize them, fight them, escape them, fear them, and love them. At least intuitively, there is no doubt that in our dreams, we live rich and colourful social lives, even if only simulated ones.

If dreaming in general can be defined as a simulated world, the question arises whether the concept of “simulation” can also be usefully applied to describe the social reality of dreams. The first task for a theory that takes the concept of simulation seriously is to simply *describe* the social contents of dreams as simula-

tions of human social reality. The descriptive questions can be formulated in more detail along the following lines:

1. What kind of social perception, social interaction, and social behaviours are simulated in dreams?
2. How frequently are different kinds of social perception, interaction, and behaviour simulated in dreams? How much variation is there in the frequency of different social simulations as a function of gender, age, culture, and as a function of the quality and quantity of social interactions during waking life?

It is possible to find answers to many of the above descriptive questions from the already-existing dream research literature where various aspects of the social contents of dreams have been reported, even if they have not been conceptualized as social simulations. In what follows, we will first briefly review some of the major findings in the literature that describe the quality and the quantity of social simulation in dreams. Once we have detailed empirical descriptions of the quality and quantity of social simulations in dreams, we may seek explanatory theories and testable hypotheses that could account for why we have social simulation in dreams.

4.1 Evidence for simulation of social perception in dreams

From the already existing literature, it is possible to find statistics that describe the quality and quantity of social simulations in dreams. However, the theoretical concept of “social simulation” is rarely used in dream research literature for interpreting the descriptive results. Here, we will briefly summarize only some of the major findings.

The minimal criterion for a dream to count as a social simulation is that the Dream Self is not alone in the dream but in the presence of at least some other animate character or characters. In less than 5% of dreams is the dreamer alone (Domhoff 1996); thus, on this minimal criterion, dreaming seems to consist-

ently simulate social reality. The other animate characters simulated in dreams are predominantly human (normative finding in adults is about 95% human, 5% animal), but the proportion of animal characters varies in different cultures and age groups, being highest (up to 30–40%) in young children and in adults in hunter-gatherer societies (Domhoff 1996; Revonsuo 2000). As human characters are reported in almost all dreams, and typically there are two to four non-self characters in a dream (Nielsen & Lara-Carrasco 2007), the presence of simulated human characters must be perceptually detected and registered in the dream by the dreamer. Thus, during dreaming, *our neurocognitive mechanisms constantly simulate social perception*.

The minimal form of social perception is to *detect or register the presence* of some human character. A more sophisticated form is the perceptual *recognition* and *identification* of the human characters who are present, first in terms of some basic perceptual and semantic categories (male/female; familiar/stranger), and then in terms of more detailed semantic and autobiographical information about the precise identity and name of the person. According to the Hall and Van de Castle norms, about 90% of simulated human characters have sufficiently definite characteristics to be semantically categorized, for example as male or female, or as familiar or unfamiliar (Domhoff 1996). Thus, social recognition and identification mechanisms are highly engaged in almost all cases of social perception in dreams. The dreamer knows, both during the dream and afterwards when reporting it, whether the simulated characters present in the dream are (or were) male or female, familiar or strange, friend or family; and in most cases, the familiar characters are identified as particular persons from real life.

Typically, a slight majority of dream characters are avatars for familiar persons, although there are well-established gender differences (Domhoff 1996) that might, however, partly depend on the gender distribution encountered in the real-world social environment (Paul & Schredl 2012). In a sample of five hundred REM dreams (Strauch & Meier 1996) familiar people

(friends, acquaintances, and relatives) were simulated most frequently (44% of all characters), strangers represented about 25% of dream characters, and undefined people about 19%. In most dreams, both familiar and unfamiliar people were simulated, but in 30% only strangers and in 20% only familiar people appeared. The mixture of familiar and unfamiliar people was true also at the individual level—there were no participants who would have simulated only strangers or only familiar people in their dreams.

For the most part, the human avatars in the dream world are quite *realistic* simulations of their waking counterparts. The degree of realism, however, is difficult to express with accuracy by any single measure or quantity, as there are several features of human characters that may independently vary along the dimension of realism (Revonsuo & Tarkko 2002). The opposite pole for realism is called *bizarreness*, which in dream research refers to deviation from the corresponding entity in waking life.

If any kind and degree of deviation from a waking counterpart is counted as a bizarre feature of a simulated person, then over half of the simulated humans in dreams (over 60% according to Kahn et al. 2002; 53% according to Revonsuo & Tarkko 2002) are not perfectly realistic simulations. In contrast to other dream characters the Dream Self is rarely distorted in any way (Revonsuo & Salmivalli 1995). Revonsuo & Tarkko (2002) also found that in the vast majority of cases (around 90% of dream characters), non-self dream characters are *perceptually* entirely realistic—they *look* the same as their counterparts look in real life. Where they deviate from their counterparts is most often their verbal and nonverbal behaviour. Thus, although the perceptual simulation of human characters is nearly flawless in dreams, the simulation of expected or predicted *behaviours* deviate from waking norms relatively often, though still at least a slight majority of behaviours by dream characters are no different from waking life.

Dream characters are also spatially and temporally quite stable and continuous within the dream, although transformations and discontinuities sometimes do happen (Nielsen &

Lara-Carrasco 2007). A simulated person sometimes appears from nowhere, is magically transformed into someone else, or suddenly disappears without a trace. But these kind of discontinuous features account for less than 5% of dream character features (Revonsuo & Salmivalli 1995; see also Revonsuo & Tarkko 2002).

By contrast, the behaviours expressed by dream characters are relatively often to some extent odd or unpredictable. Thus, the simulated social reality in dreams is *less predictable* than the corresponding social reality during wakefulness. However, it is unclear how this unpredictability should be interpreted: does it simply reflect the difficulty (and consequently failure) of simulating complex human behaviours and interactions realistically by the dreaming brain, or is there some other more functional explanation as to why the avatars in our dreams tend to behave in more erratic ways compared to their waking-life counterparts? We will come back to this question when we consider the possible functions of social simulation in dreams.

4.2 Evidence for simulation of social interactions in dreams

The Dream Self and other dream characters are simulated in almost all dreams, but how often are they engaged in mutual social interactions? According to Strauch & Meier's (1996) data (140 REM dreams in which a Dream Self was present and had an active role), in nearly 50% of these dreams the Dream Self and characters interacted, in an additional 20% they acted together, and in 20% they acted independently of each other. In the rest, the Dream Self acted alone. Thus, social interaction or acting together is typically simulated in dreams where the Dream Self is present together with some other dream characters. When social interaction takes place, there is almost always verbal communication or conversation between the Dream Self and the other characters, which tends to be focused on concrete topics (Strauch & Meier 1996), and it is understandable and something that would be sayable in waking life (Heynick 1993).

The more detailed nature of social interactions has typically been categorized in terms of “friendly” and “aggressive” interactions. Friendly interactions are on average found in about 40% of dreams, whereas aggressive interactions are somewhat more common, and occur in about 45% of dreams in a normative sample (Domhoff 1996). Strauch and Meier, however, point out that in their sample, neutral interactions were also common, and only about half of the social interactions in their sample could be classified as particularly friendly or aggressive. The third category of social interactions that has typically been quantified in dream reports is sexual interactions, but they occur at a very low frequency—in Strauch & Meier’s (1996) laboratory data, in less than 1% of REM dreams, and in the normative Hall and Van de Castle (Domhoff 1996) data, in 4% of women’s and in 12% of men’s dreams collected in a home setting.

In sum, the simulation of dream characters occurs very frequently, the characters are perceived and recognized by the Dream Self, and the Dream Self actively participates in communication, social interaction, and joint actions with the characters. The simulated characters are also for the most part realistic, stable, and represent a variety of different kinds of people. Their behaviours, however, may sometimes be unusual or inappropriate, and not exactly what we would have expected from their counterparts in real life. The tone of the interactions may be neutral, friendly, or aggressive.

When this evidence is taken together, we may conclude that dreaming simulates a rich, variable, realistic, and concrete, but somewhat unpredictable social reality, inhabited by a mixture of familiar, unfamiliar, and undefined people. Therefore, we have solid grounds to state that dreaming *is*, among other things, definitely a social simulation. If this is a universal and ubiquitous feature of dreaming, what kind of theory could explain it? *Why* does dreaming simulate social reality at all? It is by no means self-evident that this should be the case. Dreaming could as well be only a simulation of some basic features of the physical world: space, time, objects, events, and the perception of and bodily interaction with the physical world. Or it

could be a simulation of thought processes, a thinking-through of our problems, or of our emotional states and concerns. Moreover, simulation of physical objects and their behaviour, or a replay of thinking and emotions, would probably be a simpler task for the brain than the simulation of a complex social world. Simulation of human bodies and faces and interactive behaviours such as conversations seems to require a lot of energy and computing power—these are very complex phenomena to simulate realistically. Thus, *why* does the sleeping brain simulate social situations in such an intense and invariant manner? Is there any convincing theoretical answer to be found to this question?

5 The continuity hypothesis and social simulation theories of dreaming

There are, of course, countless theories of dreaming. Some have explicitly considered the role of social interactions in dreams, while others make more general statements about dream content. One of the latter is the Continuity Hypothesis (CH), which states that dreams *reflect* waking life experiences (Schredl & Hofmann 2003) or, more specifically, that our waking concerns, thoughts, and experiences have a *causal influence* on subsequent dream content. Thus, if certain types of social contacts or interactions become more frequent (or less frequent) in waking life, their simulation in dreams becomes correspondingly more (or less) frequent.

This general principle seems to hold in many cases. For example, in hunter-gatherer societies, where people perceive and interact with wild animals on a daily basis, the proportion of animal characters remains high (as it is in children’s dreams across cultures), whereas in highly industrialized societies, the animal percentage decreases dramatically from childhood to adulthood. But the CH merely restates this empirical relationship; it cannot answer the theoretical question of *why* in young children’s dreams the proportion of animal characters *is high to begin with*. TST (Revonsuo 2000) has attempted to answer this question by referring not to personal experiences in waking life, but to a universal bias that is built into the default

values of dream content during human evolutionary history.

The CH, even if on the right track in many cases, is too vague and general as a theoretical explanation of the details of dream content. It does not predict in any detail how and why the causal relationship between waking and dreaming works. It also does not specify in any detail what counts as a “continuity” and what would count as a “discontinuity” between waking life experiences and dream simulations of the same. If something happens in waking life *how closely similar* will the dream simulation be to its waking origin, *when* will the same (or a similar) content appear in dreams, *how frequently and for how long* will it be incorporated into dreams, and so on? These questions have been studied under the concepts of day residue (Freud 1950) and the dream lag effect (Nielsen & Powell 1989). The CH takes almost any similarity between waking life and dream life as a confirmation of the continuity hypothesis. But “similarity” as a relationship between two phenomena is undefined, ambiguous, and vague. Something that in one respect is similar to its waking counterpart is in another respect dissimilar from it; thus it can be interpreted as either continuous or as discontinuous with waking life. Obviously, if the very same evidence could be counted as either supporting or disconfirming a theory, there is something wrong with how the theory is formulated.²

As long as the CH remains vaguely formulated, almost anything can be counted as its support. If the hypothesis does not specify in any detail the potential empirical observations after which its predictions would be falsified, it is not an empirically testable theory. Unless it is formulated in a much more specific manner, so that risky, exact predictions can be derived from it, its explanatory power remains correspondingly weak. In one study where more precise predictions from CH were derived, the CH was found not to be valid as a general rule concerning how often different everyday activities are reflected in dreams (Schredl & Hofmann 2003).

Perhaps a more precise prediction that could be derived from CH can be formulated in the following way: according to CH, dreams represent a random sample of recent waking experiences (or a random sample of their memory representations). The quantities of different types of contents in dreams will therefore passively reflect the proportion of their occurrence in waking life in the recent past (or the memory representations of waking life). If CH is formulated in this manner, as a prediction of random sampling and passive mirroring of recent waking life, then any systematic deviation from a random sample of waking contents (or memories thereof) would count as evidence against the CH. A deviation from passive mirroring of waking life would suggest that some kind of *selective* mechanism is at work. An *active selection* bias of particular contents to be either included in dreams or to be left out would be expected to result in a disproportionately exaggerated or diminished frequency of that content in dreams as compared with waking life. This kind of formulation of the predictions of CH makes it a testable theory.

Some more specific suggestions about dreaming as social simulation have been put forward in the literature. Brereton’s (2000) Social Mapping Hypothesis suggests that dreaming simulates, among other things, the awareness of other persons (social perception) and their internal mental states (mentalizing or theory of mind-abilities). This theory proceeds from an evolutionary standpoint, and considers dreaming as a rehearsal ground for emotional and perceptual abilities related to the mapping of the body image of the self into an emotionally-salient social space. Others have also hypothesized that our mindreading abilities could potentially be a target of simulated social perception in dreams (Kahn & Hobson 2005; McNamara et al. 2007). Moreover, Nielsen & Germain (2000) have suggested that dreaming might simulate attachment relationships and interpersonal bonds in ways that would maintain their adaptive significance even today, and Humphrey (2000) has compared the social functions of dreaming to those of play. The possibility that dreaming simulates pro-social and ag-

² For a recent exchange, see Hobson & Schredl (2011) and related commentaries in the International Journal of Dream Research (2011, vol. 4).

gressive social interactions in distinct sleep stages, and that these simulations might exert a regulatory influence on our waking social lives, was put forward by [McNamara et al. \(2005\)](#). Last, [Franklin & Zyphur \(2005\)](#) have considered how the simulation function of dreams might be expanded to cover social cognition and complex socio-cultural situations.³

The problem with the above social simulation theories of dreaming is that either they are not detailed enough to be testable, or that few, if any, have ever been directly tested against competing theories. They are interesting general ideas, but not strictly formulated theories that could be directly tested, or from which detailed predictions and potential explanations for the social contents of dreaming could be derived. Thus, these theoretical ideas have not led to a strong empirical, hypothesis-driven research program that would be able to systematically test the plausibility of these theories.

Whenever we formulate theories of dreaming, or of the functions of dreaming, they should be formulated in such detail that *empirically testable predictions* can be derived from them. Statements that are too vague or too general (e.g., “dreams are continuous with waking life”; “dreams are social simulations”) are difficult to test as such. The predictions derived from general statements are too unspecific. Thus, the theories remain uninformative but of course consistent with almost anything we might realistically expect to find in dream content. If a theory makes no detailed, risky predictions about what should or should not be found in dream content (under some specific circumstances or in specific populations) it doesn’t have much explanatory power, either. So far there is no detailed, convincing, testable theory

of the nature and the function(s) of social simulations during dreaming. There is also a lack of data on the detailed quantity and quality of simulated social interactions in dreams, and how they relate to real social interactions in the waking life of the same person. In the rest of this paper, we will try to outline ideas for the theoretical basis of a social simulation theory of dreaming and to formulate some empirically-testable hypotheses directly derived from the theory.

6 Towards a testable social simulation theory of dreaming

The relatively loose idea or the general observation that dreams are social simulations needs to be turned into a theory from which testable predictions can be derived. There are several ways in which this could be done. In the rest of this paper, we will formulate some suggestions towards that end. The basic assumptions that we adopt are based on the earlier work on the definition of dreaming (and consciousness) as an internal world-simulation in general ([Revonsuo 2006](#)). Any plausible theory of social simulation should also take into consideration, and draw from, concepts and advances in the fields of social psychology and evolutionary biology, in order to create a credible theoretical context into which social simulations in dreams can be placed. We will therefore connect the idea that dreaming may function as a platform for simulating social perception and interactions to some influential evolutionary biological and social psychological theories, as well as to the earlier simulation theory of the original evolutionary function of dreaming, the TST ([Revonsuo 2000](#)).

The two generally-accepted theories in evolutionary biology that seem to be relevant for the formulation of an evolutionary SST of dreaming are the Inclusive Fitness and Kin Selection Theory ([Hamilton 1964](#)) and Reciprocal Altruism Theory ([Trivers 1971](#)). Both are general evolutionary biological theories that apply not only to humans, but to multiple other species as well. Further, both have received ample empirical support from animal and human stud-

³ Another popular theory of dreaming postulates that the realistic simulation of character-self interactions serves the function of *emotion regulation* during dreaming ([Nielsen & Lara-Carrasco 2007](#)). In this group of theories, the function of dreaming is proposed to be the calming down of emotional surges, such as we see in psychotherapy ([Hartmann 1995, 1996, 1998](#)), or as reflecting the extinguishing of fear memories ([Nielsen & Levin 2007](#)). It is increasingly apparent that sleep plays a role in the consolidation of emotional memories, but whether sleep also *regulates* the emotional charge and valence of memories is not yet entirely clear (for a recent review, see [Deliens et al. 2014](#)). Thus, whether the emotional regulation theory has specific implications or predictions for social simulations in dreaming is not evident.

ies, and could thus serve as solid ground in guiding our thinking about social behaviours in evolutionary biological terms.

The Inclusive Fitness Theory ([Hamilton 1964](#)) postulates that an individual's genetic reproductive success is the sum of that individual's direct reproduction and the reproduction of the individuals carrying identical gene alleles. An individual can improve its overall genetic success by engaging in altruistic social behaviour that is directed towards individuals carrying identical alleles. The Kin Selection Theory is a more specific form of the inclusive fitness theory, which requires that the shared alleles are identical by descent. Thus, Kin Selection Theory postulates that an individual can increase its inclusive fitness by directing acts of altruism specifically towards genetic relatives, whereas inclusive fitness as such is not limited only to cases where kin are involved. Both, however, predict that acts of altruism should more often be directed towards individuals who share identical alleles.

Reciprocal Altruism ([Trivers 1971](#)) is defined as behaviour whereby an individual acts in such a way that temporarily reduces its fitness while increasing another individual's fitness. However, individuals engage in altruistic behaviour with the expectation that the recipient of the altruistic act will act in a similar manner at a later time. A strategy of mutual cooperation may be favoured when there are repeated encounters between the same individuals. Although cheating might be more beneficial for the individual in terms of immediate rewards, co-operation might provide net gain compared to short-term benefits.

Since selection pressures act on the typical conditions present in the history of any species, consideration of the demographics of the typical evolutionary environment of humans is crucial for understanding the evolution of social behaviours in our species. Recently, [Hill et al. \(2011\)](#) analyzed co-residence patterns among thirty-two present-day foraging societies, assuming that these might reflect an ancestral human group structure. They found that primary and distant kin of an adult individual accounted for approximately 25% of the co-resident adult

members of a band, i.e., about 25% of adult members in the group were directly genetically related, whereas about half of the adults were related through spouse or siblings' spouses, and the other 25% of adults were genetically unrelated.

If we accept the assumption that this observed distribution of relatedness approximates the degree of relatedness in ancestral human bands, there have been ample opportunities for ancestral humans to be subjected to selection pressures that could be explained using strategies postulated by the inclusive fitness and Kin Selection Theory, as well as Reciprocal Altruism Theory. There is ample evidence that people are more likely to help their relatives than genetically unrelated individuals (e.g., [Burnstein et al. 1994](#)), and that lethal violence is more frequently directed towards genetically-unrelated individuals than relatives ([Daly & Wilson 1988](#)). People also tend to be more altruistic towards other people in single round prisoner's dilemma game than could be expected ([Frank et al. 1993](#)) in order to protect their reputations. This seems to be a reasonable course of action, given that the faces of individuals labelled as untrustworthy cheaters are better recalled than those labelled as cooperative ([Mealey et al. 1996](#)). There are also rather large interindividual differences in altruistic behaviour, depending on factors such as age, sex, tendency to empathize, and circumstantial conditions.

The social environment has afflicted strong selection pressures on human cognitive faculties, and there are several theories that consider our essentially social nature. [Dunbar \(1992, 2008\)](#) has forwarded the Social Brain Hypothesis, which states that the main factor in the increase of our neocortical volume has been the cognitive demand bestowed on us by the increase in hominid group size. [Sutcliffe et al. \(2012\)](#) propose the idea that the costs and benefits of social interactions have been a critical driver for cognitive evolution. While our most intimate relationships are a source of social support, they are also the most costly as the quality of these relationships is dependent on the time invested in creating and maintaining them

over time. Forming weaker and less time-consuming ties with acquaintances can provide benefits such as information exchange and access to resources without exhausting an individual's resources that are allocated for social interaction. Our individual social worlds thus consist of hierarchically-layered sets of relationships defined by relationship intimacy, and different relationship types are designed to have different kinds of functions.

Turning our attention to the potentially relevant literature in social psychology, some further concepts and measures might be considered useful for dream theory. When it comes to the simulation of social interaction, one of the most relevant concepts is the social "Need to Belong" (Baumeister & Leary 1995). This fundamental motive towards interpersonal attachment and close, supportive social bonds pervades and influences our actions, emotions, and cognitions, and is fulfilled only by social affiliation and acceptance. To help us navigate the complex social world, and attune us to socially relevant information, two further advancements have been hypothesized in the form of the Sociometer Theory (Leary et al. 1995) and the social monitoring system (Gardner et al. 2000). Sociometer Theory proposes an internal monitoring device that feeds forward information about our level of social inclusion in the form of self-esteem or self-worth (Leary et al. 1998), whereas the social monitoring system is purported to guide the processing of social information whenever people's needs to belong are not being met (Pickett et al. 2004). In sum, the concept of "Need to Belong" in general, and the suggested social monitoring systems in particular, might prove useful in postulating testable hypotheses for the functions of social simulation in dreams. The Sociometer, for example, might act in a similar fashion to the threat cues postulated in TST, and prompt dreams to simulate relevant social skills or interactions.

An interesting developmental suggestion about the interplay between simulation mechanisms and social deficits has recently been put forward by Oberman & Ramachandran (2007), who propose that in typically developing individuals the abilities of Theory-of-Mind

(ToM), empathy, perceptual recognition, and motor mimicry might be mediated by an internal simulation mechanism or mechanisms. By taking into consideration a condition—autism—where all these abilities appear to be impaired, they make the case for a possible link between deficient simulation mechanisms and behavioural and social deficits. The exact implications of this idea for the hypothesis that dreams serve a social simulation function requires further consideration. One possibility is to test whether individuals with Autism Spectrum Disorders (ASD) dream less of social interactions, or whether their dreams of social interactions are different in content from those of other people. Thus far this line of research has not been explored in depth. Daoust et al. (2008) have looked into the dream contents of people with ASD, and found that they report significantly less dream-characters and social interactions than the control group. They note, however, possible error sources in the testing procedure, such as, for example, how the reporting of dreams itself might be affected by ASD.

There has been some research linking the effects of attachment relationships to dreaming. If, as attachment theory proposes, we use our early experiences with primary caregivers and other attachment figures as model states for future social interactions and the way we view and attune to our social world, it could be assumed that this would also affect our simulations of this world. Early attachment and bonding are, after all, quintessential for our species, and according to Fonagy & Target (1997) might also work as the basis for our abilities to mentalize or to create a ToM. McNamara (1996) has developed the idea that REM sleep is the mechanism that activates and maintains early attachment relations, as well as pair-bonding in later life. Selterman & Drigotas (2009) have found that attachment style is correlated to dream emotions when dreaming about romantic partners, so that those with anxious or avoidant attachment styles reported more stress, conflict, and negative emotions.

In an exploratory study on the dream contents of those suffering from Complicated Grief

(CG) after the loss of an attachment figure, [Germain et al. \(2013\)](#) found the dreams containing family members to become significantly more frequent, while there was no marked increase in the occurrence of deceased characters. Males suffering from CG also reported more familiar persons in their dreams than the control group. Both male and female CG patients also exhibited fewer negative emotions and fewer instances of aggression in their dreams, and females also had decreased amounts of positive emotions and friendliness.

We can thus conclude that the inherently social nature of our species is deeply ingrained, and has likely been as important for our survival in the ancestral environment as threat perception and avoidance skills. SST can therefore be formulated in an analogous manner to TST, but in addition to the evolutionary background theory, also taking into consideration important social functions such as the need to belong, social bonding, social networking, and social support as essential ingredients.

TST ([Revonsuo 2000](#)) places the contents and the function of dreaming in an evolutionary-psychological context and proposes that dreams were selected for their ability and propensity to simulate threatening events in a safe way, thus preparing the individual to survive real-life dangers. The hypotheses and predictions of the TST, especially concerning the inclusion of threat simulations in dream content, have gained support from several independent sources, such as studies on the content of nightmares and bad dreams (e.g., [Robert & Zadra 2014](#)), recurrent dreams ([Valli & Revonsuo 2006](#); [Zadra et al. 2006](#)), post-traumatic dreams in children and adults ([Bulkeley & Kahn 2008](#); [Valli et al. 2006](#)), dreams anticipating a stressful experience ([Arnulf et al. 2014](#)), children's earliest dreams ([Bulkeley et al. 2005](#)), dreams and mental contents in parasomnias ([Ugucioni et al. 2013](#)), the dreams and nightmares of new mothers (which mostly depict the infant in peril and trigger protective behaviours, [Lara-Carrasco et al. 2013, 2014](#); [Nielsen & Lara-Carrasco 2007](#)), as well as dreams of the general population (for a review, [Valli & Revonsuo 2009](#)).

Thus, when it comes to emotionally negatively-charged dream contents that simulate some sort of dangerous situation or unfortunate event, the TST seems able to quite well predict and explain many features of the quantity and the quality of the threat simulations found in the data. Therefore, a similar theoretical approach might also prove fruitful in the case of social simulation theory. The SST, however, needs to be formulated in such a manner that its predictions can be clearly distinguished from those of the TST.

As negative and threatening events commonly occur in dreams, the TST alone already covers a fairly large proportion of dream content. But it also ignores a relatively large proportion of dream content, as it does not offer any explanation of non-threatening dreams or for the simulation of neutral and positive events in dreams. This raises the question: do types of dream events other than those that are threatening have some evolutionarily-based simulation function, independent of the threat-simulation function of dreaming? Are there events that are equally important targets for simulation as the negative, threatening situations simulated in threat simulation dreams?

TST covers threatening events in dreams, whether social in nature or not. Many threatening events of course do involve social interaction (such as verbal or physical aggression), but are explained by the TST as primarily simulations of specific types of threat, and therefore as rehearsals of threat perception and threat-avoidance behaviours, rather than as simulations of social interactions as such. A social simulation theory that explains dreams that TST does not cover should thus focus on social simulations that are largely independent of the threat-simulation function. In some dreams these two types of simulation may, however, be difficult to tease apart. For example, a social simulation theory might account for some social interactions that happen during a threatening event in a dream, such as how the Dream Self interacts with others and collaborates with them during a threatening situation. Furthermore, these two simulation theories may not be mutually exclusive but instead complement each other. Some specific

types of simulations of negative social interactions are better accounted for by the TST while other, positively toned simulations can be explained by the SST. For example, from an evolutionary perspective it might make sense to simulate different kinds of interactions, friendly or aggressive, with people belonging to different layers of our social hierarchy.

We are open to the possibility that social simulation is an original evolutionary function of dreams alongside the threat-simulation function of dreaming. We believe that social simulation theories hold much promise. But before this belief can be empirically justified, a testable version of the social simulation theory needs to be formulated. Such a theory should independently cover the social simulations in dreams that fall outside the scope of the TST.

Furthermore, also the predictions of the CH must be distinguished and separated from those of the SST. Therefore, the question becomes: What aspects of human social reality might dreams be specialized in simulating in such a way that these social simulations have significant consequences for cognition and behaviour during the waking state, and in virtue of which social simulations during dreaming have fulfilled important functions in the evolutionary history of the human species? What kind of social-cognitive processes and behavioural social skills might have been both critical enough both for an individual's survival and successful reproduction, as well as occurring frequently and universally enough in the human ancestral environment, to be selected for as a universal feature of human dreaming? Moreover, those processes and skills would have to be something that in fact *can* be regularly simulated by the dreaming brain, and they have to be contents that actually *are* being simulated frequently and universally in human dreaming, according to the evidence from content analysis studies of dreaming.

To sum up, a credible version of the SST should have predictions and explanations that are clearly different from both the TST and the CH. To be different from TST, the SST should predict and explain the social simulations that happen outside threatening events in dreams, and to be different from the CH, the SST

should predict that some types of social stimuli, social cognition, or social behaviours are simulated actively and selectively, so that they are overrepresented in dreams as compared to waking life.

We will first consider some basic cognitive processes that might fulfil these roles and will then proceed to more complex social behaviours and interactions. We admit that many of these ideas are at this stage speculative. But if it is possible to formulate them in an empirically testable manner, then we can figure out later on which ideas remain mere empirically unsupported speculations, and which ones might actually predict and explain central aspects of our dream content.

6.1 The simulation of social perception as a function of dreaming

Overall, there are good reasons to support the view that fast and errorless social perception abilities were universally important skills for humans during their evolutionary history, and, therefore, rehearsing them through dream simulations would have served to maintain and enhance their speed and accuracy during wakefulness. In the ancestral environment, fast and efficient social perception and recognition mechanisms were essential for telling friends and allies apart from potential enemies. Thus, detecting the presence of other human beings in the same spatiotemporal context where oneself is located, immediately classifying them in terms of familiarity, identity, and history of past interactions with them, and predicting the nature of future encounters with them must have been an important survival skill. Perhaps it was important enough that rehearsal of these social-cognitive functions through social simulations during dreaming would have increased an individual's inclusive fitness.

The social perception system needs to quickly estimate answers to the following questions: *am I alone in here or are there other humans present? Are the other humans around me familiar to me or are they strangers?* Thus, the first stage of social perception is to detect other humans in the vicinity and to classify them in

terms of unfamiliar people (strangers) vs. familiar people. As [Diamond \(2012\)](#) explains in “The World Until Yesterday”, in most traditional societies during human evolutionary history, to encounter strangers was unusual and typically considered potentially dangerous, because the social interaction that followed might not necessarily have been peaceful in nature.

The second stage of social perception deals in more detail with the familiar people that are detected. If the people in my presence are familiar to me, who exactly are they? What is my relationship with them? What have my past interactions with them been like? What should I expect the interaction between us to be like this time around? To answer these questions, familiar people need to be quickly identified. Based on semantic and autobiographical memory information that we have about people familiar to us, we quickly activate expectations and strategies as to how we should interact with the people around us in the most constructive way.

But so far this idea is mere speculation. What kind of *testable hypotheses and predictions* could be derived from this theory? How could we derive predictions that clearly distinguish the SST from the CH? The CH does not attribute any evolutionary simulation functions to dream content; according to CH, dreaming simply and passively *mirrors* whatever experiences have recently been encountered in the dreamer’s waking life (and thus impressed on long-term memory). Obviously, therefore, it would not lend sufficient (or specific) support to the SST to predict that social perception should be found in dreams in the same proportions as in waking life, because the CH predicts and explains exactly the same observation and, moreover, does it more parsimoniously, without postulating any just-so-story of evolutionary *functions* to social dream content.

The SST must thus go beyond the CH and make the risky prediction that, if social perception is the original evolutionary function of dreaming and it is therefore still expressed in our dream contents, then dreams are *specialized* in simulating social perception. If dreams are specialized in simulating social perception, then perceptual contents, cognitive processes, and

behaviours relating to social perception skills should occur (as simulations) in a selective or *exaggerated* form in our dreams. The testable prediction derived from this is that during dreaming, social perception occurs *more frequently* than in waking life (shows quantitatively an increased frequency) and/or qualitatively in a more difficult or challenging form than in waking life.

Quantitatively, dream simulations could exaggerate the proportion of the types of stimuli that were most important to recognize quickly and accurately during evolutionary history (e.g., strangers vs. familiar people; enemies vs. friends). It is important to process this information quickly because the information had high survival value in ancestral environments. Furthermore, dream simulations could present qualitatively challenging stimuli for the social perception system; for example, more variety of different kinds of stimuli (different kinds of familiar and unfamiliar simulated people), or ambiguous stimuli that are more difficult to perceive or interpret than real life stimuli (vague or unstable simulations of people).

Conversely, if the social stimuli in dreams simply mirror the social stimuli during wakefulness (and memory representations of them), quantitatively and qualitatively, then the CH gains support: dream experiences merely *copy* the patterns and rates of social stimulation encountered during wakefulness, but do not *selectively* and *actively* simulate them in ways and proportions that would reflect some original evolutionary functions and would therefore have supported important survival skills in ancestral environments.

To test these two opposing theories, SST and CH, against each other empirically, we need detailed information not only about the quantity and quality of social perception in dreams, but also about the quantity and quality of social perception during wakefulness in the same subjects’ lives during the same period of their lives. Some studies already exist that provide us with this kind of data, but most of the hypotheses remain to be tested in future studies that should be explicitly designed to test the opposing hypotheses and predictions of the two theories.

McNamara et al. (2005) conducted an interesting study that can be interpreted as testing the SST prediction that social perception is quantitatively exaggerated in dreams as compared to waking life. They conducted experience sampling from fifteen individuals over two weeks across waking, REM sleep, and Non-Rapid Eye-Movement (NREM) sleep states. The participants recorded verbal reports of their perceptual and other experiences when paged at random intervals during sleep or wakefulness.

The results showed that *more characters appeared in dreams than in wake reports*. Unfortunately McNamara et al. (2005) do not report the exact descriptive statistics of this finding, so we do not know how large this difference exactly was. In any case, this finding is better in accordance with the predictions of the SST than CH: Stimuli requiring social perception (human characters) are present at higher frequencies during dreaming than during wakefulness, when experiences from both states are sampled and reported in a similar manner.

This important finding suggests that the basic processes and skills required in social perception are more engaged during dreaming than during an equal stretch of time in wakefulness. This lends support to the hypothesis that *dreaming is specialized in the simulation and rehearsal of social perception*, which may thus be one of the original evolutionary functions of dreaming. It has to be added, however, that McNamara et al. (2005) is the only study so far that provides us with this kind of data, where the frequencies of the social contents of dreaming and waking experiences have been directly compared with each other. Replications are obviously required in different populations and in larger samples of dreams and waking experiences. But so far, so good for SST.

The same study can be taken to test the additional prediction of SST, namely that dream simulations of human characters should exaggerate the proportion of the particular types of stimuli that were, during evolutionary history, most important to recognize quickly. Meeting strangers posed a threat in the original evolutionary context; thus, the SST predicts

that *strangers or unfamiliar people should be overrepresented in dreams as compared to waking life*, to simulate and rehearse the type of perceptual categorization (familiar vs. unfamiliar) that was most important in the evolutionary context. McNamara et al. (2005) report that the proportion of strangers (or unfamiliar people) encountered in dreams is indeed significantly higher than in waking life. Only 25% of people present in the waking episodes were unfamiliar, whereas about 50% of the (simulated) people in dreams were unfamiliar. Again, this discrepant pattern is well predicted by and accounted for by the SST, but goes against the predictions of the CH.

The recognition and identification of familiar people as who exactly they are could also potentially be a target of useful simulation in dreams. It might be argued from SST that quick and correct recognition of familiar people enhances the quick selection of the appropriate social strategies and behaviours when we interact with them. As about 50% of simulated people in dreams are familiar, there are still plenty of opportunities to rehearse these recognition skills. There are, however, no studies that would have directly and quantitatively compared the frequency of face recognition during dreaming and wakefulness. But still, there are some studies that question whether face recognition is engaged during dreaming and to what extent.

Kahn et al. (2002) report, in a character recognition study, that about 45% of familiar dream characters were recognized through their appearance (including facial features), and an additional 12% by their observable behaviour. Thus, nearly 60% of dream characters are recognized perceptually. However, about another 12% of dream characters are recognized intuitively, by “just knowing” who they are, which suggests that in those cases, the “recognition” happens in a top-down manner and is therefore independent of the perceptual and facial features of the dream character.

If familiar persons are *not* overrepresented in dreams to begin with (as the McNamara et al. 2005 study suggests), and only well *under 50% of the familiar people simulated in dreams*

are recognized through their facial features, this pattern of data does *not* particularly support the idea that dreams are specialized in rehearsing familiar face recognition. However, we still lack knowledge about the frequency of face recognition in waking vs. dreaming, and only a study directly making that comparison could properly test this idea. So, the case remains open, but the expectations are not particularly high that this prediction of the SST will gain strong support in the future.

6.2 The simulation of mindreading as a function of dreaming

In addition to the processing of familiarity and identity, another aspect of social perception is called Theory-of-Mind (ToM) or “mindreading”. This refers to the interpretations we automatically make about the internal mental states of the people around us. We not only categorize the people around us as familiar and unfamiliar, and assign an identity to familiar persons, we also attribute thoughts, beliefs, motives, and emotions to them. As mindreading is crucial for our ability to predict and explain other people’s behaviours, our mindreading abilities could potentially have been a target of simulation during simulated social perception in dreams (Kahn & Hobson 2005; McNamara et al. 2007).

The study by Kahn & Hobson (2005) quantifies the frequency of mindreading activities in dreams. In one sample of thirty-five participants and about nine dream reports per participant, about four dream characters per report were observed on average. In over 80% of these dreams, the participants reported having had engaged in mindreading (at least one of) the other dream characters’ internal mental states. In another sample, 24 subjects reported on average six dreams per participant. Each dream was divided into separate dream events (on average four events per report were found), and the participants were asked to report, concerning each event, whether or not they were engaged in mindreading the other dream characters. In 50% of the episodes, mindreading was reported to have occurred. Thus, on the basis of these results, we may say that mindreading fre-

quently occurs during dreaming. Kahn & Hobson (2005) in fact suggest that this may be evidence for a specific simulation function being at work:

The two studies undertaken here support the idea that dreaming may provide a simulation of waking life as suggested by Revonsuo (2000), though not restricted to only threatening events. Instead, the data of these studies suggest that if dreaming is a simulation process, it is a simulation that provides a way of knowing and dealing with the intentions of others, both positive and negative. (p. 56)

The above studies show that mindreading is well represented in dreams, but they cannot tell us whether mindreading is *overrepresented* in dreams, as its frequency of occurrence cannot be directly compared to waking life. However, McNamara et al. (2007) have conducted a direct comparison of the frequency of mindreading between waking experiences, REM dreams, and NREM dreams of the same subjects. This is what they found:

REM reports were three times as likely to contain instances of mind-reading as were wake reports and 1.3 times as likely as NREM reports. Of 100 reports per state, there were 39 instances of mind-reading in REM reports, 29 in NREM reports, and 12 in wake reports. (McNamara et al. 2007, p. 211)

In conclusion, from looking at these studies, we may say that mindreading activities frequently occur in dreams, and that their frequency of occurrence is significantly greater during dreaming than during wakefulness: Mindreading is overrepresented or exaggerated during dreaming. Thus, this data *supports the SST prediction that dreaming specifically simulates mindreading* in order to maintain and rehearse our mindreading abilities, rather than the CH prediction that dreaming simply reflects the amount of mindreading we engage in during wake experiences.

Another finding that might indirectly lend support to the SST-mindreading idea is that the behaviours and communications of dream characters are often bizarre (Kahn et al. 2002; Revonsuo & Salmivalli 1995; Revonsuo & Tarkko 2002); that is, they are unusual, unexpected, and thus unpredictable on the basis of our waking expectations. Studies on intentional social interactions between the Dream Self and other avatars in lucid dreaming suggest that dream characters are largely independent of the dreamer and behave autonomously (Stumbrys et al. 2011; Tholey 1989). Unusual and unpredictable behaviours could be interpreted simply as failures of the dream simulation to produce credible sequences of real-life behaviour. But they could also be interpreted as particularly engaging and activating social stimuli that serve to challenge our mindreading skills. That is, bizarreness in this case could be functional in the sense that it makes the simulation more challenging. Perception of unexpected behaviours may trigger a reconsideration of what is going on in the character's mind in order to produce such unexpected behaviour, and thus present a frequent need to engage in mindreading as we interact with unpredictable characters in our dreams. This idea could be empirically tested by studying whether bizarre behaviours on the part of dream characters tend to trigger mindreading in the Dream Self, and whether this feature of dreams might partially explain the apparently frequent engagement in mindreading in dreams.

6.3 The simulation of social interactions as a function of dreaming

Humans are an essentially social species and an individual's survival in the ancestral environment was most likely entirely dependent on the individual's ability to form long-lasting positive social bonds with close kin and other group members who offered protection, access to nutrition and other crucial resources for survival, collaboration, friendship, social support, mating opportunities, and opportunities to gain a better social status within the group.

Social interaction in dreams is a more complex affair than simple social perception. There need to be some behaviours that link dream characters and the Dream Self, where the intentional behaviour of one character (or the Dream Self) is directed at another character (or at the Dream Self), and the recipient somehow registers it or reacts to it. Traditionally, in the Hall & Van de Castle (1966) content analysis system, social interactions have been classified into three different categories: aggression, friendliness, and sexual interactions. It may be, however, that these three categories are too broad, and do not cover or identify all theoretically-interesting types of social interaction.

When it comes to the simulation of social interactions, the predictions of the SST should, again, be contrasted with the predictions derived from competing theories. In this case the SST needs to be distinguished from two other theories: CH and the TST. The TST is a simulation theory that describes and explains the simulation of aggressive behaviours in dreams, by including them under the category of "threatening events". The function of dreaming, according to TST, is not to specialize in the simulation of social interactions *per se*, but in threatening events; thus, any social interactions are simulated in dreams not because they are social events but because they are threatening events. No independent social simulation theory is required to explain the simulation of social interactions involving a threat; and aggressive behaviours between dream characters are, obviously, social interactions where the wellbeing of the Dream Self or some other dream character is potentially threatened.

Compared to CH or SST, the TST can account for the overrepresentation of threatening events and aggressive interactions in dreams (as compared to waking life, McNamara et al. 2005; Valli et al. 2008). The TST, however, gives no description or functional explanation for neutral and positive types of social interactions (unless they occur as parts of a threatening event). The TST assumes that neutral and positive events in dreams are either parts of a threat simulation (e.g., responding to a threat by helping others who are targets of a threat) or that they repres-

ent some kind of superfluous, non-functional dreaming that simply goes on automatically even if the threat simulation mechanisms are not activated. Thus, when it comes to social interactions, the SST should in particular predict and explain the neutral and friendly types of social interactions, and show that some of them are actively selected as targets of dream simulation. In contrast, the CH predicts that neutral and positive types of social interactions should only occur in the same proportions as they occur in real life, passively reflecting their waking-life frequencies.

If, according to SST, the simulation of neutral and positive social interactions in dreams serve to represent and strengthen important social connections and to rehearse prosocial behaviours in relation to those connections, then these types of interactions should frequently occur in dreams. This would serve the function of maintaining, rehearsing, or strengthening our waking life social bonds and networks, and would satisfy our social need to belong to groups that enhance our survival. After dreaming about prosocial behaviours, our social bonds during wakefulness would automatically be experienced as stronger and we would be more likely to engage in behaviours that further strengthen those bonds. Some tentative steps towards examining how the affects and contents of social dreams predict subsequent waking behaviour have been taken by [Selterman et al. \(2014\)](#). They discovered that an increased frequency of dreams involving significant others was associated with higher levels of intimacy and interaction the following day, whereas dream infidelity predicted less intimacy. Reported arguments in dreams were also found to be correlated with subsequent conflict in waking life. They leave open the question whether this is due to the conscious reflection of the reporting procedure, a more implicit association, or a mixture of the two.

Again, there are no detailed content analysis studies that have investigated the exact nature of social interaction in dreams by taking into account the social context of the interaction; that is, by studying who is engaged in what type of interaction and with whom. From

previous studies based on home dream diaries we know that dreamer-involved aggression, adjusted to take into account all social interactions except sexual interactions, is present in 60% of male dreams and half (51%) of female dreams ([Domhoff 1996](#)). When male strangers appear in a dream, the likelihood that physical aggression will occur in that dream far exceeds what would be expected on the basis of chance. Basically this means that male strangers signal physical aggression. The dreamer, however, is an aggressor in 40% of male dreams and a third of all female dreams ([Domhoff 1996](#)).

Yet, as the Hall and Van de Castle norms indicate, there are friendly interactions in dreams—slightly more often in female (42%) than male (38%) dreams ([Domhoff 1996](#)). Females also dream more often of familiar people (58%) than of strangers (42%) while the opposite is true for males (45% vs 55%, respectively); which might suggest that when there are more familiar people in dreams, there is also more friendliness. The dreamer participates in the majority of interactions that involve friendliness (84% for females, 90% for males), and the befriender proportion is 50% for males and 47% for females. Thus, both sexes initiate friendly interactions in their dreams approximately as often as they are befriended. Helping and protecting is the most frequent type of friendly behaviour in both sexes, followed by friendly remarks and compliments, and giving gifts or granting loans. Surprisingly, however, there is very little mutual or reciprocal friendliness, so although friendly interactions are initiated in dreams by the Dream Self or other characters, in less than 10% of friendly interactions the act is reciprocated immediately. This observation goes against any social simulation theory that predicts reciprocal friendliness should be highly represented in dreams: this does not seem to be the case.

[McNamara et al. \(2005\)](#) investigated whether types of social interaction are different in REM than in NREM dreams compared to wakefulness, and noticed that aggressive interactions were more often simulated in REM dreams, whereas friendly interactions were more often simulated in NREM dreams. Furthermore,

dreamer initiated friendliness was more typical for NREM than REM dreams. What is most interesting in this study, however, is that they also found that social interactions in general are more often depicted in both REM and NREM dreams than in wake reports. While aggression was more often simulated in dreams than encountered in waking life, the number of reports with at least one occurrence of friendliness did not differ significantly across sleep–wake states. Thus, these observations imply that dreams do not seem to overrepresent friendly interactions as compared to waking experiences.

In sum, aggressive interactions seem to be more prominent in dreams than neutral or friendly interactions, which would lend more support to the TST than to SST, and friendly interactions are not more prominent in dreams than in waking life, which would lend support to CH and the TST. Nevertheless, if simulations are biologically functional, and if these two types of simulation functions are not mutually exclusive, might there be enough room in the dream content for simulation of neutral and positive interactions, in such a way that it could have contributed to the inclusive fitness of our dreaming ancestors?

6.4 Some testable ideas derived from SST

Let us see how this general approach to social simulation in dreams could be translated into some directly testable hypotheses. Now, a general thesis derived from the SST could be formulated as follows:

Dreams are *specialized* in simulating *the most important social connections and networks* of the dreamer to give an additional selective advantage and to enhance the survival of the dreamer in waking life. The simulations of particular people (the frequency of their presence in a person's dream life), and the simulations of positive interactions with particular people, should focus on the people closest to us in waking life and on the social bonds most important for our inclusive fitness in the real world.

This thesis could be directly tested by deriving some empirical predictions from it, telling

us what kind of simulations of social interactions and to what extent they should appear in dreams. If dreams are specialized in the way predicted by SST, then the most important social networks and the people in them *should appear more frequently in dream life than in a corresponding stretch of waking life*. That is, their frequency of occurrence should be targets of active selection and inclusion into dreams, and hence over-represented and exaggerated in dreams.

This empirical prediction could be tested by identifying a person's most important social networks in waking life, and by quantifying the frequency of interactions of the dreamer with those people during dreaming vs. during wakefulness. In the already existing literature, there are some data relevant to the hypothesis, but data that directly compares waking social life and dream life in the manner required to test the hypothesis seems to be lacking.

The data scattered in the literature describes the relative frequency of dreams in which a certain type of close person appears on average in the dreams of the general (or the student) population. For example, romantic partners occur in 20% of dreams and this frequency correlates with the time spent together in wakefulness (Schredl 2011; Schredl & Hofmann 2003). Core family members occur in 10%–30% of dreams; parents in about 8%–20% of dreams, and siblings from 2%–7.5% of dreams (see Schredl 2013). Friends occur in about 20% of dreams (Roll & Millen 1979), but during long-term isolation from social contacts with friends in one case (Merei 1994) this declined to 10%. In studies of long dream series from a single person, a close family member or spouse has been found to be the person most often dreamed about. In a sample of over two hundred dream reports, reported by a married woman (Arlie) with four grown-up children, the most frequently occurring character is her husband; whereas in a sample of over three hundred dreams from an unmarried woman in her thirties (Merri), the most frequently occurring character is her sister, who was no longer alive at the time when the dream reports were collected (Schweickert 2007).

In Schredl's studies, interesting analyses of a long dream series from a single dreamer were conducted, revealing the proportions of schoolmates (2012) and family members (2013) simulated in dreams across a period stretching over twenty years. Old school mates continued to appear in about 5% of dreams over the years when the dreamer had nothing to do with them any more in real life. Similarly, family members, even when the participant was not living with them anymore, still retained a strong if somewhat reduced presence in the same dream series, being present in approximately 15–20% of the dreams over a twenty-year period.

These results show that the probability of occurrence of a character in dreams is to some extent related to the amount of real life contact with that person and to the closeness of the relationship in real life, thus supporting the CH. However, people who have at some point in life been close and important *do not seem to disappear totally* from the dream simulations even though they have long ago totally disappeared from the real life of the dreamer. This feature of the already-existing data suggests that simulations of social contact might serve the function of maintaining or strengthening close relationships over time. When the frequency of a previously close and important social contact falls to zero in waking life, and the person is no longer encountered in waking life (like old school mates after leaving school, or after the death of a family member), the simulation of such a person seems never to totally disappear from dream life, even if the frequency of dream simulations of that person to some extent diminishes. Social simulations in dreams thus seem to maintain an active storage and rehearsal of the most important and closest social relationships of our entire lives, even when those relationships are broken or discontinued for good, or are temporarily on hold in our waking lives.

What happens if a relationship that has disappeared from waking life is reactivated after years of disconnection? In Schredl's (2012) study, old schoolmates met for a reunion twenty years after going their separate ways. Interestingly, when the same relationships are re-activated in real life for just one day, the dream sim-

ulation of those social relationships is increased significantly and for a long period of time (compared to the time of actually meeting). The mechanism that reactivates old targets of simulation might be analogous to that proposed in TST for the re-activation of old threats. The frequency with which the most important real threats are simulated (e.g., in post-traumatic nightmares) increases when, during wakefulness, new cues are encountered that are associated with the old threat possibly reoccurring in real life.

These considerations suggest a more precise function of social dream simulations that could be formulated along the following lines. We may call it the Strengthening Hypothesis: *the function of social simulations in dreams is to maintain and strengthen the dreamer's most important social bonds from waking life*. Consequently, a prediction derived from the Strengthening Hypothesis can be formulated as follows: if strengthening important social bonds is a function of social dream simulations, then dreaming should include with high frequency social interactions in which the (current or past) most important social bonds are strengthened through various types of simulated positive social interactions and prosocial behaviours. Thus, the frequency of prosocial, positive interactions (bond-strengthening) with the most important persons should clearly surpass the frequency of negative (bond-weakening) interactions within dreams, and also be more frequent in dreams than in a corresponding stretch of waking life.

Schredl's (2012, 2013) findings are to some extent consistent with both the CH and the SST, but do not allow any firm conclusions about which theory better predicts the occurrence of the most important social connections in dreams. Studies that collect data from both waking life and dream life during the same period of life from the same people, as well as from the life history of these individuals, are necessarily required to test whether the representation of the most important connections is exaggerated in dreams, or if they just reflect the waking frequency. In practice, this prediction could be tested by identifying all the interactions between the dreamer and the people in his

or her most important social networks, in both dream and waking reports. Then the interactions could be classified according to whether they tend to strengthen or weaken the relationship with that particular person. If the frequency with which dreaming simulates positive interactions surpasses the frequency of those interactions in real life, then the SST would gain credence over the CH.

Another potential simulation function to consider can be called the Practise and Preparation Hypothesis. According to this hypothesis, the function of social simulations in dreams is to force the dreamer to *practise important social bonding skills*, such as how to give social support to others. The prediction derived from this hypothesis states that if practising social bonding skills is a function of dreaming, then the dreamer should frequently offer various types of social support to other dream characters, for example emotional, instrumental, or informational support. Furthermore, the types of social support offered should be dependent on the degree of relationship intimacy, i.e., the distance between the self and the recipient in the hierarchy of the social world of the individual. If the Practise and Preparation Hypothesis is correct, then the frequency of simulating social support should be higher than comparable behaviours in real life.

These ideas are testable, but dream content studies are to be carefully designed with the specific aim of testing them. In the literature already published, friendliness percentages in different dream samples and descriptive statistics concerning who initiates friendliness in dreams might shed some light on these questions. However, without any data about the frequency of occurrence of these same behaviours in the waking state of the same person, the purely descriptive findings from dreaming alone will not be able to separate CH predictions from SST predictions. The comparable waking data is crucial as a baseline against which the dream data can be evaluated and in relation to which the CH predictions can be contrasted with the SST predictions.

In an ideal setting the hypotheses for the SST and its proposed functions would also be

tested cross-culturally and in particular, as the theory makes bold evolutionary claims, in traditional small-scale human societies. As [Henrich et al. \(2010\)](#) have pointed out, the concentration of behavioural research into the so-called Western, Educated, Industrialized, Rich, and Democratic (WEIRD) societies are highly unrepresentative of the species, and might pose problems for the generalizability of the results. Furthermore, by contrasting, for example, the differences between the social simulations of small-scale and Western societies, we might uncover useful information about the plasticity and ontogenetic mechanisms of the social simulation function.

7 Conclusions

The concept of “simulation” is a useful theoretical concept for dream research. It unifies definitions and descriptions of the basic nature of dreaming, and helps to formulate testable theories of the function of dreaming. Applying this concept to the social reality of dreams means that we start to describe the persons and social interactions in dreams as simulations of their counterparts in real life. Consequently, we can ask: How does the simulated social reality relate to the actual social reality in the same person’s waking life? Is it plausible to hypothesize that the avatars in the dreaming brain might in fact be there in order to force us to maintain and practise various evolutionarily important functions of social perception and social bonding?

In this paper we made an attempt to clarify what it means to put forward the theoretical statement that “dreaming is a social simulation”, especially when this claim is offered as an expression of a theory of the *function* of dreaming. The SST can be formulated in a testable manner, and a number of testable predictions can be derived from it. Some of those predictions, concerning basic social perception and mindreading abilities, already receive rather strong support from the published literature. Many more hypotheses remain to be tested. To achieve theoretically-informative results and to directly contrast the predictions of different theories, future studies have to be designed in a

strictly theory-driven and hypothesis driven manner—which, unfortunately, is not a common approach in dream research.

If the SST, or some parts of it, prove successful, we have to be able to show that the SST predicts the nature and the occurrence of social simulations in dreams more accurately than its main competitors, the CH and the TST. To fare better than the CH, the data would have to show that the most important social contents are actively selected for incorporation in dreams as social simulations, and therefore rehearsed in an exaggerated quantity or form in dreams. To show that the CH is on the right track, the data would have to show that dream simulations merely reflect, both quantitatively and qualitatively, whatever experiences waking life has recently presented to the same person. To go beyond what the TST predicts and explains, the data supporting the SST would have to show that dreaming over-represents and actively runs positive or neutral social simulations in dreams that strengthen the skills of social perception and bonding, but that have nothing specifically to do with threat-perception and avoidance.

At this point, we are not yet sure how strong the empirical case for SST is going to be, and whether the evidence will mostly turn out to be for or against it. We shall wait for the kind of studies that directly test SST and set it against other theories' predictions. However, what we are confident about is that SST *is* an empirically testable theory, and that dream research would in general gain much if dream content studies were rigorously designed to test the predictions derived from opposing theories, and if dream data were in general collected and analysed in a manner that provides us with strong tests of different theoretical hypotheses rather than just producing more and more purely descriptive data of dream content (and then presenting vague, post-hoc theoretical interpretations of them). In that way, dream research would be able to find and test new, promising theoretical ideas, perhaps derived from cognitive and social neuroscience and from evolutionary psychological considerations. New theoretically-guided studies would help leave behind old

ideas if they did not generate any clear and testable predictions or if such predictions did not gain sufficient empirical support.

Even if we will at some point be able to explain some of the functions of social simulation in our dreams, we might not be able to explain the *underlying mechanisms that generate* the simulations. The fundamental metaphysical nature of the simulated persons inhabiting our dreaming brain might after all be almost equally mysterious as the immaterial nature of a Cartesian ghost, because, like everything we experience in our dreams, the avatars in our dreams are built out of features that have no objective, physically observable, or measurable substance. Instead, they consist of subjectively-experienced phenomenal features, and at least at the present state of consciousness science, the only way for us to get any empirically-based data about them is through the introspective reports carefully collected from the dreamers. How the sleeping brain produces vivid, dynamic, complex phenomenality and organizes it into subjective spatiotemporal hallucinations, inhabited by avatars and social simulations, still remains beyond any current theoretical explanations of dreaming and consciousness. Any plausible explanation of the actual brain mechanisms that do the trick would have to solve the hard problem of consciousness (Chalmers 1996) and cross the explanatory gap (Levine 1983) between the objective neural mechanisms in the brain and the subjective experiential realities going on in subjective consciousness. We are not quite there yet.

The Multifunctionality of Dreaming and the Oblivious Avatar

A Commentary on Revonsuo & Colleagues

Martin Dresler

Sleep and dreaming do not serve a single biological function, but are multifunctional. Their functions include memory consolidation and integration, emotion regulation, creativity and problem solving, and preparation for waking life. One promising level of description is that of dreaming as a virtual reality: The dreamer interacts with a simulated environment including other simulated avatars. While dreaming can be considered a multifunctional general reality simulator, the threat simulation and social simulation functions of dreaming are unique among other dream functions in their ability to explain a striking feature of dream phenomenology: obliviousness towards the true state of mind.

1 Introduction

Sleep is an almost ubiquitous phenomenon within the animal kingdom, existing in all higher and many lower species. The specific function of sleep, however, is still an enigma:

sleep helps an organism to save energy through extended periods of inactivity, yet at the same time leaves it in a potentially dangerous state of non-responsiveness. While several possible functions of sleep have been discussed in recent years (Frank 2006; Vassalli & Dijk 2009), the function of dreaming might be seen as an even bigger mystery: the hyper-realistic imagery experienced during dreaming does not inform the organism about its current environment, and the virtual motor activity processed in interaction with these hallucinations is not executed to affect the external world—or even worse, in pathological conditions like REM sleep behavior disorder it is, thereby threatening the health of the dreamer and his bed partner. After awakening from a dream, the often emotionally-toned preoccupation with the dream narrative can confuse the dreamer and distract him from potentially dangerous conditions in the real world.

An increasingly widespread idea is that the function of dreaming consists in the simulation of waking life. In a variation of their threat simulation theory (TST; Revonsuo 1995, 2000), Revonsuo et al. (this collection) now propose a social simulation theory of dreaming (SST), according to which dream function could best be characterized as simulating social reality. Considering the social nature of most of our dreams, SST is an intuitively plausible approach, and Revonsuo et al. review a number of studies that provide support for SST. Nevertheless, several questions remain to be clarified: is the prime function of dreaming threat simulation or social simulation—or something completely different? What is the relationship between the various proposed functions of sleep and dreaming, including TST and SST? If the TST and SST turn out not to be the sole or even prime functions of dreaming, do they nevertheless provide unique insights into the function of dreaming?

In this commentary, I shall review several widely propagated functions of sleep and dreaming. I shall then compare these functions with the social and threat simulation functions of dreaming, and finally discuss why and in which regard these two functions might be special. I shall argue that the merit of TST and

SST is not the conclusive explanation of the function of dreaming—which I consider a multifunctional state—but that they are the only candidates among the variety of dream functions that are capable of explaining a striking feature of most dreams: obliviousness towards the current state of mind.

2 Sleep physiology and the function of dreaming

When speculating about the function of dreaming, some clarifications about the level of explanation are necessary. By definition (e.g., Windt 2010), dreaming is a phenomenon occurring during sleep. In an account of biological realism (Revonsuo 2006), the function of dreaming cannot be discussed independently from the neurophysiology of sleep. Even if the phenomenology of dreaming serves a function that can be conceptually (and maybe evolutionarily) differentiated from the original function realized by its physiological correlates, this function is not independent from the neurophysiology of sleep and its specific functions: if the neurophysiological functions change their mechanisms, this would also affect the phenomenological aspects of dreaming—philosophically speaking, phenomenal properties of dreaming supervene on neurophysiological properties of sleep. However, neither can the function of dreaming be equated with the function of sleep, since there are functions of sleep for which it is rather unlikely that any phenomenological aspects play a role, e.g., myelin sheath proliferation (Bellesi et al. 2013); synaptic downscaling (Tononi & Cirelli 2006); metabolite clearance (Xie et al. 2013); or general metabolic (Morselli et al. 2012) and immunological functions (Besedovsky et al. 2012). There are also functions of sleep that might be described conceptually without referring to phenomenal aspects, but in fact happen to be biologically associated with dream mentation, e.g., physiological microprocesses underlying memory consolidation (see below). And in these cases, one can differentiate dream phenomenology and sleep physiology on a conceptual, but not biological level—unless one adopts a radically dualistic approach, that is. Hence, speaking of the

function of dreaming—in contrast to the function of sleep more generally—always implies both phenomenological and physiological aspects.

When considering the neurophysiology of dreaming, coarse sleep stages as defined by classical polysomnography have been the prime targets of investigation. Among these, REM sleep harbors the most prototypical dreams, with a story-like dream narrative including interactive visuomotor hallucinations and often intense emotions. In addition, REM sleep dreams can be most elegantly related to their neurophysiological correlates (Hobson & Pace-Schott 2002). Nevertheless, dream-like mentation can be found in all sleep stages (Nielsen 2000), and hence also the neurophysiology of other sleep stages has to be taken into account when investigating the function of dreaming. In conclusion, when speculating about the function of dreaming, all those REM and NREM sleep functions have to be considered that can reasonably be expected to be associated with phenomenal aspects. In the following, I will highlight four clusters of such sleep functions.

3 Dream function 1: Memory consolidation and integration

In recent years, the most widely discussed function of sleep and dreaming concerns the consolidation of declarative memory, including semantic, episodic, and autobiographical information; and procedural memory including perceptual and motor skills (Rasch & Born 2013). In particular the role of REM sleep in memory consolidation has been studied for several decades. While many studies from the 1970s have been criticized for being heavily confounded by too stressful REM sleep deprivation procedures (Horne & McGrath 1984), research in the 1990s raised interest in the role of REM sleep for memory consolidation: Karni (1994) demonstrated that a basic visual discrimination task improved after a normal night's sleep, but not after selective REM sleep deprivation. Following this, a leading research aim in the field has been to identify which memory systems benefit from which sleep stages: it was demonstrated that

early deep sleep benefits declarative memories, while late REM-rich sleep supports procedural skills (Plihal & Born 1997). Further support for the role of REM sleep in procedural memory consolidation came from studies showing that REM sleep intensity (total number of REMs and REM densities) increased following procedural-task acquisition (Smith et al. 2004) and improvements in procedural memory performance after a night of sleep were proportional to time spent in REM sleep (Fischer et al. 2002). Moreover, brain areas activated during a procedural learning task were more active during REM sleep in subjects who were trained at the task (Maquet et al. 2000; Peigneux et al. 2003).

More recent studies, however, speak against a prominent role of REM sleep in the consolidation of procedural motor skills or other forms of non-emotional memories, and instead emphasize non-REM sleep processes (Genzel et al. 2014). On the neurophysiological level, it has been suggested that dreaming represents the phenomenological reflection of a neural replay of activation patterns associated with recent learning experiences (Wilson & McNaughton 1994; Wamsley & Stickgold 2011; Wamsley 2014). Although memory reactivations have been observed in REM sleep as well (Louie & Wilson 2001), the most advanced models of sleep-related memory consolidation propose that neural replay is orchestrated by an interaction of non-REM sleep microprocesses, including slow oscillations and sleep spindles (Genzel et al. 2014).

Events and episodes from waking life are sometimes incorporated into dreams, either as classical day-residues the following night or after a “dream lag” of about 5–7 days (Nielsen & Powell 1989; Nielsen et al. 2004). Supporting the idea that such dream incorporations reflect processes of memory consolidation, items that were incorporated into dreams have been observed to lead to better memory retention (de Koninck et al. 1990; Cipolli et al. 2004). While an actual episodic replay of waking events was found in no more than 1–2% of the dream reports (Fosse et al. 2003), with NREM-sleep dreams appearing to include more identifiable episodic memory sources than REM-sleep

dreams (Baylor & Cavallero 2001), it has been suggested that particularly engaging learning experiences have a more robust influence on dream content relative to more passive experiences (Wamsley 2014).

In contrast to recent episodes, incorporations of autobiographical memory features could be identified in the majority of dreams (Malinowski & Horton 2014). This suggests that dreaming might serve to assimilate recent memory fragments into autobiographical memory schemas and thus supports autobiographical self-model maintenance (Metzinger 2013). For semantic memories, evidence of a relationship between dreaming and neural memory reactivations stems from studies of declarative memory that present memory cues during sleep: these cues, when associated with the pre-sleep learning session, induce associated dream imagery (Schredl et al. 2014) and enhance post-sleep memory retrieval (Rasch et al. 2007). For procedural memories, learning of an engaging visuomotor task led to integration of task-related imagery into dream-like activity during non-REM sleep (Wamsley et al. 2010a), and such dream-incorporations of recent learning experiences were associated with later memory performance (Wamsley et al. 2010b). This memory-enhancing re-experience reminds us of motor imagery training during wakefulness, which has been repeatedly demonstrated to improve motor skills (Driskell et al. 1994; Schuster et al. 2011).

Recently it has been suggested that instead of consolidating memories, REM sleep serves as a state of elaborative (re-)encoding, during which the hippocampus integrates recent episodic memory fragments into remote episodic memories (Llewellyn 2013). It has been proposed that this process relies upon principles that also underlie the mnemonic encoding strategies of ancient orators, such as vivid, complex and often bizarre associative imagery, narratives with embodiment of oneself, and associations with known locations, later serving as retrieval cues. Subjectively, this process would be experienced as the typical dream mentation with its hyper-associative and bizarre imagery. However, despite being intuitively appealing,

several theoretical considerations and empirical findings are inconsistent with the idea of mnemonic encoding strategies acting during dreaming (Dresler & Konrad 2013).

To sum up, a first important function of sleep and dreaming is memory consolidation and integration, including the rehearsal of procedural motor skills, replay of episodic and semantic memories, and integration of memory episodes into autobiographical memory schemas.

4 Dream function 2: Emotion regulation

Converging evidence suggests that the regulation of emotional processes is an important function of sleep and dreaming. Early content analyses of REM sleep dreams showed that many dreams are highly emotional, with unpleasant emotions prevailing (Hall & Van de Castle 1966; Snyder 1970). This is in line with neuroimaging studies of REM sleep, demonstrating that neural areas involved in emotion regulation like the amygdala, medial prefrontal cortex, and anterior cingulate cortex are highly activated during REM sleep (Nir & Tononi 2010). Several REM-sleep characteristics differ between healthy subjects scoring low in depression scales and those with higher but still sub-clinical depression scores (Cartwright et al. 1998). After highly emotional life events, REM sleep changes can be observed in those subjects that react with symptoms of depression (Cartwright 1983), and dreams of depressed subjects differ from patients in remission (Cartwright et al. 2006). Likewise, in depressed patients the distribution of rapid eye movements in REM sleep differs in nights after which mood is estimated better than in the preceding evening compared to nights after which mood is unchanged (Indursky & Rotenberg 1998). It was therefore proposed that REM sleep dreaming serves as a mood regulation system and that a disturbance of this process might play a role in the development of affective disorders (Cartwright 2011). Changes in REM sleep are symptomatic of affective disorders and the sleep-memory relationship is altered in these diseases (Dresler et al. 2014). In healthy subjects, the consolidation of emotional texts

(Wagner et al. 2001) or pictures (Hu et al. 2006; Nishida et al. 2009) is enhanced through REM sleep, an effect that has been shown to last for several years (Wagner et al. 2006).

While at first sight it might look as if REM sleep unequivocally strengthens emotional memory processes, some studies suggest a more complex picture: referring to the fact that emotional experiences are remembered better than neutral ones, however their emotional tone during retrieval decreases with time, it was proposed that REM sleep serves an emotional decoupling function: we sleep to remember emotionally-tagged information yet at the same time to forget the associated emotional tone (Walker & van der Helm 2009). While some studies support this model (Hu et al. 2006; Nishida et al. 2009), others suggest that the affective tone of emotional memories is preserved rather than reduced during REM sleep (Groch et al. 2013).

Besides negative emotions, sleep and dreaming have also been associated with positive affects. Recent dream report analyses suggest that positive emotions in dreams have been underestimated in previous studies and might be even more common than negative emotions (Malcolm-Smith et al. 2012; Sikka et al. 2014). In addition, the processing of reward has been associated with REM sleep and dreaming. For example, the expectancy of a reward enhances memory consolidation processes during sleep (Fischer & Born 2009), and reactivations of neural activity related to a reward-searching task have been observed in reward-related brain regions such as the ventral striatum during sleep (Pennartz et al. 2004). Instead of a simulation of purely aversive content such as threats, according to this account sleep favors the activation of representations of high emotional and motivational relevance in general (Perogamvros & Schwartz 2012, 2014).

In summary, a second important function of sleep and dreaming is the regulation of emotions, including both an enhancement of emotionally-tagged information and a decoupling of this information from its associated emotional tone.

5 Dream function 3: Creativity and problem solving

Anecdotal reports on scientific discovery, inventive originality, and artistic productivity suggest that creativity can be triggered or enhanced by sleeping and dreaming. Several studies confirm these anecdotes, showing that sleep promotes creative problem-solving compared to wakefulness. For example, when subjects performed a cognitive task that could be solved much faster through applying a hidden rule, after a night of sleep more than twice as many subjects gained insight into the hidden rule as in a control group staying awake (Wagner et al. 2004). Similarly, subjects benefited in a creativity task from an afternoon nap but not from staying awake (Cai et al. 2009; Bejjamini et al. 2014), and the likelihood of solving a problem encountered before sleep can be increased by cued reactivations during sleep (Ritter et al. 2012).

According to the classical stage model of creativity, creative insights may be described by a process consisting of several stages, of which the incubation phase appears to be most intimately associated with sleep and dreaming (Dresler 2011, 2012; Ritter & Dijksterhuis 2014). The most common psychological approaches support this view: psychoanalytical models of creativity emphasize the primary process concept, which denotes free-associative and dream-like thinking, compared to the more rational and analytical secondary-process thinking (Kris 1952). Cognitive models propose that a state of defocused attention facilitates creativity (Mendelsohn 1976)—creative individuals seem to have less narrowly-focused attention than uncreative ones, which leads to unorthodox connections of remote ideas that might eventually lead to creative cognitions. In a similar vein, creative individuals are thought to have relatively flat association hierarchies (i.e., more, yet weaker associations between cognitive elements), which accounts for the ability to make remote associations; whereas uncreative individuals are thought to have relatively steep association hierarchies (Mednick 1962). Physiological models emphasize the level of cortical arousal as an important variable influencing cre-

ativity: both a lower level of cortical arousal—particularly in the prefrontal cortex—and a higher variability in cortical arousal levels are expected in creative compared to uncreative individuals, depending on specific phases of the creative process (Martindale 1999). In addition, low levels of norepinephrine are thought to facilitate creativity, shifting the brain toward intrinsic neuronal activation with an increase in the size of distributed concept representations and co-activation across modular networks (Heilman et al. 2003). The prefrontal cortex seems to be of particular importance for creative processes; however there is evidence that both prefrontal activation and prefrontal deactivation facilitate creativity—maybe depending on the specific phase of the creative process. Brain areas showing selective activation for insight events are—besides the prefrontal cortex—the visual cortices, the hippocampus, and in particular the anterior cingulate cortex, which is thought to be involved in breaking the impasse that marks the critical step of insight into a problem (Dietrich & Kanso 2010).

Both theoretical models and empirical neuroscience of creativity suggest that sleep and dreaming provide an ideal environment for creative incubation: primary-process thinking is explicitly conceptualized as dream-like, and the hyper-associative nature of dreams can be considered a prime example of a flat associative hierarchy. Defocused attention is a phenomenal feature of most dreams, physiologically probably caused by prefrontal cortex deactivation. And daydreaming has the potential to increase creativity (Lewin 1989), while the level of engagement in such mind-wandering in contrast to explicitly directed thoughts is associated with creative performance (Baird et al. 2012). The sleep cycle provides the brain with highly alternating arousal levels, and the chaotic activation of the cortex in REM sleep through brain stem regions in absence of external sense data leads to a much more radical renunciation of unsuccessful problem solving attempts, leading to co-activations of cognitive data that are highly remote in waking life (Kahn et al. 2002a). These co-activations, woven into a dream narrative in a self-organizing manner, repeatedly receive further

innervations by the brainstem, leading to bizarre sequences of loosely associated dream topics that might eventually activate particular problem-relevant cognitions or creative cognitions in general (Hobson & Wohl 2005). In addition, in REM sleep, which is characterized by low levels of norepinephrine, visual cortices, the hippocampus, and the anterior cingulate cortex have all been shown to be strongly activated, potentially facilitating insight events. In conclusion, the phenomenological and neural correlates of sleeping and dreaming provide ideal conditions for the genesis of creative ideas and insights.

In summary, a third important function of sleep and dreaming is the association of remote cognitive elements in order to facilitate creativity and problem solving.

6 Dream function 4: Preparation and simulation of waking life

Consolidation, integration, regulation, and re-evaluation of acquired information during sleep prepare the organism for its waking life. However, such processes do not necessarily need to be purely reactive, depending solely on the experiences of the preceding day: several authors propose that a major function of sleep and dreaming might include primarily preparational mechanisms. Since REM sleep dominates sleep more during early developmental periods in comparison to later in life, some researchers have argued that REM sleep plays a role in early brain maturation (Roffwarg et al. 1966; Marks et al. 1995; Mirmiran 1995); however, also a life-long preparational function of REM sleep has been proposed. One of the first approaches in this direction was offered by Jouvett (1979), who combined the brain maturation hypothesis with a metaphor offered by Dewan (1970), in which he claims that the brain is a computer that is programmed during REM sleep—suggesting that innate behaviors are rehearsed during REM-sleep dreaming in order to prepare the organism for their application in waking life. Jouvett later revised his approach, assuming that REM sleep constitutes an iterative genetic programming that helps to maintain

the process of psychological individuation (Jouvet 1998). In a similar vein, Hobson (2009) proposed that REM sleep may constitute a “protoconscious” state, preparing the organism for waking conscious experiences. The development of consciousness during ontogenetic development in this view is a gradual and lifelong process, building on the more primitive innate virtual reality generator, which is phenomenally experienced as dreaming. With the recent integration of Friston’s (2010) predictive coding approach into this theory, the brain is thought to run a virtual world model (see also Revonsuo 1995, 2006; Metzinger 2003) that is continuously updated by processing prediction errors during wakefulness. Freed from external sensory constraints, processing of prediction errors in the dreaming brain actively refines intermediate hierarchy levels of the virtual world model. Dreaming thereby minimizes internal model complexity in order to generate more efficient predictions during subsequent wakefulness (Hobson & Friston 2012; Hobson et al. 2014).

One of the first and today the most widely discussed preparational approach is based on the observation that during dreaming particularly threatening experiences are overrepresented: the Threat Simulation Theory (TST) proposes that one function of sleep is to simulate threatening events, and to rehearse threat perception and threat avoidance (Revonsuo 1995, 2000). Such a mechanism of simulating the threats of waking life over and over again in various combinations would be valuable for the development and maintenance of threat-avoidance skills. Several empirical studies support TST (Revonsuo 2006; Valli & Revonsuo 2009), however some inconstant findings have been reported (Zadra et al. 2006; Malcolm-Smith et al. 2008, 2012). In a variation of TST, Revonsuo et al. (this collection) propose the Social Simulation Theory (SST), according to which the function of dreaming consists in the simulating of “the social skills, bonds, interactions and networks that we engage in during our waking lives”. The SST aims to predict and explain the simulations of social interaction of dream avatars that happen outside threatening events in dreams. Like the TST, predictions of the SST

are supported by a number of studies, but face inconsistent data (Revonsuo et al. this collection).

On a neurobiological level, empirical support for simulation theories of dreaming comes from a recent study demonstrating that the ventromedial prefrontal cortex subserves the simulation and evaluation of possible future experiences, integrating arbitrary combinations of knowledge structures to simulate the emergent affective quality that a possible future episode may hold (Benoit et al. 2014). As the ventromedial prefrontal cortex is known to be activated in REM sleep (Nir & Tononi 2010), this mechanism might also underlie episodes of reality simulation during dreaming. Further neurobiological support for the preparational role of sleep comes from recent research demonstrating a neural “preplay” of future learning-related place-cell sequences in the hippocampus (Dragoi & Tonegawa 2011, 2013). In contrast to the intuitive view that such activation patterns are established for the first time during a novel experience, according to these findings the specific temporal firing sequence during learning seems rather to be selected from a larger repertoire of preexisting activation patterns, thus suggesting that sleep plays a role not only in the subsequent consolidation, but also in the preceding preparation for new experiences. It has been demonstrated that sleep preceding the learning experience indeed influences memory acquisition during the following day (van der Werf et al. 2009). Interestingly, support for the hypothesis that sleep mentation constitutes a virtual reality model preparing for waking life comes also from research outside of sleep neuroscience: approaches probing artificial intelligence demonstrate that robots perform better in navigational tasks if they create and update models of their own structure and actions during a state of motoric inactivity (Bongard et al. 2006). Not surprisingly, this process of evaluation and simulation of prior and future actions was interpreted as dream-like (Adami 2006).

In summary, a fourth important function of sleep and dreaming is preparation for waking life. This includes proposals of REM sleep as an iterative genetic programming system, dreaming

as a state of protoconsciousness and virtual world model optimization, and dreaming as a simulation of threats (TST) and social interactions (SST).

7 The multifunctionality of dreaming

Numerous suggestions for solving the mystery of sleep and dream function can be found in the literature. In the previous sections I have reviewed four clusters of proposed functions of sleep and dreaming: 1) consolidation of recently acquired memories, including procedural motor skill rehearsal, replay of recently acquired memories, and integration of memory episodes into autobiographical memory schemas; 2) emotion regulation, including both an enhancement of emotionally-tagged information and a decoupling of this information from its associated emotional tone; 3) creativity and problem solving; and (4) preparation and simulation of waking life, including iterative genetic programming, virtual world model optimization, the simulation of threats (TST), and the simulation of social interactions (SST). The question thus remains what the real or primary function of sleep and dreaming is—and what the relationship between the different candidates might be. SST aims to independently cover the social simulations that fall outside the scope of TST, thereby describing an “original evolutionary function of dreams alongside with the threat simulation function of dreaming” (Revonsuo et al. [this collection](#)).

The concept of evolutionary function has been one of the main topics in the philosophy of biology (Mahner & Bunge 2000) and philosophy of mind (Millikan 1984; Neander 1991). Several notions of biological functions exist (Wouters 2003); however a general idea is that the biological function of a trait is determined by its contribution to evolutionary fitness (Walsh & Ariew 1996). Darwin (1871) differentiated between selection occurring as a consequence of ecological factors that directly threaten the organism’s survival, such as predators or other potentially life-threatening dangers of nature, and interactions with members of the same species in order to compete for mating partners.

Both principles, dubbed natural and sexual selection respectively, eventually determine reproductive success as the ultimate decision points for selection. In contemporary accounts, sexual selection was generalized to the concept of social selection, of which the former is considered a subtype (Lyon & Montgomerie 2012; West-Eberhard 2014). The concept of runaway selection, famously illustrated by the evolution of the peacock’s tail, was thought to also be applicable to the evolution of social skills in higher animals, eventually leading to the development of theory of mind, language, dance, or artistic creativity in humans (Flinn & Alexander 2007). This process of an arms race of social skills would require increasing cognitive capacity—and in fact, at least in primates, relative brain size has been related to social group size (Dunbar 1992; Dunbar & Shultz 2007).

It is tempting to associate natural and social selection as the main principles of evolution with TST and SST, respectively. This interpretation would strongly support TST and SST, as it would equate the function of dreaming with two main principles of evolution in general. In this broad sense, however, certain attributes like learning capacity or motor skills increase fitness in terms of natural selection, but do not necessarily serve to help us avoid direct threats. Likewise, certain attributes such as emotion regulation or artistic creativity increase fitness in terms of social selection, but are not necessarily themselves social in a strict sense. Ultimately, of course, all these functions serve reproductive success—however, if any skill ultimately helping us to acquire sexual partners is interpreted as social and any possible obstacle to reproduction is interpreted as a threat, then TST and SST would be trivial, as a biological function is by definition one that supports reproductive success. In contrast, if TST and SST are interpreted in a more narrow, non-trivial way, there is ample space in dreams for further functions: consolidation of navigational information acquired during exploration; rehearsal of a recently learned motor sequence; facilitation of a behavior recently rewarded with food; incubated creative insight into the solution of a recent unsuccessful attempt to build a helpful

tool; refinement of the discriminative skills regarding recently perceived pattern, etc.—all these potential benefits of sleep and dreaming increase inclusive fitness of the individual, but do not directly refer to the simulation of threats or social interactions.

This problem can further be illustrated by Revonsuo's (1995, 2006) approach, where he considers any phenomenal experience as a virtual world model: what is the function of waking consciousness, threat avoidance, or social interaction? Both threat avoidance and social interaction, of course—and many others. That this rather uninformative answer can also be transferred back to the function of dreaming might be illustrated with another ubiquitous example of simulation: in child's play, simulation of real life and the practice of skills needed therein is considered one of the main functions—play allows children to simulate coping with threats in a safe environment, and to develop the social skills needed later in life (Mellou 1994; Pellegrini & Bjorklund 2004). However, these aspects, while important, are not the only functions of play—it also offers the rehearsal of motor and sensory skills, training in predatory behavior, and general intellectual development. Hence, child's play can be considered multifunctional, as can waking or dreaming consciousness.

Segmentation of reality (including dream reality) is possible along numerous lines. In a sense, TST and SST could be interpreted as expressing two orthogonal dimensions of dream space: a security dimension with the directions threat vs. safety, and a sociality dimension with the directions social vs. individual. Dreamed accidents or natural disasters would be characterized by low security and sociality, dreamed experience of bullying by high sociality and low security, and dreamed bonding by high sociality and security, etc. Threat and social interactions in a narrow sense are important aspects both of waking and dreaming life, however they are not the only aspects. Other segmentations are also possible, e.g., by a dimension of motor activity vs. inactivity, or emotional vs. neutral dream content, or a novelty dimension. In the broad sense of natural and social selection, threat and

social interaction would be the two main drivers of evolution, however to the cost that the answer to the question of the function of dreaming becomes a trivial “to support reproductive success”. Of note is that also the other discussed functions might be interpreted within a simulation framework: e.g., simulation visuomotor activity after learning a respective task in the memory function, simulating affective experiences in the emotion regulation function, and simulating problem solving attempts in the creativity function. These different functions are neither mutually exclusive nor strictly independent from each other. In particular the emotion-processing function largely overlaps with both TST and SST—all threats and at least the most important social interactions induce strong emotions, and successful coping with these emotions would be of considerable help when facing threats or social situations. Also other functions of dreaming overlap with TST and SST: consolidation of threat-related information or social gossip improves threat avoidance or social skills, as does creative incubation on threat-related or social problems. On a more abstract level, all these simulations serve the integration of recently experienced information into the behavioral repertoire in order to adapt it to the current waking environment (Hobson et al. 2014).

Identifying the original function of a given trait has proven to be a notoriously difficult issue in the philosophy of biology (Wouters 2013). Dreaming might have originally developed as an epiphenomenon of rather basal neurophysiological sleep functions, and this phenomenological level might eventually have acquired additional functions. Such exaptations (Gould & Vrba 1982) might have been further adapted and in turn developed further neurophysiological exaptations without phenomenological correlates, etc. The original function of dreaming might be unimportant today compared to subsequently evolved functions. Instead of singling out one or two functions of dreaming as original, dreaming might be best seen as a multifunctional general reality simulator, including the simulation of motor skills, emotional processing, problem solving attempts, threats, and social interactions. To follow specific research questions, of

course certain functions still could be highlighted and followed as research heuristics with a given purpose. All functions of sleep and dreaming serve reproductive success ultimately, even though some might be more important than others from a selection point of view. For all dream functions discussed in this chapter, there are convincing supporting but also inconsistent data. The fact that dreaming is not an unselective simulation of the waking world as, e.g., the continuity hypothesis suggests (Schredl & Hofmann 2003), is a sign that some simulation functions might be more important than others. We should note, however, that quantitative overrepresentation of a specific function does not necessarily prove the primacy of this function: different functions might rely on different processes with different timescales, with a highly important function potentially requiring only seconds to be processed, while an unimportant function might take hours. In times of sufficient sleep, dream content related to the relatively unimportant function might thus be overrepresented. The relative importance of one function over another might be tested in cases of scarcity of sleep, e.g., under sleep deprivation, when different functions would have to compete for restricted simulation time. Also of interest in this regard is a comparative approach: it has been demonstrated that sleep propensity, and particularly REM sleep, negatively correlates with predatory risk across species (Lima et al. 2005), which would rather speak against TST. Concerning SST, the tendency to sleep in groups has been reported to negatively correlate with sleep time, which, however, has been interpreted either in terms of social sleep being more efficient due to reduced predatory risk, or as more social species sacrificing sleep to service social relationships during wakefulness (Capellini et al. 2008). Against this background, sleep and dreaming pose an optimization problem: how much time is best spent asleep, spent in specific sleep stages, and spent engaging in specific dream mentation in order to optimize the interplay between the different functions of sleep and dreaming? Dreaming as a general reality simulator might dynamically change its functional priorities, favoring one

over the other of its several functions, depending on the current requirements and constraints of the environment.

8 The oblivious avatar

Even though it is likely that no ‘original’ function of dreaming can be acknowledged, but rather a multiplicity of functions depending on specific research questions and segmentations of the dream space, one aspect of dreaming might distinguish TST and SST from other functions of sleep and dreaming, including other simulation functions: obliviousness of the avatar about being in a dream. Impaired insight into the own state of mind is a hallmark of normal dreaming, (Dresler et al. 2015a). The well-known exception of this symptom of most dreams is the case of lucid dreaming (Dresler et al. 2015), which in turn can be used to test whether state obliviousness is indeed a characterizing feature of TST and SST when compared with other dream functions.

There is no obvious reason why obliviousness about the dream state would be necessary for the memory function of sleep and dreaming. For procedural memory consolidation, lucid dreaming has even been suggested as a state that allows for a hyper-realistic mental training of recently learned motor skills (Erlacher & Chapin 2010). Several studies support this idea: lucidly dreamed training of coin tossing (Erlacher & Schredl 2010) or a finger tapping task (Stumbrys et al. 2015) has been demonstrated to be effective, and a considerable number of professional athletes use lucid dreams to practice sports skills, with most of them having the impression that their performance is thereby improved (Erlacher et al. 2011). For the creativity and insight function of sleep and dreaming, obliviousness regarding the current state of mind is no prerequisite, and lucid dreaming has explicitly been suggested and shown to be used as a tool to increase creative processes (Stumbrys & Daniels 2010; Schädlich & Erlacher 2012; Stumbrys et al. 2014). As with non-lucid dreaming, lucid dreaming is associated with defocused attention and flat association hierarchies—lucid dreams have been reported to include

even more uncommon and bizarre elements than non-lucid dreams (McCarley & Hoffman 1981). At the same time, regained reflective capabilities enable the creative dreamer to evaluate new associations and ideas, a step in the phase model of creativity that for non-lucid dreams is reserved for subsequent wakefulness. This mechanism is illustrated by two interesting case studies: Barrett (2001) describes the case of a painter who in his lucid dreams visited galleries, and then searching for interesting motifs to be painted soon after awakening from the lucid dream. A comparable strategy was used by one of our own study participants (Dresler et al. 2011, 2012), a music composer: when he aimed to compose a new piece of music, he turned on a radio in his lucid dreams and changed radio stations until he heard a composition that he considered interesting. He then woke himself up and wrote the new composition down. In line with these data, questionnaire studies reported that frequent lucid dreamers might be more creative than less-frequent lucid dreamers (Blagrove & Hartnell 2000).

For the emotion regulation function of sleep and dreaming the situation is less clear, however here there is also some evidence indicating that obliviousness is not generally necessary: for the case of positive affects, subjects often report that lucid dreams are associated with particularly positive emotions. And for negative affects, the successful use of lucid dreaming as a therapeutic tool in affective disorders indicates that dream lucidity does not interfere with the emotion regulation function of dreaming (Holzinger 2014).

In contrast, for those cases where a general emotion regulation function of dreaming overlaps with the TST, the necessity of staying ignorant about the true state of consciousness becomes obvious: to successfully serve as an authentic simulation of a threat, the dreamer has to take the threat as real and thus be oblivious towards his true state of mind. The cognitive insight that everything encountered consists only of hallucinated dream imagery and thus cannot harm the dreamer in reality immediately takes the sting out of the threatening experience. This mechanism has been successfully utilized

for recurrent nightmares, where lucid dreaming has been demonstrated to be of therapeutic value (Spoormaker et al. 2003, 2006; Dresler et al. 2015; Rak et al. in press). Thus, for the threat simulation function of dreaming, obliviousness regarding the current state of mind is essential.

For SST, several lines of evidence indicate that obliviousness regarding the current state of mind is a prerequisite for social simulation to be effective. During normal dreams, non-self dream characters are attributed with feelings and thoughts just like in waking life (Kahn & Hobson 2005). Being oblivious about the true nature of these dream characters might ensure that non-perfect social simulations are also taken as autonomous agents instead of mere puppets controlled by the dreamer: dream characters are often implausible compared to their real-life waking counterparts (Kahn & Hobson 2003), however, are nevertheless recognized and identified without major puzzlement (Kahn et al. 2000, 2002b). During a lucid dream, implausible dream characters might be treated less seriously by the dreamer, rendering the social simulation much less effective. This is illustrated by a recent study demonstrating that being tickled by an intentionally-controlled non-self dream character during a lucid dream was comparably ineffective as self-tickling during wakefulness, whereas being unexpectedly tickled by another dream character felt more ticklish (Windt et al. 2014). Non-self dream characters lead to different predictions depending on their perceived autonomy, and their respective simulation thus serves different functions. Lucid dreaming frequency correlates with the amount of control over the dream (Wolpin et al. 1992; Stumbrys et al. 2014), implying that frequent lucid dreamers would conceive dream characters as less autonomous than less frequent lucid dreamers. Thus, although non-self dream characters appear to have quasi-independent mental lives during lucid dreams (Tholey 1989), convincing training of social skills would require the dreamer to be oblivious to the fact that dream characters are not real, but hallucinated.

In summary, in contrast to other functions of sleep and dreaming, TST and SST essentially

depend on state obliviousness of the dreamer. State obliviousness in dreaming might therefore be seen as a prime example of an epistemic constraint of phenomenal experience that leads to new and beneficial functional properties (Metzinger 2003). While both TST and SST (and other functions of sleep) might be applicable to humans and other social animals alike, state obliviousness might be a function that specifically developed in humans: it is unlikely that animals without sophisticated language skills possess the ability to reflect on their current state of mind and compare it to alternative mind-states. In turn, such animals do not need a differential mechanism switching state reflectiveness on and off depending on the current vigilance state. Of note, neural correlates of state reflectiveness, i.e. lucid dreaming, strikingly mirror brain differences seen in humans vs. non-human primates (Dresler et al. 2013).

9 Conclusion

Sleep and dreaming do not serve a single biological function, but are multifunctional states. Their functions include memory consolidation and integration, emotion regulation, creativity and problem solving, and preparation for waking life. One promising description level is that of dreaming as a general reality simulator. TST and SST describe two important purposes of simulation, namely successful coping with threats and social interactions. The merit of TST and SST is not so much that they conclusively explain the function of dreaming—although they represent the two classical principles of evolution, natural and social selection, there are also several other sleep and dream functions. TST and SST might be the only candidates among the multiple functions of sleep and dreaming that explain a particularly striking feature of dream phenomenology: dreaming is a remarkably realistic simulation of waking life, with the exception of a complete failure to successfully reflect on the current state of consciousness. Veridical insight into the dream state is biologically possible, as the phenomenon of lucid dreaming demonstrates. The fact that state reflectiveness is nevertheless generally ab-

sent in dreaming—dream lucidity is a rare phenomenon (Schredl & Erlacher 2011), and even during lucid dreams, lucidity lapses are common (Barrett 1992)—, suggests that state obliviousness during dreaming has an important function. As demonstrated here, among the different candidates for explaining the function of dreaming, TST and SST are the only ones that are capable of elucidating this specific function: state obliviousness is necessary for the effective simulation of threats and social interactions.

Even though recent neurobiological research has begun to reveal the neural correlates of state reflectiveness and, by contrast, of state obliviousness (Voss et al. 2009, 2014; Dresler et al. 2012), the specific neural mechanisms preventing the dreaming brain from realizing its full repertoire of cognitive capabilities are still largely unclear. Further research into these mechanisms might enable exciting opportunities for sleep and dream research by revealing simple methods of dream-lucidity induction. However, if such ways to induce a simulated reality under full control of its user become available too easily and broadly, this might also lead to unforeseen problems, as at least two important functions of dreaming—simulation of threats and social interactions—probably cannot be processed without state obliviousness. This proposed necessity generates a testable hypothesis: individuals with very frequent lucid dreams can be expected to differ from the majority of infrequent lucid dreamers in their threat-avoidance and social skills.

The Simulation Theories of Dreaming: How to Make Theoretical Progress in Dream Science

A Reply to Martin Dresler

Antti Revonsuo, Jarno Tuominen & Katja Valli

Among the most pressing challenges for dream science is the difficulty of establishing theoretical unification between the various theories, ideas, and findings that have been presented in the literature to answer the question of how it is possible to construct a solid scientific theory with predictive and explanatory power in dream science. We suggest that the concept of “world-simulation” serves as the core concept for a theoretically unified paradigm to describe and explain dreaming. From this general concept, more specific theories of the function of dreaming can be derived, such as the Threat Simulation Theory (TST) and the Social Simulation Theory (SST), as we argued in our target article. We agree with Dresler that these two functions may not be the only functions of dreaming, but we still have grounds to believe that they are the strongest contenders. In our reply we first clarify why the functions of sleep should be considered separately from the functions of dreaming. Second, we outline what a good scientific theory of dreaming should be like and what it should be capable of. Furthermore, we evaluate the current state of simulation theories within this context. To conclude, we propose that instead of a general multifunctional theory of sleep and dreaming, where no hypothesis is excluded, the future progress of dream science will benefit more from opposing, competing and mutually exclusive theories about the specific functions of dreaming. This, however, demands that the opposing theories and their predictions must be risky, clearly formulated, and empirically testable.

1 Introduction

We are grateful to [Martin Dresler \(this collection\)](#) for his thorough and insightful commentary on our target article ([Revonsuo et al. this collection](#)). Dresler's commentary places the proposed simulation functions of dreaming into the wider context of other functions for sleep and dreaming, demonstrating that these phenomena may have multiple different and partly overlapping functions. He also suggests the threat simulation and social simulation functions are unique. They can neatly be connected to evolutionary theory and only they explain why the suppression of reality testing and the lack of lucidity are necessary features of these simulation functions of dreaming (i.e., they require an "oblivious avatar"). While we agree with many of the points presented in Dresler's analysis, we believe that it is possible to regard the different proposed functions of dreaming as representing different (preliminary) scientific theories of dreaming. When viewed from this theory-driven perspective, it is also possible to present more definitive evaluations as to which of them are more plausible theoretical explanations than others.

2 Function of sleep vs. function of dreaming

Many of the findings [Dresler \(this collection\)](#) mentions in his commentary are not about dreaming, but rather about sleep, its different stages, and their potential correlates, effects, and functions. While it is encouraging that there is much evidence about the functions of sleep that relates to memory and learning, and that emotionally significant information seems to hold a special place, most of those studies have very little or nothing to do with dreaming as a subjective experience. In most of the sleep studies, whether or not the sleeping participants have been dreaming or not, and what their dream contents have been, is irrelevant for the hypotheses being tested (e.g., whether a certain stage of sleep enhances memory consolidation of particular types of stimuli) and usually remains unknown. In sleep studies purely objective

neurophysiological and behavioural phenomena are investigated with objective measures. In contrast, in dream studies purely subjective phenomena are explored by collecting subjective introspective reports describing the contents of phenomenal consciousness. Modern theories of the functions of sleep are undoubtedly quite strong as scientific theories of sleep and its relationship to some neurocognitive mechanisms of memory and learning, but they are not in any direct sense theories of dreaming. Of course, any proposed theory of dreaming should be at the very least *consistent* with the leading theories of sleep, because the phenomenal level of organization supervenes on the lower, neurophysiological level. However, the opposite is not necessarily true. As [Dresler \(this collection\)](#) points out, lower-level functions can be carried out independently of the higher, phenomenal level of organization. Thus, we would like to strongly emphasize that the merits and the predictions of theories of dreaming primarily have to be tested by using data that reflects subjective dream contents, not the objective features of sleep.

3 What is it like to be a strong scientific theory of dreaming?

Any theory of a phenomenon should include a precise definition and description of its target phenomenon (or *explanandum*), as well as clear demarcation of conceptually and empirically different phenomena. Theories of dreaming should clearly state i) in what way dreaming is a different type of phenomenon from sleep (or any particular stage of sleep), and ii) in what way dreaming is a special form of mental activity occurring during sleep. In our approach the starting points are that while sleep and its different stages can be defined by objective behavioural and neurophysiological criteria, dreaming is a subjective phenomenon; a special, complex altered state of consciousness that can be differentiated from simple sleep mentation. Quite independently from any functional considerations, the general, universal *form* of dreaming, as most dream researchers currently agree, is a complex,

multi-modal *simulation* of the sensory perceptual world, inhabited by a simulated self or a self-model (Hobson 2009; Metzinger 2003, 2013; Nielsen 2010; Windt 2010). A fruitful idea in biology is that *form suggests function*; thus the form that dreaming takes, a world-simulation, most likely suggests that the major functions of dreaming have something to do with world-simulation. The most frequent dream contents are therefore the most likely candidates for reflecting the specific function(s) of dreaming: how, when, under what circumstances, and what contents to simulate. Thus, to state that dreaming is an internal world-simulation is to describe the general form that this phenomenon universally takes, but not necessarily its function. The function(s) of the simulation, according to our view, are mainly related to the specific contents selected for simulation.¹

Furthermore, a proper theory of dreaming should be *simple yet covering*, so that the same general principles apply to many types of dreams, including the pathologies of dreaming, animal dreaming, and other special cases; the theory should be *fruitful*, so that it leads to new ideas, hypotheses, and new directions for active research; it should be *empirically testable*, so that it leads to risky predictions whose accuracy can be objectively checked. It should have both predictive and explanatory power.

Of course, these virtues are desirable in any scientific theory of any phenomenon. When there are rival theories of the same phenomenon, they should be compared with regard to their overall strengths and weaknesses as scientific theories. If they are consistent with each other, perhaps they can be combined into a single, more covering theory. If they are inconsistent with each other, their differing predictions should be empirically tested. After their relative strengths and weaknesses are compared, it should be possible to say which ones are stronger than others.

¹ Further, Dresler (this collection) raises the question of whether the frequency of specific dream contents can be regarded as evidence for the importance of its underlying functions. If we consider the function of dreaming more broadly to be that of a training ground for essential and adaptive behaviors, it becomes rather clear that the observed frequency of these behaviors can be viewed as a valid measure of their importance. This, however, is evident only when comparing the contents within the phenomenal level of explanation.

4 Simulation theories of dreaming

According to the simulation view, dreaming is a special case of phenomenal consciousness, or the phenomenal level of organization being activated in the brain. Waking consciousness and dreaming are manifestations of the same natural biological phenomenon in the brain, but they occur in different contexts and under different conditions. The simulation theory of dreaming is anchored to a more general theory of consciousness, which in turn is anchored philosophically to weak emergent materialism and multi-level explanation (Bechtel 2008, 2011; Craver 2007; Revonsuo 2006, 2010). In a multi-level explanation of a mental phenomenon, several different explanatory dimensions surround the target phenomenon: the *downward-looking* explanation specifies its neural correlates and mechanisms; the *backward-looking* mechanisms specify what has causally brought about or modulated the phenomenon (e.g., day residues or traumatic experiences that directly influenced specific contents of dreaming; the ontogeny of dreaming—how dreaming came about during individual development; phylogeny—how dreaming emerged and might have been selected for during evolutionary history²); and the *upward-looking* (functional) explanation—how does dreaming guide or change consequent mental states or external behaviours? Only after all these explanatory dimensions can be accounted for may we be said to have a comprehensive theory of dreaming, including its function(s) (see also Revonsuo 2006, 2010; Valli 2011).

So far, one general and three separate, more specific simulation theories have been proposed. From a more general perspective, some versions of the Continuity Hypothesis (CH) can be regarded as a simulation theory, as some proponents of it consider the world-simulation itself to be a functional *form* of dreaming (e.g., Foulkes 1985, pp. 201–202). Three other, more specific simulation theories have been proposed:

² We should, however, also keep in mind the option that dreaming does not serve any function at all and was not selected for, but is merely epiphenomenal, as suggested, for example, by Flanagan (2001), and implied by the Continuity Hypothesis (CH). This notion should be the null hypothesis against which the proposed functions of dreaming are to be pitted.

Figure 1: Simulation theories of dreaming. All simulation theories assume that dreaming can be defined as a world-simulation, the form of which is functional. The protoconsciousness-theory is more focused on explaining the form of dreams instead of their specific contents. Threat simulation and Social simulation theories try to explain the content of dreams as having a specific function, while the Continuity Hypothesis assumes the content of the simulation to be evolutionarily non-functional.

the protoconsciousness theory (Hobson 2009), which covers the role of dreaming in ontogeny; the Threat-Simulation Theory (TST), which covers the negative contents of dreaming and provides an evolutionary account for them; and the Social Simulation Theory (SST), which covers the social contents of dreaming, including the positively charged ones. Taken together, these theories are at the same time both covering and economical: the simple principle of “internally activated world-simulation” underlies all of them (see figure 1). The proto-consciousness theory accounts for how and why the basic form of the virtual-reality generator comes about in the developing brain, and how during early brain maturation both dreaming and waking consciousness emerge together in interaction. It is, however, the most speculative of the three simulation theories, as we cannot hope to

test it with data about subjective experiences describing the postulated fetal dream experience: what is it like to be a proto-conscious dreaming fetus? Thus, its weakness is that dream reports or any other direct evidence of the existence of subjective dream-like states cannot conceivably be empirically collected to test the validity of the theory.

The TST and SST, as we have explicated in our target article (Revonsuo et al. this collection) and in earlier publications elsewhere (Revonsuo 2000, 2006; Valli & Revonsuo 2009) are testable as they issue specific predictions concerning the frequency and quality of dream contents under different circumstances. They are also covering, TST potentially accounts for normal dreaming as well as several special types of dreams, where negative dream contents are particularly abundant and dominate (bad

dreams, recurrent dreams, nightmares, post-traumatic dreams, children's earliest dreams, dreams in parasomnias such as RBD, night terrors, and so on). Together TST and SST potentially cover a very large proportion of the statistically most frequent dream contents, and the predictions derived from these theories have specific empirically testable consequences as to the quantity and quality of these types of dream contents. As [Dresler \(this collection\)](#) points out, simulation theories also have the advantage of being highly consistent with the peculiar behavioural, neurophysiological, and phenomenal features of dreaming such as isolation from sensory input, motor activity, cognitive reflection, and reality testing. These features are necessary preconditions for running powerful, phenomenologically realistic but behaviorally isolated virtual reality simulations in the sleeping brain. The simulation theories thus have a lot of explanatory power. The concept of world-simulation unifies numerous separate phenomena related to dreaming and makes sense of them under a single concept. In this the simulation theories of dreaming fulfil the requirements of simplicity, coverage, and economy as well as having predictive and explanatory power. Compared to some of the other ideas Dresler presents in his commentary, it appears that currently the simulation theories are amongst the strongest frameworks for the form and function of dreaming.

5 Rival paradigms in dream science

Of the theories that are directly applicable to dreaming, we have already addressed the Continuity Hypothesis (CH) in our target article ([Revonsuo et al. this collection](#)). As we say there, it has never been formulated in a sufficiently precise manner such that risky, testable predictions can be derived from it. The CH, largely because of its vagueness, might actually be consistent with simulation theories. The particular contents of dreams are neither selected through an active process, nor do they reflect any function(s); they are selected through a passive and more or less random mirroring of the experiences that have been lived through. Further, CH does not consider how to deal with

potential anomalies for the theory: the relatively frequent cases where either something very alien to our waking world (and thus entirely discontinuous with it) appears, or where something very common in our waking life fails to appear in our dream contents. Can the theory be regarded as falsified when evidence of such blatantly discontinuous dream contents appear over and over again in dream data? One version of the CH, presented by [Foulkes \(1985\)](#) states that the mnemonic sources of dream contents are random and unpredictable; thus dream contents are unselective random samples of our memories; but the general form of dreams as world simulations as such is highly predictable—thus the function of dreaming would be more related to the general form than to the specific contents of dreams. However, as we have argued, dream contents are *not* random, but selective, and in particular they select threatening and social events into dreams. Thus, the basic assumption behind Foulkes's version of CH has turned out to be empirically false. The CH thus does not look very promising. But, as we argued in our target article ([Revonsuo et al. this collection](#)), some testable predictions can and should be derived from CH, to render its predictions as the null hypothesis “no selectivity, no functionality”, and thereby directly test its predictions against those derived from TST and SST.

Another major functional theory of dreaming, the Emotion Regulation Theory (ERT; also reviewed by [Dresler this collection](#)), also seems relatively weak as a scientific theory. It has been presented by many different authors in many different formulations (e.g., [Cartwright et al. 2006](#); [Hartmann 1996](#); [Kramer 1991](#)). There seems to be no standard, detailed, or shared version of this theory among its supporters; thus it also suffers from a vagueness similar to that of CH. The shared core in all of the different versions appears to be the idea that dreaming works with and processes difficult, unpleasant emotions and events, and through this dream processing makes us get over them and feel and function better in our lives. An often-used analogy compares dreaming with psychotherapy ([Hartmann 1995](#); [Walker & van der Helm 2009](#)).

Again, when looking at the evidence it is important to separate sleep from dreaming. When it comes to emotional processing during sleep, the analogy to psychotherapy gains some support (Walker & van der Helm 2009). But when applied specifically to dreaming and dream contents, the idea runs into difficulties. Its theoretical roots appear to originate predominantly from the clinical tradition, and more specifically from the idea that the function of dreaming is to protect sleep from strong surges of emotion and to solve emotional problems. The negative contents of dreams originate from interpersonal conflicts and current concerns, thus being consistent with the continuity between dreaming and waking, in fact so much so that the CH coupled with the ERT could perhaps be seen to form one specific paradigm of dream theorizing. Perhaps one of the core differences between the ERT+CH paradigm and the simulation paradigm is their relationship to biological explanations. The ERT+CH favours psychological-level explanations and emphasizes recent individual experiences (learning, nurture) as proximate explanations of dreaming. The simulation paradigm emphasizes biological explanations of the form and contents of dreaming, and links dream consciousness to both the underlying neurophysiological levels as well as the ontogenetic and phylogenetic, ultimate biological history of dreaming as explanations of the form and contents of dreaming. A further core difference between these paradigms is that the psychological paradigm sees the function of dreaming as contributing to our psychological well-being and psychological adaptation to our lives, whereas the biological paradigm sees the origin of dreaming in its ability to increase fitness in all mammals and in humans during their evolutionary history; but dreaming need not *necessarily* contribute to our psychological well-being in order to fulfill its original biological function.

As these approaches represent different paradigms with differing core ideas, it might not be possible to integrate them, in the manner that Dresler (this collection) suggests, into one overall multifunctional theory of dreaming. Some of the core assumptions of ERT are incon-

sistent with TST, especially when it comes to the function(s) of dreaming and to the explanation of nightmares and bad dreams. According to TST, post-traumatic dreams, recurrent dreams, nightmares, bad dreams, and the earliest dreams in childhood are the best and strongest manifestations of the function of dreaming, when the function is fully at work and typically activated by ecologically valid threat cues and dangerous events observed in the environment, often displaying universal threat scripts consistent with evolutionarily relevant threats. In parasomnias the threat-simulation system can be overactivated, or activated in an inappropriate context and therefore seen as psychologically dysfunctional, so that it might in actuality either decrease the well-being of the individual or hamper with other functions of sleep and dreaming, even though it at the same time carries out its original biological function perfectly. By contrast, according to ERT, such highly negative dreams are malfunctions and failures of the core function of dreaming itself, because such dreams disturb sleep and make us feel negative emotions. Nightmares cause psychological suffering and sleep disturbances, thus they are like a failed psychotherapy session that increases the individual's psychological distress, instead of calming the individual down. As such, very large and important categories of dreams (and their functionality) are explained in squarely opposing ways by the two paradigms.

6 Concluding remarks

Consequently, it is not only possible but theoretically necessary to separate the basic assumptions, the predictions, and the hypotheses of the simulation theories from those of ERT and others. We can have multiple *theories* of dream functions, but dreaming as a specific phenomenon cannot have multiple *conflicting functions*! If one theory says that recurrent dreams, nightmares, and bad dreams are types of dreams that most strongly carry out the TST functions and thus were selected for in human evolutionary history, and another theory says that such dreams are, from the functional point

of view, total failures of dream function, it becomes impossible to construct from those mutually opposing ingredients a “multifunctional” theory.³ A theory that combines TST and ERT would have to say that on the one hand the function of dreaming is to have many threatening events in dreams, bad dreams, nightmares, and recurrent negative dreams, in order to rehearse threat perception and avoidance, but on the other hand the function of dreaming is also to calm down or suppress exactly those types of dreams to make the dreamer feel better. What is the dream production system supposed to do: increase or decrease the number and impact of these kinds of dreams? The multifunctional theory cannot derive coherent testable predictions about the quantity and quality of these types of dreams.

This situation, however, is far from a scientific catastrophe; in fact, it is highly *desirable*. The problem is not that there is a lack of different theories, hypotheses, ideas, or suggestions about the nature and functions of dreaming, but rather that there are too many. Consequently, it is not only possible, but theoretically necessary to separate the basic assumptions, predictions, and hypotheses of the simulation theories from those of ERT, CH, and others. We can have multiple independent *theories* of dream functions, but dreaming as a specific phenomenon cannot have multiple *mutually inconsistent functions*. We hope that the simulation theories of dreaming, whether they turn out to be correct or not, will at least push dream science forward. The progress of any science is best served by the directly opposing predictions issued by rival, clearly stated, empirically testable hypotheses. Thus it is, from the scientific point of view, much more desirable to

have many squarely opposing testable hypotheses than one all-inclusive theory that is unfalsifiable or too vague to be tested. When the opposing theories have been well-formulated and put through fair but strict empirical tests several times, we will know which ones to adopt for the time being and which ones to leave behind for good, in order to keep dream science a progressive branch of science.

³ The multifunctionality of dreaming might be possible in different populations, so that in a population that lives in a very threat-filled environment a strong threat simulation system would be selected for, whereas in a population living in more peaceful conditions the psychotherapeutic function and taming of threat simulations dreams would be more likely candidates for selection. However, one and the same population cannot manifest both functions at the same time. Just as in some species of moths, in one environment individuals are selected for towards being white because white provides the best camouflage, while in another environment the color of individuals in the same moth species is selected for towards being dark gray or black, because in that environment all the white individuals are too easily detected by predators.

Davidson on Believers

Can Non-Linguistic Creatures Have Propositional Attitudes?

Adina Roskies

Donald Davidson has argued that only language-users can have propositional attitudes. His strongest argument in support of this claim is one that links having propositional attitudes to language via a concept of belief. Here I consider various possible interpretations of this argument, looking first at the canonical conception of a concept of belief from the Theory of Mind literature, then at a weaker notion of the concept of belief corresponding to a conception of objective reality, and finally at an intermediate notion involving the ability to attribute mental states. I argue that under each of these various interpretations, analysis and appeal to empirical evidence from developmental and comparative psychology shows the Davidsonian argument to be unsound. Only on a reading of the argument that slides between different interpretations of “concept of belief” are all the premises true, but in that case the argument is invalid. I conclude that Davidson doesn’t provide sufficient reason to deny that non-linguistic creatures can have propositional attitudes.

1 Introduction

More often than not, great divides have been postulated between humans and other animals: it has variously been maintained that only humans have souls; that only humans laugh; that only humans play; that only humans are rational. The status of these claims is not merely of theoretical interest: human exceptionalism has long been used to justify or discount arbitrary and often inhumane treatment of animals, including the abuses perpetrated in factory farms and the devastation of habitats for human gain. While the issue of the soul is beyond empirical confirmation or disconfirmation, many

other claims about the uniqueness of humans have been shown to be untrue or only half-true. Recently, in response to philosophical and empirical work, there has been significant political pushback. For example, the Great Ape Project (<http://www.projetoap.org.br/en/>) aims to establish great apes as persons with recognized legal rights. Whether we should stand behind such a project or other less ambitious efforts to treat animals as entities with moral worth depends at least in part on what kind of capacities they have, both cognitive and affective.

Here I combat a philosophically prominent claim of human uniqueness: Donald Davidson's famous argument that only humans can think. In the light of the complex cognitive activities of which animals are clearly capable, one might think this patently untrue. However, Davidson means by this not that animals have no cognitive capacities at all, but that nonhuman animals cannot have beliefs, desires, and other propositional attitudes. What the thesis does is set animal cognition apart from human cognition as a different natural kind, due to radically different representation schemes (see also arguments in [Malcolm 1972](#)). This is not a straw man, but an interesting and challenging thesis. In critically evaluating the arguments Davidson provides in light of empirical evidence from developmental psychology and ethology, insight can be gained into the nature of the relationship between thought and language. Despite its *prima facie* plausibility, I conclude that in light of contemporary studies from human and animal cognition, arguments for restricting propositional attitudes to humans fail.¹ The implications of this result could be far-reaching. Language as a cognitive ability has held a special status in analytic philosophy, where it is often assumed to be foundational to thought and cognition. Rethinking the role of language as a cognitive newcomer and possibly in large part a cognitive overlay resting atop a toolbox of already-powerful cognitive abilities may lead us to rethink a number of fundamental issues in philosophy, as well as to reconsider our cognitive and ethical relationship to the rest of the natural world. This critique of Davidson is illustrative of Dennett's caution:

[p]hilosophy of psychology driven by the concerns of philosophy of language does not fall happily into place. ([Dennett 1987b](#), p. 204)

The various arguments Davidson supplies for thinking that humans are unique in having propositional attitudes all rest upon the idea that

having language is an enabling condition for having propositional attitudes. Since only humans have language, it follows that only humans have propositional attitudes.² Thus, his main argument against animal thought is:

P1 If something has propositional attitudes, then it has language.

P2 Animals don't have language.

C Animals don't have propositional attitudes.

The logic here is unassailable: if [P1](#) and [P2](#) can be established then the conclusion that animals lack propositional attitudes follows. For [Davidson](#), having language is having the ability to speak ([1984](#), p. 167, [2001a](#), p. 99), to express one's thoughts, and to understand the speech and propositional attitudes of others. It is generally accepted that nonhuman animals don't have this ability, despite some evidence that certain birds and higher mammals have some nontrivial linguistic abilities ([Kaminski et al. 2004](#); [Pepperberg 2000](#); [Savage-Rumbaugh 1986](#)). Therefore, we will grant [P2](#).³ The success of this argument denying propositional attitudes to nonhumans therefore rests on the ability to establish [P1](#), namely the claim that having propositional attitudes requires language. In this paper I consider the various avenues by which Davidson tries to establish [P1](#), for his arguments make contact with a broad range of research concerning mind and language, and serve as a good guide to attempts to link propositional attitudes to language. I begin by situating Davidson's arguments in his larger theoretical context, and raise a few methodological worries about his approach. I then briefly consider some of his minor arguments, before turning to his strongest argument linking propositional attitudes to language. I argue that on the most plausible consistent readings of

¹ However, some very interesting and very recent (currently unpublished) work by Susan Carey calls into question the interpretation of some of the extant pro-propositional attitude empirical work.

² Davidson equates thought with propositional attitudes. He famously expresses his denial of propositional attitudes to nonhuman animals as the claim that animals can't think. See [Davidson \(2001a\)](#). Here I focus upon arguments found in his 1975 paper "Thought and Talk", and his later paper "Rational Animals".

³ Another reason for focusing on [P1](#) rather than is that finding counterexamples to [P2](#) will at most make room to usher specific species into the thought-capable fold, but will not challenge Davidson's argument directly.

his arguments, one or another premise can be empirically falsified. I conclude by considering how to proceed to better understand the nature and limitations of animal thought.

2 Initial considerations

2.1 Propositional attitudes

A creature is said to have a propositional attitude when she stands in some appropriate relation (i.e., hoping, wanting, fearing, believing, etc.) to a proposition.⁴ What propositional attitudes are, and who may enjoy them, may well be influenced by what one takes propositions to be. For instance, a skeptic about propositions may deny that anyone has propositional attitudes in the above sense. For our purposes it is not necessary to resolve questions about the nature of propositions, provided that we accept that humans can (and do) have propositional attitudes—meaning that there is something *proposition-like* to which a thinker can be appropriately related, whether this be a sentence (Fodor 1978), a set of possible worlds (Lewis 1979; Stalnaker 1984), or a state of affairs (Marcus 1990). What remains to be determined is whether appropriate relations to proposition-like entities can be supported in non-linguistic creatures.

2.2 Methodological attitudes

Davidson's arguments are offered in the context of his larger theoretical commitments to the nature of mind and meaning, commit-

ments that stem from his interpretationist philosophy.⁵ In general, interpretationist strategies answer the following three questions simultaneously: “In virtue of what does a creature have propositional attitudes?”, “which propositional attitudes do they have?” and “when is one justified in attributing these attitudes to a creature?” According to interpretationism, a creature has propositional attitudes in virtue of being interpretable; the most coherent, charitable interpretation that accurately (or accurately enough) predicts behavior is the justified interpretation; and the contents of that interpretation serve to determine the contents of the creature's propositional attitudes. As Byrne puts it, in an interpretationist strategy, “there is no gap between our *best judgments* of a subject's beliefs and desires and the *truth* about the subject's beliefs and desires,” (1998). Thus, if a creature's behavior can be accurately predicted or explained by an attribution of beliefs and desires in conjunction with the assumption of rationality, we are justified in attributing propositional attitudes to the creature.

Davidson's strongest arguments for why thought requires language are motivated by his interpretationism. On a strict interpretationist view, meaning does not exist without interpretation; so if a system is uninterpreted, it lacks contentful states. Davidson believes that language is a prerequisite for entering the world of interpretation. If no language, then no interpretation, so no content. But let us consider, from an interpretationist stance, why one might think that language is a prerequisite for interpretation.

One might think that Davidson is moved by the idea that only linguistic behavior can be interpreted. However, this cannot be Davidson's position. If it were, Davidson's approach to propositional attitude attribution would be at odds with his own interpretive strategy for attributing content to mental states. The basic idea of Davidson's interpretationism is that in ascribing content to another person's mental states, we

⁴ Some have argued that there is no account of what a proposition is that is both coherent and satisfies the various criteria that propositions are traditionally supposed to satisfy (that tradition stemming initially from Frege). See e.g., Dennett (1987a), and Churchland (1981). It is unfortunate, but true, that if our notion of a proposition is fundamentally incoherent, and no compromises can be reached on the criteria propositions must satisfy, then there is no such thing as a proposition. *A fortiori*, we can't stand in any meaningful relation to propositions, so we lack propositional attitudes. Such is the position of some eliminativists. Others have compromised on the demands put on propositions. Quine, for instance, while being no friend of abstract entities such as propositions as usually conceived, found sentences to be less ontologically troublesome stand-ins for them, and held that to have a propositional attitude is to stand in some relevant relation to an eternal sentence—thereby still satisfying our philosophical intuitions about the role of propositional attitudes in explanations of human thought and behavior.

⁵ In the literature, “interpretationism” is often used interchangeably with “interpretivism”. Since “interpretivism” is more commonly used to denote a strategy of legal interpretation, I will use “interpretationism” here.

assume that that person is rational, and we ascribe content to her utterances, behaviors, and mental states in such a way as to maximize the coherence of that person's beliefs and desires in light of her behavior. Undeniably, there is a class of behaviors that humans have and animals lack, namely linguistic behaviors. However, both humans and animals share a wide range of non-linguistic behaviors that admit of interpretation. On the face of it, those behaviors provide ample evidence upon which to base attributions of mental content, and Davidson himself would not refuse to attribute propositional attitudes to a silent person. However, Davidson pointedly refuses to apply a straightforward interpretationist strategy to non-linguistic animals. To avoid arbitrariness, an independent argument is needed to privilege language over other behaviors.

Perhaps Davidson believes that rationality is impossible without language. If we cannot attribute rationality to a creature, the interpretationist strategy does not apply. More than a few people have argued that animals are not rational, yet there is reason to believe, under some plausible construals of rationality, that they are. To hold that rationality presupposes language commits one to a narrow view of rationality, already colored by a linguistic bias. Such a view implicitly begs the question in which we are interested. Admittedly, what rationality is is a vexed question in philosophy, and determining whether a creature is rational falls prey to the same holistic problems as determining whether it has propositional attitudes. A theory of rationality predicated upon a conception of practical reason instead of upon linguistic manipulation appears to be more neutral. There is abundant evidence for practically rational behavior in the animal world. After all, animals of all stripes are here now because they have been evolutionary successful, and to have succeeded requires in some nontrivial sense that goals are achieved by instrumental behavior.⁶ All animals exhibit some degree of ration-

ality, construed in this way. Building on this view of rationality promises to enable us to posit criteria or hallmarks for minimally rational behavior that are independent of language, yet also to concede that some rational behaviors are linguistically dependent, and thus unique to humans. Indeed, one might think that a good way to assess rationality would be to see to what extent an animal's behavior is predictable or explicable with reference to survival requirements and common sense belief-desire psychology. A wide range of animal behaviors certainly seem apt for explanation with reference to the rational interplay of ecologically-relevant propositional attitudes. If one thinks that aptness for explanation in terms of rationality is sufficient evidence for rationality, and accepts, as Davidson does, that rationality rests on the interplay of propositional attitudes, then we have ample evidence that animals have propositional attitudes, rather than that they do not.

Davidson, however, obviously thinks that the reasons to deny animals propositional attitudes supersede reasons to attribute rationality to them; he applies *modus tollens* to my *modus ponens*. Since he denies that animals have propositional attitudes, and he thinks rationality requires propositional attitudes, he denies that animals are rational. We are led to very different conclusions about the nature of animals' mental lives depending upon whether we take ourselves to be more justified in attributing rational behavior to them or in refusing to attribute to them propositional attitudes. Because the questions of propositional attitudes and of rationality are both equally troubling and closely linked, arguments against animal thought based on assumptions about rationality are not compelling.

Thus, we have as yet failed to find ample reason to refuse to apply the basic interpretationist strategy to non-linguistic animal behavior. Perhaps Davidson thinks that, in the absence of language, we have insufficient evidence for attributing propositional attitudes to animals. Perhaps it is because Davidson thinks that "having the gift of tongues" is both necessary and sufficient for having propositional attitudes (1984, p. 156, 2001a, p. 104), he views language

⁶ Decision theory, for instance, gives us one model of rationality. Interestingly, in many ecological studies of foraging behavior that use decision theory to assess animal choice, animal behavior is found not to just be adaptive, but optimal. For example, animal foraging decisions approach optimality. See e.g., Stephens & Krebs (1986).

possession as *the* evidential criterion for propositional attitude attribution. He consequently denies that we can be justified in attributing propositional attitudes to creatures on the basis of non-linguistic behavior. Language gives the radical interpreter the green light: evidence of linguistic behavior licenses application of the radical interpretive strategy.

Even if we grant that language is the best evidence for propositional attitudes, we should be immediately suspicious of the presumption that the only evidence relevant for deciding whether something has propositional attitudes is the presence of a necessary and sufficient condition for having them. In normal empirical inquiry, criteria that are necessary and sufficient are rarely the only ones that qualify as evidence for assessing empirical claims. For instance, a rash may be relevant evidence for determining whether a person has Lyme disease, despite the fact that not all people with rashes have Lyme disease, and not all people with Lyme have rashes. Might there not be evidence highly indicative of whether a creature has propositional attitudes, despite the fact that the evidence is not decisive? Reasonable, predictable behavior is surely a clear source of evidence for the existence of propositional attitudes, despite the fact that it only provides defeasible reasons for thinking they exist.

Furthermore, unlike instrumentalists like Dennett, Davidson seems to favor the idea that beliefs are real; his anomalous monism posits a physical-causal substrate for mental states, albeit one that exempts psychology from being reduced to physical laws.⁷ One might think, nonetheless, that it would be reasonable for a realist to accept the possibility that beliefs involve some internal representational structures, and that there could therefore be other types of reliable evidence besides linguistic evidence for the presence of propositional attitudes. Thus, Davidson's exclusive focus on language is in tension with his realist leanings. Furthermore, if

one is a realist about thought, it is not the evidential question, but rather the question of the grounds of possibility for having propositional attitudes that should be of primary interest. The Davidsonian mix of interpretationism and realism creates an uneasy tension, for while he tends toward realism about belief, he often seems to think the metaphysical and epistemological construals of the question amount to the same thing: a creature has propositional attitudes if we ought to interpret him as having them. I suspect that this collapsing of the issues accounts for Davidson's view that the question of whether a creature has propositional attitudes is closely tied to the evidential question of what evidence is relevant for deciding whether something has propositional attitudes.

There is, as far as I can tell, a lack of a substantive argument for requiring that a creature has language to be a candidate for interpretation, as well as for holding that only the presence of language provides sufficient evidence for attributing propositional attitudes. Thus, neither the interpretationist strategy itself, nor Davidson's concerns about evidential warrant justify the position that only language-speaking creatures can be candidates for propositional attitudes. Now let us turn to the specific arguments Davidson offers for denying animals propositional attitudes: the reasons he offers for holding that language is necessary for thought.

3 Minor arguments

Why might someone think that language is necessary for having propositional attitudes? A common reason for supposing that language is necessary for thought is that one is in the grip of a picture about the nature of thought—namely that thought is a type of language, or is linguistic or language-like. If propositions are linguistic entities, then creatures that lack the capacity for linguistic representation might well be unable to represent propositions and thus be unable to hold an attitude toward a proposition. However, since there are competing accounts of what propositions actually are, several of which see them as non-linguistic in nature, the intuitive language-like characteristics of pro-

⁷ The debate about propositional attitudes, language, and capacity for thought has implications beyond philosophy of mind to ethics. As Davidson himself noted, personal and sub personal levels of description refer to different logical subjects, and thus Davidson's argument has implications for the possibility of attributing *personhood* to animals. See again, <http://www.projeto-gap.org.br/en/>.

positions does not settle the question (Lewis 1979; Stalnaker 1984).

In several places Davidson gestures at related arguments for denying non-linguistic creatures propositional attitudes (1984, p. 156, 2001a, p. 98). These stem from an implicit commitment to propositional attitudes having certain characteristics that only languages possess. For instance, Davidson claims that propositional attitudes have definite content, and that only things expressed in language have definite content. Drawing on the discussion of Malcolm (1972) before him, he gives an example of a dog chasing a cat up a tree. Like Malcolm, he notes that we cannot attribute to the dog the thought that the cat ran up the maple, as opposed to that the cat ran up the tree. If there is no particular thought we can attribute to the dog, then the dog hasn't had a thought with definite content, and so hasn't had a propositional attitude. Davidson elsewhere claims that propositional attitudes are opaque⁸, and that language accounts for their opacity (Davidson 2001a, p. 97). Although these claims can be combatted directly, I will not pursue those arguments here. Both the definite content claim and the opacity claim lose their teeth when it is recognized that they take the following form:

P1	Propositional attitudes have a property, p
P2	Language has property p
<hr/>	
C	Therefore, language is necessary for propositional attitudes

This argument is fallacious—it would only be valid if nothing *but* language had property p. But no such argument is on offer. It is worth noting, moreover, that whether propositional attitudes have the property p in question is itself contentious—do all our beliefs have definite content? Finally, even if having property p were somehow constitutive of thought, and to have p thought had to be linguistic, this would still not entail that a creature with beliefs and desires must have language in Davidson's sense. Fodor

(see Fodor 1975), for instance, thinks that a creature must have a language of thought to have propositional attitudes, but he holds that it need not be able to speak or understand a public language to have a language of thought. Even if claims about definite content and opacity were true, that is, if Fodor is right, Davidson has erred in thinking that thought requires an external as opposed to an internal language. If animals have a language of thought, they are non-language-using believers.

4 Davidson's Master Argument

The above minor arguments don't play a central role in Davidson's support of P1. The strongest support for the crucial premise is found in what I will call his Master Argument.⁹ The Master Argument puts psychological restrictions on what it is to be an interpreter, and it supports the claim that one cannot have propositional attitudes without language. If the Master Argument succeeds, then Davidson's arguments for denying that animals have propositional attitudes is compelling. But, as I shall argue, the Master Argument ultimately fails, and thus also fails to support the denial of propositional attitudes to animals.

According to Davidson's interpretationism, having beliefs entails being an interpreter. The basic idea of the Master Argument is that possessing certain concepts is a prerequisite for being an interpreter, and that an organism must have language in order to have these concepts.¹⁰

⁹ Davidson nowhere presents his Master Argument in this precise form. I reconstruct the logical form of his argument from "Thought and Talk" and "Rational Animals".

¹⁰ This ought to be distinguished from the idea that having propositional thought requires having some concepts, and that the contents that can be entertained by a creature in propositional thought are constrained by the set of concepts that the creature possesses. This view, held by a variety of thinkers from Frege to Fodor, stems from the belief that the propositions to which a thinker stands in relation in having a propositional attitude are complex entities composed of concepts. But then the question of whether animals have propositional thought can be recast as the question of whether animals have concepts. If, additionally, one combined this view of the cognitive structure of propositions with a view according to which concept possession requires language, one would have an argument for why language is necessary for propositional thought. However, whether concept possession requires language is a question that depends, among other things, on what concepts are. Whether the vehicles of thought are language-like, as I argued earlier, is orthogonal to the issue of whether an organism possesses the capacity to speak or understand speech. Therefore Davidson's argument cannot rest on the nature of concepts.

⁸ Substitution of co-referring terms in "opaque" contexts may not preserve truth. Such is the case with propositional attitudes. Thus, while it is true that Lois Lane believes "Superman is a hero", it may be false that she believes "Clark Kent is a hero", despite the fact that Clark Kent is identical to Superman.

Davidson's position differs from the more widely-held view that having *some* concepts is required for having propositional thought, by supposing that there are *specific* concepts that a creature must possess in order to have propositional thought. The Master Argument links thought to language by way of higher-order thoughts. Specifically, Davidson suggests that a concept of *belief* is a prerequisite for propositional attitudes, and that a concept of belief is unavailable without language. Here is Davidson's Master Argument:

M1 If S has propositional attitudes, then S has beliefs.

M2 If S has beliefs, then S has a concept of belief.

M3 If S has a concept of belief, then S has language.

MC If S has propositional attitudes, then S has language.

The argument is clearly valid. But is it sound?

M1 is plausible; it just highlights Davidson's view that beliefs are a fundamental propositional attitude, and that to have any propositional attitudes at all, a creature must have some beliefs. **M2** and **M3**, the remaining premises, are interesting, but their meaning is unclear, for they contain a clause that needs to be unpacked: what exactly is a "concept of belief"? Let us distinguish three different conceptions of a "concept of belief", varying in stringency. One conception of the concept of belief is robust, in which the concept of belief is the fully articulated belief-concept that is taken to be definitive of a mature theory of mind. On this robust view, having a concept of belief is an epistemologically-rich notion that entails having an ability to pass the "false belief test". That is, it is criterial for having the concept of belief that one has the ability to attribute to others a mental representation of the world that may differ from the way the world is, as well as a recognition of the perceptual circumstances that would engender false representations. In contrast, a deflationary conception of what it is to have the concept of belief merely requires an understanding that the world is distinct from how it appears

or how one takes it to be, or that belief can come apart from reality. On a deflationary view, then, having the concept of belief is rather like having the concept of an objective reality. Finally, we might consider an intermediate notion of the concept of belief that involves the ability to attribute representational mental states to oneself and others, without satisfying all the constraints that a robust conception must meet. Which, if any, of these conceptions of "concept of belief" is important for Davidson's argument linking belief to language?

4.1 The robust conception of belief

The robust conception of belief became important in developmental psychology in the context of concerns about Theory of Mind: having a notion of false belief was taken to be diagnostic of a mature TOM, and, according to many researchers in the field, only develops in humans at around four years of age (Saxe et al. 2004; Wellman et al. 2001; Wimmer & Perner 1983). However, requiring a concept of belief in the robust sense seems too demanding a condition for having propositional attitudes. While we might plausibly doubt whether prelinguistic infants really have propositional attitudes, it is hard to deny that young children who have already acquired a sophisticated facility with language have propositional attitudes. Children of two and three, for instance, clearly refer to objects in the world using language, and they readily express their desires ("I want the green monkey!"), beliefs ("I think the ball is under the bed"), as well as fears and other propositional attitudes. They understand others, refer to their own and others' mental states, and communicate effectively. We typically and with great conviction attribute propositional attitudes to children of these ages. Nonetheless, according to most developmental psychologists (See e.g., Perner et al. 1987; Call et al. 1999; http://youtu.be/8hLubgpY2_w), until the age of four (two years after they develop considerable language abilities) children lack a concept of belief in the robust sense.¹¹ And if so, we

¹¹ Kristen Andrews takes autistic subjects to be counterexamples to Davidson's view, which would also argue against **M2**. (Andrews 2002).

make ordinary propositional attributions to children well before they possess the robust concept of belief. Thus, [M2](#) is false.¹²

Not all psychologists agree that a robust concept of belief doesn't develop until about four years of age. Some have argued that the methods used in many of the classic false belief studies rely too much on language or on inhibitory control, and that tests other than the classic false belief test are sufficient for demonstrating understanding of false beliefs. For instance, a recent study suggests that children have a concept of belief at far earlier ages than previously thought—earlier, in fact, than the development of language ([Onishi & Baillargeon 2005](#); [Baillargeon et al. 2010](#); [Caron 2009](#)). However, if this is so, then [M3](#) is false, for the robust conception of belief does not depend on having language. This version of the Master Argument depends upon a tight connection between competence in the false-belief task and belief. On one conception of what evidence is sufficient to reflect performance on the false-belief task, [M2](#) is false, and on another conception, [M3](#) is false. Either way, the Master Argument is empirically refuted, and the robust conception of “the concept of belief” fails to link language possession and propositional attitudes.¹³

Davidson may well be unperturbed, for there is no textual evidence that he means to implicate the robust conception of belief when he claims the concept of belief is necessary for having beliefs. After all, from the standpoint of his radical interpreter, one can only be a believer in virtue of interpreting others, but it is unclear why the possibility of such interpretation should rest upon a grasp of others' mental states being beliefs in this robust sense, rather than in some weaker sense. In “[The Second Person](#)” (1992), for instance, [Davidson](#) argues that for our mental

states to have determinate content we must interact with another being in order to “triangulate” and thus make determinate the referents of our thoughts. Nothing in this picture requires that an interpreter have a robust concept of belief as opposed to a more deflationary one.

4.2 The deflationary conception of belief

In line with the idea that Davidson has a more deflationary view in mind, in both “[Thought and Talk](#)” and “[Rational Animals](#)” he mentions a different criterion for having a belief, which he also thinks links the possession of language to the ability to have propositional attitudes. This is the criterion of possessing a concept of “objective truth.” Davidson's argument for language via the criterion of objective truth is as follows:

O1 In order to have propositional attitudes, one must have beliefs.

O2 In order to have beliefs, one must have a concept of objective truth.

O3 In order to have a concept of objective truth, one must have language.

OC Propositional attitudes require language.

The logic here is again unproblematic, but unpacking the premises is not. At times Davidson seems to equate the concept of objective truth with that of belief. I take this as evidence that he intends “the concept of belief” in the Master Argument in its most deflationary interpretation: as an understanding that how the world is can come apart from how one takes the world to be. Given this interpretation one could believe that the concept of objective truth co-occurs with that of belief, or that the cognitive conditions that make possible the concept of belief are the same as those that make possible the concept of objective truth. In any case, Davidson sees a tight connection between the notions of belief and objectivity.

How are we to understand the “concept of objective truth” in [O2](#) and [O3](#)? If Davidson means it to be a metasemantic concept, such as having a Tarskian definition of truth, or an understanding that truth applies to propositions, and so on, then it would be almost assured that

¹² In addition, at ages far younger than those at which children pass the false-belief task, they act as interpreters, in Davidson's sense. Any parent knows that their children interpret speech well before they are speakers, and long before the age at which they pass the false-belief task. So if interpretation is central to having propositional attitudes, it doesn't require a robust theory of mind.

¹³ Of course, Onishi and Baillargeon's interpretation is subject to refutation. Should their findings (they developed a nonverbal task that suggest that infants much younger than previously supposed represent others' mental states, such as goals, perceptions and beliefs.) reflect something like proto-beliefs rather than full-blown propositional attitude-sustaining beliefs, [M3](#) would not be falsified.

one could not grasp the concept of truth without language. It would explain the *prima facie* plausibility of the Objective Truth version of the Master Argument. However, if we adopt that reading of objective truth, O2 would be false, for people certainly have propositional attitudes even if they never become philosophers, and even if they never have an inkling about metasegmental notions.

Another clue about what Davidson means by objective truth comes from his emphasis on triangulation. Davidson thinks we need to interact with another person in order to come to see the world as external to us—in order to develop a notion of objectivity. By linguistically triangulating on an object with another, we are forced to recognize that object as part of an objective reality. Davidson illustrates this view in “The second person”:

Belief, intention, and the other propositional attitudes are all social in that they are states a creature cannot be in without having the concept of intersubjective truth, and this is a concept one cannot have without sharing, and knowing that one shares, a world, and a way of thinking about the world, with someone else. (2001b, p. 121)

However, there are two fundamental problems with using triangulation as an argument for the necessity of language for thought. First, there is nothing apparent about triangulation that requires spoken language as opposed to some other sort of joint interaction or non-linguistic communication. It is, indeed, difficult to see why language as opposed to action would be operative in developing a notion of a world external to ourselves. So triangulation fails to show that language is necessary for thought. Second, it is difficult to see how triangulation could itself suffice for a notion of objectivity. In order for me to triangulate with another, I must *first* see the other as part of the external world, as opposed to an element in my mentality. As long as the other is merely a part of the way I take things to be, it cannot fulfil the role of the second person (see for example, Roskies 2011).

So triangulation also fails as a mechanism for constructing the concept of objectivity. Nonetheless, Davidson’s emphasis on triangulation strongly suggests that by “objective truth” he is referring to the appearance/reality distinction.

This interpretation is further strengthened by taking seriously the fact that Davidson thinks the concepts of belief and truth are closely linked (1984). As mentioned earlier, having the concept of objective truth is nothing other than understanding that how the world is can come apart from how one takes the world to be. What evidence do we have that language is required for this?

4.3 Surprise

As further evidence that Davidson intends a deflationary view of the concepts of belief and objective truth, we can turn to another formulation of the Master Argument. In his most forthright explication of what he means by “concept of belief”, he suggests that there is a behavioral mark that is coextensive with having such a concept: surprise.

In order to have any propositional attitude at all, it is necessary to have the concept of a belief, to have a belief about some belief. But what is required in order to have the concept of a belief? Here I turn for help to the phenomenon of surprise, since I think that surprise requires the concept of belief. (Davidson 2001a, p. 104)

The willingness to consider some sort of non-linguistic behavior as relevant to the question of whether a creature has propositional attitudes is a methodological breakthrough, for it provides an avenue independent of language for assessing whether an animal has the requisite cognitive machinery to be a believer. Davidson maintains that the ability to be surprised is diagnostic of having the concept of belief. It indicates recognition that one’s own mental representation fails to conform to that which it represents, and as such it constitutes necessary and sufficient evidence of the concept of belief.

Following this intuition, we can amend Davidson's Master Argument to incorporate this insight:

S1 If S has propositional attitudes, then S has beliefs.

S2 If S has beliefs, S has a concept of belief.

S3 S has a concept of belief iff S has the capacity for surprise.

S4 If S has the capacity for surprise, S has language.

SC Propositional attitudes require language.

The idea that surprise goes hand-in-hand with the concept of belief is not implausible: if surprise issues from the recognition that one's belief about how the world is fails to correspond with the way the world is, then surprise is good evidence for the concept of belief. Moreover, because this idea does not have implications for the ability to attribute propositional attitudes to others in an operative sense, it suggests that the interpretation of "concept of belief" that Davidson favors is a deflationary interpretation: one that involves appreciation of the appearance/reality distinction, or, as discussed above, the concept of objective truth. Thus, S2 takes the deflationary interpretation of the concept of belief, and for the argument to be valid, S3 must also take that interpretation.

Unfortunately for this version of the argument, S4 is false. There is clear and abundant empirical evidence that the ability to be surprised at the mismatch between the world and one's own representation of the world is independent of language (Dupoux 2001; Feigenson et al. 2002; Hauser & Carey 1998; Santos et al. 2002; Wynn 1992). Take, for example, an invaluable tool in the developmental psychologist's toolkit: the violation of expectancy looking method (V) for testing infants. Many studies performed on pre-linguistic human infants employ this paradigm in order to explore what an infant knows. The idea is simple: infants look longer at stimuli that fail to correspond with their expectations. This method has been used to determine, among other things, that infants have an innate (or very early developing) concept of number. In now classic experiments,

Wynn and colleagues demonstrated that infants can do simple arithmetic (Wynn 1992). She showed infants as young as five months a toy, and placed it behind a screen. Then she showed them another toy and also placed it behind the screen. The screen was then lowered, revealing either two toys (the expected outcome), or only one toy. Infants looked longer at the unexpected outcome. The same paradigm was used with different numerical combinations, demonstrating that for numerosity up to three, infants can do simple addition and subtraction, and are surprised when what is revealed behind the screen does not comply with their expectations. Significantly, this robust effect, which is due to surprise, precedes the development of language by more than a year.

Davidson might reply that it is not actually possessing language, but rather possessing the *capacity for language* that is important for surprise, and thus for the concept of belief. Maybe, even though they cannot yet speak, infants possess a language faculty, which, immature as it may be, is sufficient to support surprise. However, this attempt to patch the argument also fails. The VELM is used frequently in studies with nonhuman primates, and while they never develop language nor seem to have a capacity for natural language, they too exhibit surprise when their expectations are violated (Hauser 2000; Hauser et al. 1996). So, it seems, language is not a requirement for surprise, nor is surprise evidence for the presence of or capacity for language.

The empirical studies of developmental psychologists and primatologists undermine the Surprise version of the Master Argument: surprise does not depend upon having language. Moreover, if premises S2 and S3 are true—if the capacity for surprise is evidence of the concept of belief, and if propositional attitudes depend upon possession of the concept of belief—then propositional attitudes do not depend upon language.

Let us briefly revisit the Objective Truth version of the Master Argument. I have argued that only a deflationary notion of objective truth is a candidate interpretation for the argument. I have also suggested that this is the only

notion of “the concept of objective truth” that meshes with the arguments Davidson raises regarding belief and surprise. Thus, having a concept of objective truth is having a concept that the way the world is can come apart from how one takes it to be. If this is correct, then the Objective Truth version of the Master Argument is false.

In Wynn’s looking-time studies discussed above, the child has clearly developed expectations of what lies behind the screen, and must somehow represent this to herself. When the screen is lowered and the child sees what is behind the screen, there must be some sense in which correspondence with the expectation or lack of correspondence is noted, and in which the data coming in from the senses is privileged over the internal representation. This is, in essence, what it is to recognize that beliefs about the world can come apart from the way the world is. Clearly this sort of grasp of reality does not depend upon language: pre-linguistic infants and non-linguistic animals possess it. One can easily imagine how violation of expectation can be instantiated in a system with imagistic thought. The languageless child need only conjure up an image of the objects behind the screen and compare this with the visual scene before him. As long as the child privileges the sensory information over the mental representation, we might say that he has a concept of reality and of the belief/reality distinction. In summary, then, language is not required for a concept of objective truth.

4.4 The intermediate conception of belief

We have ruled out both the robust and weakest notions of “concept of belief” as candidate notions for a successful interpretation of Davidson’s argument linking belief to language. Perhaps an intermediate notion can do the job. This notion involves the ability to attribute representational states to oneself and others; it is less sophisticated than that required to pass the false-belief task, but more complex than the recognition of an appearance/reality distinction.

One potential reason why representational-state attribution may be important for having

beliefs involves self-reflection: perhaps being a believer requires being able to think of oneself as a believer, and thus requires the concept of belief. This amounts to the claim that beliefs cannot be held non-reflectively. Since we clearly do have beliefs that we do not have beliefs about, what is at issue is not the actuality of having beliefs about beliefs, but the possibility or capacity to do so. However, while there are arguments that the ability to think about oneself as a believer is required for a rich construal of theoretical rationality (see [Bermúdez 2003](#), Ch. 7), there is no clear argument why such reflective ability should be constitutive of having beliefs. Indeed, it seems like the ability to believe things about one’s beliefs would require that one could believe things, so that belief is conceptually prior to self-reflection. In any case, self-reflection is not Davidson’s stated reason for thinking that the concept of belief is important for having beliefs.

The other reason to hold that having belief requires having a concept of belief under the intermediate conception links the ability to attribute mental states to others with having the concept of belief. Thus there are two different strengths of intermediate interpretations to consider. According to the less demanding interpretation, a concept of belief is required in order to attribute contentful states to other creatures; whereas the more demanding interpretation holds that a concept of belief is required to attribute propositional attitudes to others: one must be an interpreter, not just an interpretee.

We can discount the less demanding of these interpretations for the purpose of this argument linking thought to language,¹⁴ because if [M2](#) (“If S has beliefs, then S has a concept of belief”) is interpreted in this way, then [M3](#), the claim that language is required for a concept of belief, read in this way, is false. There is growing evidence that non-language-using animals are able to attribute representational states to other animals. One compelling illustration of this comes from ([Hare et al. 2000](#)), who show

¹⁴ We ought to reject this interpretation for the purposes of Davidson’s argument, despite the fact that we may ultimately agree with it as a necessary condition for having propositional thought.

that subordinate rhesus monkeys only approach food in the presence of a dominant male when they know that the male is unable to see the food (interestingly, dominant males appear not to care whether or not a subordinate male sees food, pointing to yet a further level of sophistication in the cognitive processes of non-linguistic animals). Thus, if it is the case that to believe requires having the ability to attribute contentful mental states to others, then it is not the case that believing requires language. Indeed, recent work on non-human primate theory of mind suggests that monkeys and chimpanzees have a theory of mind that represents goal states and distinguishes between knowledge and ignorance of other agents (the presence and absence of contentful mental representations), even if it fails to account for misrepresentation (Call & Tomasello 2008; Kaminski et al. 2008; Martcorena et al. 2011). Although they may have a less articulated theory of mind than we do, we may nonetheless adequately characterize their representational system with mental-state terms (Butterfill & Apperly 2013; Martcorena et al. 2011).

What remains is the notion that the ability to attribute beliefs qua propositional attitudes to others is necessary for having beliefs. That is, not only must they attribute mental states to others, but those mental states must possess the characteristics of beliefs. Remember that we have already discounted the robust notion of belief as too demanding, so what is necessary is not that animals have a notion of false belief per se, but rather that they have a notion of a belief as a representational mental state that can play a role in behavioral explanation or prediction. So far there is no compelling evidence that nonhuman animals have this, consistent with the possibility that such a representational ability as this may indeed require language, or at least some sophisticated ability to symbolize abstractions and predicate them of objects. Whether this is so is ultimately an empirical question. However, at least some philosophers think monkeys may be able to do this. As Lurz characterizes the above studies, animals do have the ability to represent propositional mental states in others—not as attitudes

aimed at representing objective truth, but instead as attitudes with propositional contents that provide information regarding motivation to act (2011a). Lurz characterizes this as a kind of belief–desire attribution. Baillargeon’s data proves relevant here too, for her results are best explained by taking the infants in her study as postulating representational mental states of the actor in order to predict her behavior; violation of their expectation causes them to look longer. Thus, without imputing these infants some understanding of others’ representational mental states, we would be unable to account for this data. However, in this case M3 would then be false, for the linguistic abilities of fifteen-month-old infants typically are minimal—certainly not of the sophistication we would expect would be necessary to linguistically encode a belief-concept. While the evidence that bears on this case is perhaps the least well-established, and this study involves infants at an age when they are poised to develop language, the burden of proof is shifted to the person who wants to argue that language is necessary for a concept of belief. That burden is not discharged: Davidson lacks a positive argument for why this relatively demanding notion of attributing content to others is the one required for an organism to be a believer.

5 Beyond interpretationism

Davidson argues that language is required for thought. His Master Argument posits that having a concept of belief is a necessary intermediary for having propositional attitudes, and that language is necessary for having a concept of belief. Of the various conceptions of “concept of belief” that might play a role in Davidson’s argument, the robust conception is too strong, and empirically falsified. While the robust conception may require language, we attribute propositional attitudes before children are clearly in possession of such concepts. Davidson’s examples and arguments support only deflationary interpretations of the concept of belief and the associated concept of objective truth: those that involve distinguishing between appearance and reality, or those that involve attributing

mental content. However, as numerous studies in developmental and comparative psychology have shown, the deflationary conception is one that many creatures without language enjoy. Even an intermediate conception does not seem to play the role Davidson's argument requires, for the ability to attribute mental content does not require language, and neither does the ability to attribute to others representational mental states, though here the evidence is less clear. Davidson's arguments seem compelling because their plausibility relies upon a slide between less and more demanding conceptions of the concept of belief. For instance, a weak conception of "concept of belief" in [M2](#) and a robust one in [M3](#) yields an argument with apparently true premises, but because the argument equivocates on "concept of belief", the argument is invalid. This analysis, as well as an appreciation of the methodological considerations for using non-linguistic behavior as evidence of propositional attitudes, supports the view that some mental states of non-linguistic animals can aptly be classified as propositional attitudes.

In empirical circles it seems to be taken for granted that at least some non-linguistic animals have mental states best described as propositional attitudes. But this acceptance is merely the first step in a larger project. For example, even if there is good reason to think that non-linguistic creatures have propositional attitudes, how they could have these remains to be elucidated. That is, what is the nature of the representational resources available to them? And given these representational resources, what sorts of contents are they capable of representing? What kinds of reasoning and inference could such representations support? What are the cognitive limitations necessitated by their representational architectures? One can begin addressing these fascinating questions empirically either at the functional psychological level or at the level of representation, and from either level one can work toward answering questions about the other.

Instead of thinking that language itself is what makes complex, structured, or propositional thought possible, we should consider: 1) how non-linguistic capacities could underlie

complex representational abilities 2) the unique elements of linguistic competence and what they may or may not make possible vis-à-vis thought. In an example of the first, [Proust \(1999\)](#); see also [this collection](#)) provides an illuminating philosophical discussion of structured non-linguistic representational abilities (or "structured competences") and how they could make possible objective representations. Structured representations as such could form the building blocks of propositional attitudes. Bermúdez argues for abilities and for certain logical limitations on both the inferential and representational abilities of non-linguistic representers ([Bermúdez 2003](#)). Whether such limitations necessarily obtain is a matter of dispute ([Lurz 2007](#)).

When considering how linguistic abilities could augment thought, it is useful to identify elements of language that could contribute to representational complexity even if present without all the components of language. For example, [Clark](#) suggests that the human language-like ability to use symbols to represent abstract objects allows us to objectify our own thoughts and operate upon them ([2000](#)). Depending on what things can be symbolized, this could make possible metacognition or higher-order thought that might not otherwise be possible. Thus, the ability to represent symbolically can influence the kinds and complexity of reasoning available to a creature, even if that creature is not linguistic in Davidson's sense. Symbolic capacities are necessary but not sufficient for linguistic competence, and could be present even when language is not. And if mere use of symbols is taken to be sufficient for language, then some nonhuman primates are capable of language and thus again can have propositional attitudes. Indeed, it is clear that some nonhuman primates can be trained to use abstract symbols, even if they do not do so naturally. Boysen and colleagues, for example, relate how naïve chimps fail to learn to make second-order generalizations about object classification, but those trained to associate objects with symbols (for relations of "same" and "different") are able to succeed on a second-order classification task ([Thompson et al. 1997](#)). These interesting res-

ults give causal punch to the notion that symbolic objectification is a prerequisite for higher-level or abstract thought, and help to explain the competences that appear to come along with linguistic abilities.

Focusing less on the vehicles and more on the ways in which they can be exploited, Fitch and colleagues argue that recursion, which is a core element of natural language processing, can only operate on symbolic structures subject to rules, and that neither rules nor the objects on which they operate can exist without language-like representations (Hauser et al. 2002). If so, one might expect that forms of reasoning that rely on recursion may only be possible for creatures that also possess linguistic capacities. Thus, use of symbols and recursive rules are two candidates that could help explain the different representational capacities of linguistic and non-linguistic creatures.

6 Conclusion

Here I have argued that Davidson's arguments that nonlinguistic creatures lack thought are either unsound or invalid. While this negative project does not allow us to conclude that they have propositional attitudes or thoughts, it makes room for positive arguments that will take advantage of recent and future empirical work on animal cognition and on the nature of nonlinguistic representations and their role in cognitive processing, as well as for novel negative arguments that might set limits on the capacities of nonlinguistic creatures. Much current research in animal cognition focuses on whether animals have theory of mind paralleling that of humans (Martcorena et al. 2011), or metacognition (Bermúdez 2003; Carruthers 2008; Lurz 2007, 2011a, 2011b; Proust 2010). One might therefore think that the debate has not progressed much since Davidson asked the question about whether animals can have a concept of belief. But Davidson's interest in these questions was narrow, driven by his interpretationism and the view that these states are necessary for being an interpreter and thus for possessing mental content. In contrast, contemporary research does not aim to disprove the existence of

propositional attitudes, but rather to elucidate the scope of these attitudes and understanding the ways in which they may be limited by limitations in representational resources. In the most exciting work, the philosophical and psychological projects come together. This interdisciplinary approach takes seriously evolutionary relationships and has a more nuanced view of the human being's place among other animals. The arguments that result will be of great interest to philosophers of language and mind, as well as to those interested in ethical issues that transcend academia. And while they may vindicate a certain kind of human exceptionalism, they may also articulate our place on a spectrum that will ultimately lead to a more integrated and humane picture of our place in the world.

Crediting Animals with the Ability to Think: On the Role of Language in Cognition

A Commentary on Adina Roskies

Ulrike Pompe-Alama

Davidson's argument for the claim that animals cannot be credited with beliefs rests on the assumption that possessing beliefs—as propositional attitudes—pre-supposes the possession of language. Based on Roskies' reconstruction of Davidson's argument, I want to discuss the implications of overemphasizing the role of language in thinking. I will offer a (tentative) explanation as to why this overemphasis occurs, namely due to a preoccupation with the way we experience ourselves while thinking or "having thoughts"; I further attempt to defend why a bottom-up strategy for the investigation of thought-invoking mechanisms might be a more promising way to study thought and the role of language therein.

1 Introduction

What are the defining differences between human and animal cognizers? This concern has driven philosophers and scientists for a long time,¹ well before [Darwin's \(1871\)](#) theory of evolution and its inherent claim of developmental continuity between the species. The prevailing intuition has been, and often still is, that

even though we stand in a direct developmental line with other mammals in a physiological sense, our cognitive and affective abilities far exceed theirs, not only in a quantitative, but also in a qualitative sense. Criteria to support this notion are frequently sought in an array of special cognitive abilities, such as the ability to speak (e.g., [Savage-Rumbaugh et al. 1985](#)), the

¹ See for example, Aristotle's *De anima*.

possession of concepts (e.g., Newen & Bartels 2007), or behavioral traits like altruism or cooperation (Hamann et al. 2011; Warneken 2013; Warneken & Tomasello 2009). All of these are to varying degrees attributed to humans, but are either to a much lesser degree or not at all ascribed to animals, thus representing the cornerstones of the critical divide between “us” and “them” (Hare 2007). The problem raised by Davidson and discussed by Roskies concerns the special case of beliefs and the general case of the attribution of propositional attitudes to nonlinguistic creatures.

According to Davidson, it is only in the domain of human cognition that we can sensibly apply the notion of thinking. His reasons for holding this conviction are manifold, as Roskies uncovers beautifully in her treatment of Davidson. The general line of argument will be sketched out and discussed below. Roskies refutes Davidson’s arguments mainly on empirical grounds, with the aim of establishing that nonlinguistic animals can be cognitive agents with beliefs and mental representations, which function as kinds of propositional attitudes. In this commentary, I would like to complement this line of reasoning by questioning what it takes to credit human cognizers with thoughts; or rather, what we consider to be the prerequisites for attributing thoughts and beliefs to humans. Davidson puts much weight on the possession of language. Here, I want to argue that focusing on language as a necessary cognitive instrument for being able to think poses a methodological barrier for examining what the human ability to think actually amounts to. Stressing the point that the introspectively experienced properties of thinking, a term that requires careful consideration in itself, should not be identified with and reduced to experiencing inner speech, I want to show that our understanding of what thought is needs to be complemented by a bottom-up investigation into the neural processes and mechanisms that produce higher cognitive states, such as thoughts. I argue, therefore, that our introspective access to the way thinking presents itself to us as thinkers is only one part that needs to be considered. What is required in order to understand the phenomenon of think-

ing is first a suitable conceptual framework of the notions “thought” and “thinking”, which distinguishes between their intentional and phenomenological aspects, i.e., between the content of propositional attitudes and the phenomenal states of subjects making use of these attitudes. Second, we need to show how the sub-personal and personal levels of these factors can be distinguished from each other in order to show if and how they are interconnected. These considerations will be discussed in detail after a review of Roskies’s discussion of Davidson’s account of language and belief.

2 Roskies’ reconstruction of Davidson

What Roskies dubbed Davidson’s Master Argument is a reconstruction of Davidson’s position, capturing in a nutshell both his basic assumptions about how we understand others and the background to his claims about human cognition. As Roskies puts it:

According to Davidson’s interpretationism, having beliefs entails being an interpreter. The basic idea of the Master Argument is that possessing certain concepts is a prerequisite for being an interpreter, and that an organism must have language in order to have these concepts. [...] the Master Argument links thought to language by way of higher order thoughts. Specifically, Davidson suggests that a concept of *belief* is a prerequisite for propositional attitudes, and that a concept of belief is unavailable without language. ([this collection](#), pp. 6–7)

According to Roskies, then, Davidson is forced to endorse the view that a cognizer must know what beliefs are in order to have them. Can Davidson’s view be sound? It might be correct to claim that a cognizer must possess the concept of belief to recognize *herself* as having them or to be able to attribute such a state to herself. This seems to be an act of metacognition, in which a subject scrutinizes her own mental states and recognizes them as mental states of a special kind. But is having the concept of belief necessary for first-order cognit-

ive acts, i.e., simply believing a proposition of some kind without reifying this state *as* a belief state?

Before delving into this line of thought, let us review Roskies' structural reconstruction of Davidson's Argument.

M1 If S has propositional attitudes, then S has beliefs.

M2 If S has beliefs, then S has a concept of belief.

M3 If S has a concept of belief, then S has language.

MC If S has propositional attitudes, then S has language.

M1 seems to be correct, if a belief is seen as a paradigmatic kind of propositional attitude.

M2 is a critical premise of Davidson's Master Argument, as we have already indicated above. The question in play here is: does having a belief automatically entail the possession of the concept of belief? We will discuss this point once again further below.

M3 is refuted by Roskies with the help of studies on false belief comprehension in prelinguistic infants (e.g., Onishi & Baillargeon 2005). However, a further point might be made here: M3 might indeed hold if having any concept at all implies the possession of language. However, there are models of non- and pre-linguistic concept possession (cf. Mandler 2004; Newen & Bartels 2007), which allow us to explain concept acquisition during development; theories presupposing language as necessary prerequisite for the possession of concepts, however, fail to do so.

Roskies' main criticism targets the notion of the "concept of belief". She aims to show that Davidson employs the concept of belief inconsistently throughout his argument. If this is so, then the argument fails due to equivocation.

According to Roskies, Davidson's conception of belief can be understood in three ways. She distinguishes three kinds of conceptions of belief: "on this robust view, having a concept of belief is an epistemologically-rich notion that entails having an ability to pass the 'false belief

test'" (this collection, p. 7); the so-called deflationary conception, in which "belief can come apart from reality", (ibid.) and which amounts to "having the concept of an objective reality"; and last, the so-called intermediate concept of belief, which "involves the ability to attribute representational mental states to oneself and others", (ibid.). The intermediate concept of belief, as its name implies, is intended to be a weaker notion than the robust one. In the remainder of the paper, Roskies deconstructs each reading, providing empirical examples with the aim of showing why and how Davidson fails to make his decisive point, namely, that language is a necessary prerequisite for holding beliefs.

The robust conception of belief is convincingly refuted by studies on the ability to understand counterfactual beliefs in others, as demonstrated by the so-called false belief test. Children only display the possession of a concept of belief when they pass the false belief test, usually at around the age of three to four years.² It is implausible, though, not to ascribe propositional attitudes to them (in a first-order sense) prior to having acquired such a robust notion of belief. It can even be claimed that they need the ability to ascribe propositional attitudes to develop a robust notion of belief in the first place. Thus, the robust conception of belief is not linked to having propositional attitudes and Davidson's premise M2 fails, if belief is understood in the robust sense.

The second reading of belief, the deflationary view, can be read out of Davidson's stance on so-called triangulation³ as a means of understanding objects as part of a reality external to us—via linguistic interaction with another person. However, as Roskies rightly states, the ar-

² See however, Apperly & Butterfill (2009) and Butterfill & Apperly (2013).

³ The notion of *triangulation* that appears in Davidson's later works, replacing the notion of the so-called *omniscient interpreter*, captures the idea that we can only attribute mental (propositional) attitudes to others by interpreting their utterances. In both instances, we identify contents: the content of the utterance as well as the content of the underlying mental attitude. This is, according to Davidson, a necessary unit: without an utterance, we cannot ascribe determinate propositional attitudes, which is why Davidson is committed to the view that non-linguistic creatures cannot be interpreted, at least not in a way that allows for the ascription of thoughts. This does not imply that Davidson has to negate mental states in animals, but it does mean that we cannot understand these mental states. The issue of interpretability will be raised below (see issue #3).

gumentative force of forging the link between language as a means of recognizing the external as external, making it thus objective, is quite weak. Further, it would strike us a bit of an overreach, if not as absurd, to assume that non-linguistic creatures cannot develop any sense of the external world as being external to them.

The third and final understanding of belief à la Roskies, the so-called intermediate view, stating that animals understand other animals as having mental representations of some sort, which are behaviorally relevant, rests on empirically undecided ground; here, however, the tight connection between having beliefs and possessing the concept of belief is called into question.

Having a concept of belief might be important for reflective capacities, as we want to attribute them to rational agents that must be capable of justifying their actions, but not important for having beliefs:

perhaps being a believer requires being able to think of oneself as a believer, and thus requires the concept of belief. [...] However, while there are arguments that the ability to think about oneself as a believer is required for a rich construal of theoretical rationality (see Bermúdez 2003, Ch. 7), there is no clear argument why such reflective ability should be constitutive of having beliefs. (Roskies [this collection](#), p. 11)

Roskies has thus shown that the connection between propositional attitudes and the possession of a concept of belief (and its dependence on language possession), which Davidson tries to establish, cannot be held in light of the diverging readings of the notion of the concept of belief. Thus, Davidson's strategy fails.

3 Beyond animal cognition: The case of understanding human thought

Davidson's standpoint, from which his thesis makes sense and is plausible, begins from his assumption that "radically different representation schemes" (Roskies [this collection](#), p. 2) gov-

ern in animals and humans.⁴ However, such an assumption clearly opens up a plethora of new issues. Roskies targets these by drawing attention to the empirical concerns mentioned above, thereby showing that an empirical foundation to support Davidson's background assumption is missing.

To my mind, these further issues resulting from Davidson's background assumption are the following:

1) How can we defend the intuition that animal and human cognition differ in kind? In order to defend this view, it would seem that one needs to identify a distinguishing criterion that can account for the diverging representation schemes. It also has to be shown that this factor is responsible for abilities that one group of cognizers has and that is at the same time missing in the other group. If language possession were to count as such a factor, it remains to be shown which abilities hinge on its possession and execution. At the same time, following this approach, it apparently needs to be established that no non-linguistic creature cannot execute a similar ability, not even in a partial or proto-form. This difficulty leads us to issue 2:

2) How can we understand representation schemes in animals if we do not suppose a kinship to our own cognition? As Roskies rightly states, we cannot but credit animals with numerous cognitive abilities, given their at times complex and often obviously intelligent behavior. Interpreting this behavior without acknowledging any dependence on sensory states, memory, and certain motor skills, affects, and even social competencies, seems impossible. The representation schemes employed crucially depend on physiological implementation. If the physiological basis for the acquisition of environmental information is alike in humans and

⁴ The reason why Davidson is committed to this view can be derived from the triangulation argument: since animals do not possess language, we cannot attribute determinate propositional attitudes to them. We have thus no way of knowing how they represent the world, since this is not graspable to us through our usual means of interpretation. The question, however, is whether this epistemic opacity with regard to animal cognition necessarily entails the ontological statement that their representation schema are in fact different from ours, if representation schema are seen to comprise sensory and affective states as well, and perhaps even doxastic states preceding properly expressed, i.e., propositionally coined, beliefs.

animals, how different can the representation of environmental information in terms of sensory and affective representations be? Even if a complete overlap between human and animal perception cannot be argued for on the basis of isomorphisms, we can (and perhaps must) commit ourselves to the systematicity of behavioral cause-and-effect relations. It is this systematicity that leaves little room for interpreting animal cognition (at least in the sensory and affective domain) as being radically different from ours.

3) In light of Davidson's interpretationism, how much weight does language possession carry in terms of our ability to interpret other cognitive agents? When we think of how we "make sense" of another person, we rarely rely exclusively on the other's verbal utterances. Rather, it would seem that we generally seek to compare the contents of their verbal utterances with their overt behavior; we hold another responsible, as a rational agent, if her expressed intentions diverge "too much" from her behavior. Think of the following case: your neighbor tells you about his plans to save some money for the upcoming summer vacation; the next day you see him walk into the local casino where you know he spends quite some time—and usually loses a fair amount of money. In this case, we would probably be inclined to disregard the verbal utterance ("I'm saving up for a nice summer vacation overseas"), and rather take his actions (which might involve compulsion or gambling addiction) as indicators of his real motivations and driving forces.

4) Considering this case, we can ask which role the analysis of another's beliefs play in interpreting and whether verbal utterances are a true mirror of internal thought mechanisms and proper beliefs.

5) To my mind, the most salient question is whether we can understand human cognition, especially thought, with the help of notions like beliefs (regardless of whether they are faithfully uttered or not) and their conveyance via language. Since the discussion of this issue will require some space, I shall dedicate a proper section to it below.

3.1 Experiencing oneself while thinking—the bias towards language

We can understand why Davidson (and with him many others)⁵ posits the possession of language as a necessary condition for having propositional attitudes. Namely, one may come to the view that the way a human cognizer experiences her thoughts is predominantly conveyed by her sense of inner speech.⁶ Consider for a moment what it feels like to think.⁷

Probably the most prominent, identifiable feeling related to thinking is that of your inner voice, commenting on the world around you and the world inside you, making you feel distinct from, yet embedded within it. Let's call this phenomenon—if you can follow me here—the inner-speech view⁸ with regard to thinking. I will argue that this view is misleading. Our intuitive description of what the inner-speech view comes down to is intricately linked to our ability to express the contents of our thoughts in words—the form of thoughts are, presumably, sentences that are composed of concepts and words, in our minds.

But is this identification of thought with mental speech justified? For [Vygotsky \(1934/1987\)](#), it is clear that there are large parts of thinking that do not rely on verbal expression: "There is a large range of thinking that has no direct relationship to verbal thinking" ([Vygotsky 1934/1987](#), p. 115). Such a view

⁵ In fact, my point is here not to claim that this is Davidson's motivation proper, but that we, as philosophers, can easily fall for the language-bias, language being not only the instrument but also most often the object of our trade.

⁶ One might object that Davidson's focus on language is a result of his roots in British analytic philosophy. While that is certainly true, it remains to be seen where the preoccupation with language as a "window" into the workings of the mind is derived from within this tradition; I have a hunch that the inner-speech bias I sketch plays a role here as well.

⁷ It is debated whether there is a special (that is, a unique, proprietary and distinctive) phenomenology of thinking (cf. [Bayne & Montague 2011](#)). I suspect, however, that this debate suffers from a lack of distinction between the contents (or intentional aspects) of thought and the phenomenal aspects of consciousness. The point I wish to make is that the characterization of thought we gain through introspective observation of ourselves while thinking does not grant insight into the processes that precede and produce thoughts – and this point is neutral with respect to the question whether there actually is such a thing as a distinct phenomenology of cognition.

⁸ See, for example: [Vygotsky \(1934/1978\)](#); [Watson \(1920\)](#); [Carruthers \(2002\)](#). Inner speech in Vygotsky's view means the overlap (so to speak) of our faculty of thought and our faculty of speech (cf. [Jones & Fernyhough 2006](#)).

thus allows for other, non-verbal types of thought, such as pictorial or imagistic ones, such as come to bear, for example, in mental-rotation tasks or mental imagery (Shepard & Metzler 1971; Weiskrantz 1988; Kosslyn et al. 2006).

If these instances can be found, and identified as kinds of thinking, the hypothesis that language is the one and only tool for producing thoughts in us seems simply false. That thought is exclusively verbal appears thus as a form of theory-induced illusion. One might say that the fixation on language prompted by the analytic tradition has thus resulted in the projection of the method (the analysis of language) onto the phenomenon (the human mind).

Contemporary philosophy of mind left the method of linguistic analysis behind some time ago, and in order to get away from the language-bias we should shift our focus from the surface structure of thinking, namely its intentional and phenomenological (inner-speech) characteristics, to the sub-personal level of the underlying mechanisms and production schemes of thinking.

Such a reductive approach is already in place in the numerous research efforts in cognitive science that aim at describing and explaining information processing in the brain: sensory and affective components of cognition, as well as aspects of motor behavior and memory are studied in a very promising way—in the animal as well as the human domain. The problem is that our faculty of “thinking” is in this research program a rather elusive phenomenon, for various reasons: unlike when studying the neural basis of perception, for example, thought processes cannot be studied on a cellular level, since the identification of a stimulus is virtually impossible: in vision, a stimulus is light hitting the retina, whereas the “stuff” of thought is information provided by the stimulus-processing areas, thus, an “inner-system” medium. Localizing brain areas involved in thought and thinking, on the other hand, is possible. The prefrontal cortex has been shown to be involved in planning future actions and other high-level cognitive tasks (Goldman-Rakic 1996; Fuster 2008); however, this structure is strongly con-

nected to a wide network of other cortical areas and imaging studies show that high-level cognitive tasks often if not always result from correlated activity in multiple areas across the whole of the cortex (Fuster 2008) which makes the individuation of the “center of thought” rather difficult.

In light of these complications, it is helpful to highlight the function that higher-cognitive abilities have with regard to our overall behavior. Most researchers and philosophers would agree that what this involves is the conscious representation of objects, including the deliberate manipulation of information, retrieved from memory as well as from present and actual stimuli, for the purpose of problem solving, decision making, social interaction, communication, and action planning. The involvement of language-processing areas in the execution of these tasks has already been shown (see e.g., Goel et al. 2000)—but does this suffice to support the claim that language is a necessary cornerstone of the neural basis of higher-level cognition in humans?

When “thinking” is divided and described in terms of its functional rather than phenomenal properties, the question of how far thinking relies on our capacity to speak or use language can be replaced by the question of which brain areas and input-output relations we find involved in the faculties mentioned above. This program requires a reorientation in terms of research methods and a redefinition of the phenomenon: the phenomenological description of “thinking”, e.g., in terms of inner speech, does not supply us with an understanding of its underlying processes and mechanisms. It is these, however, that we should know first before we can put our finger on the role that language (the inner and external version alike) plays in the execution and the production of the cognitive capacities listed above.

When we cannot help but attribute the ability to manipulate information in a creative way to animals and intuitively call this “thinking” (think of the Kea, a species of bird known for its curiosity and astonishing abilities in handling difficult mechanisms—they can virtually break into a safe; cf. Auersperg et al. 2009;

Huber & Gajdon 2006; Werdenich & Huber 2006) we seem to have found a satisfactory criterion for crediting animals with a form of demanding cognition, not unlike our own, even though we cannot claim to understand what it feels like or how the world represent itself to the Kea.

Such a language-independent form of high-level cognition might rule in us as well, such that it precedes the formation of beliefs we form on states of the world and their linguistic representation. It might be the case, and this is the point I want to stress in this commentary, that we fall in a systematic way for a fallacy of experienced thinking, which presents us with a linguistic representation of the contents of thought, whereas the mechanisms producing these thoughts may not rely and are not caused by speech and language involving neural mechanisms.

One can object that this is not what Davidson had in mind when he claimed that thought depends on language. Davidson's idea rests (so goes the defense) upon the assumption that language is a universal format of information processing unique to humans (in the first place) and an instance of cognition, which lies at the core of human cognition, regardless of its temporal and causal involvement in the production of thoughts. But this—so I want to claim—amounts to a phenomenological argument, even if Davidson presents it as a theoretical one. So even if language were the universal format of human thought, the empirical basis for such a claim would be quite opaque, and any theoretical argument so far rests on this weak empirical basis.

4 Conclusion

The question of whether thought is exclusively verbal or linked to language capacity is not answerable from a phenomenological point of view, since we can think of instances of mental symbol-use that do not rely on language; on the contrary, we know that language “fills in the void”, so to speak: when we acquire language, it fulfills the cognitive demands to express references and relations among them. In this view,

thought and thinking precede the linguistic representation of the involved concepts.

If one wants to follow this line of thought, it remains to be shown how the Davidsonian *dictum* that animals do not have a special form of cognitive ability, namely, propositional attitudes such as beliefs, desires etc., relates to the general argument on higher-cognitive faculties, which do not depend on language possession and which are of the same kind across the animal and human realms. It would thus have to be argued for a language-independent form of propositional attitudes.

Does the inner-speech bias bear not only on thinking at large but also our self-attribution of desires and beliefs? It might. Roskies rightly raises the question, contra Davidson, of whether all our beliefs have definite content ([this collection](#), p. 6). In my view, as soon as we hold a belief *qua* belief, some kind of cognitive meta-representation must come into play. Such a form of meta-representation strikes me as probably being conveyed by the inner speech mechanism and as thus being subject to the phenomenological inner-speech fallacy.

Roskies nicely disassembles Davidson's arguments and reconstructs them in a clear and easy-to-follow fashion. She exposes their argumentative weaknesses (such as the issue of interpretation and behavior) and provides ample empirical examples of, and conceptual arguments for, why we should not follow Davidson in his assessment of animals' cognitive abilities. However, I have tried to show that a further underlying claim can be made, namely that not only is animal cognition a matter of speculation, but that even our own inner workings are less transparent than we commonly like to assume. Davidson's claim rests, to my mind, on the rashly embraced yet unfounded assumption that language plays a key role in higher cognition in humans (1984, 2001). In my view, contemporary research efforts in the cognitive sciences, but also in philosophy, undermines—or at least calls into question—this assumption. Certainly we are dealing with an important philosophical claim, which could only be properly backed up by extensive empirical evidence pointing to the ubiquitous involvement of language-processing

brain areas and mechanisms in higher-level cognitive tasks such as decision-making, action planning, deliberation, etc. Doubtless, human cognition benefits from the linguistic format; abstract thoughts about, e.g., liberty can probably only be executed at a significantly deep level if the relevant concepts have been provided by a linguistic community. But the need to express a certain feeling, like freedom as the opposite of (the feeling of) constraint, for example, certainly originates in a pre-verbal or non-verbal manifestation of this feeling.

Focusing on language, therefore, blocks a fuller examination of what thinking in humans amounts to. We have, I believe, misled ourselves in the face of the phenomenology of inner speech as to what it is like to think, for us as humans. But this gets us only part way towards a full understanding of the underlying mechanisms, structures, and sources of thoughts.

Thought, Language, and Inner Speech

A Reply to Ulrike Pompe-Alama

Adina Roskies

Pompe-Alama's commentary raises interesting issues regarding the nature of thought and its relation to language. She underlines the evolutionary relationship we have to other animals and results from cognitive science to argue that human thought is probably not fundamentally linguistic, and notes that the pull of the phenomenal experience of inner speech may mislead us into thinking it is. While I agree with these claims, I disagree that Davidson's own arguments are predicated on an inner speech view, and raise problems for the idea that functional imaging will easily resolve the debate about the relation of thought and language.

1 Introduction

I largely concur with Pompe-Alama's commentary on my contribution to this collection. She nicely summarizes my arguments against what I call Davidson's "Master Argument," an argument that he levies against the possibility of propositional attitudes for nonlinguistic animals. As Pompe-Alama notes, aside from conceptual clarifications, my arguments are largely empirical. As such, the strength of my arguments depends on the solidity of the empirical facts they are based upon. But provisionally, since all the logically valid reconstructions of Davidson's arguments have what look to be em-

pirically false premises, none serves to establish the impossibility of animal thought.

Pompe-Alama then offers an interesting discussion of the Davidsonian claim that nonlinguistic animals cannot have propositional attitudes. She locates the source of the dispute at the phenomenological level, citing the phenomenology of thought as "inner speech", and suggests that it is this that leads Davidson, and us, to mistakenly think that thinking is fundamentally a language-dependent phenomenon. While I disagree that this is the source of Davidson's perspective, I appreciate Pompe-Alama's

discussion of some important practical consequences of the Davidsonian view, or any view that posits human thought processes to be qualitatively different than those of all other animals. In her discussion, Pompe-Alama tells us that contemporary cognitive science indicates that Davidson is wrong, and suggests that our own understanding of our own thought processes may be adversely influenced by our introspective recognition of our thoughts as embodied in inner speech. She cautions that too much attention to the phenomenological or introspective sense of inner speech can prevent us from exploring the representational aspects and physiological bases of thought that we share with other animals, and moreover, she suggests that taking language to be a necessary prerequisite for thinking poses a barrier to understanding human thought as well. As a remedy, she suggests that we discount the phenomenal aspects of thinking and instead focus on a reductive strategy for exploring the neural basis of human and animal thought in a bottom-up fashion.

2 Inner speech

Pompe-Alama calls attention to the “feeling of what it is like to think”, which she identifies as the experience of our thoughts as inner speech. There is of course debate about whether it feels like anything at all to think. However, regardless of whether our recognition of inner speech is a feeling or a cognitive introspective conclusion, this phenomenon certainly plays a role in the general tendency to and perhaps our willingness to identify thought with language. But Pompe-Alama’s easy identification of the phenomenology of inner speech with Davidson’s denial of animal thought threatens to trivialize what I take to be a fairly sophisticated, if incorrect, view about the nature of animal thought. Davidson’s interpretationism is the root of his denial, and his target is specifically propositional thoughts and related attitudes, not cognitive processing more generally. Pompe-Alama cites Vygotsky’s claim that lots of thought is not verbal thought, and she suggests that pictorial or imagistic thought should be possible

for non-linguistic creatures. I don’t suppose Davidson would refuse to recognize that animals have complex representations and even some relatively high-level cognitive capacities. But he would deny that these forms of thought had propositional contents. So the real question at issue is whether the representational power afforded by representations in nonlinguistic animals allows them to represent propositions.

That said, Pompe-Alama’s claim that the restriction of thought to verbal vehicles may be a “theory-induced illusion” is well taken. The tendency to think that only language-like formulations allow propositional content to be captured or delineated seems ungrounded, especially since philosophy has supplied us with non-linguistic means of representing propositions (Stalnaker 1987), or alternatives to propositional attitudes (Churchland 1992). Undoubtedly, propositional content requires some kind of framework that permits complex structural relationships between representations, but there is no a priori reason to think that such structure can only be achieved with linguistic implementation. Pompe-Alama is correct to point out that in our own interpretation of others, we often privilege behavior over self-report, and much social science has suggested that words, and indeed even one’s own introspective thoughts, are not a reliable window into higher cognitive processes. She also mentions that our own interpretational skills, applied to animals, yields attributions of cognitive processes that are in many ways akin to our own. Indeed, we easily attribute to them propositional attitudes. These observations put pressure on Davidson’s view, and raise the question of what our own propositional attitudes may endow us with, cognitively speaking, that the presumptively propositional-attitudeless animals are missing, if in fact he turns out to be right.

Pompe-Alama doubts whether language really plays a key role in human higher cognitive functions. We know it certainly does in one of them: Linguistic cognition. Whether it plays a fundamental role in other aspects of higher cognition is yet unknown. Davidson himself is not clear about whether he thinks language is necessary as a vehicle for thought. This distin-

guishes him from Fodor, who also thinks language is central to thought, but posits a mental language to serve as the vehicle of thought, and that is available to linguistic and non-linguistic creatures alike. Davidson's view is more subtle, and seems to depend more on social/interpersonal factors and abilities or dispositions than on vehicles per se. Thus, for Davidson, the fact that we can identify instances of non-linguistic symbol use in high-level thought is not telling, since it is the fact that we are language-using creatures that is of prime importance. It is within Davidson's purview to claim that our mastery of language makes possible thoughts that rely on non-linguistic (yet symbolic) properties.

3 Methodological difficulties

Pompe-Alama suggests that to lessen the grip of the illusion, we must pay attention to the low level realization of our thoughts. That is of course a goal of many cognitive neuroscientists, but as Pompe-Alama well recognizes, it is a difficult one to achieve. Unlike perception and action, both which can be correlated with measurable external phenomena (perception with the stimuli occurring in the external world; action with elicited motor activity), thoughts are seemingly spontaneous, and largely uncoupled from immediate environmental stimulation and control. The unpredictability of the content and occurrence of our thoughts, together with the fact that we have no idea how they are realized in neural activity (and thus which aspects of the remarkably complex signals we can record from the brain are relevant), has the consequence that thoughts promise to be extremely difficult to measure scientifically. What exactly are we supposed to look for in signals from neural tissue that is supposed to correspond to propositional thoughts as opposed to other (non-propositional) forms of mental representation? Unless we discover some means of answering this question, it will be difficult to determine empirically whether other animals have the capacity for propositional thought or not.

Taking a reductive approach, [Pompe-Alama](#) says "the question of how far thinking

relies on our capacity to speak or use language can be replaced by the question of which brain areas and input-output relations we find involved in the faculties mentioned above" ([this collection](#), p. 6). She suggests that the progress we have made in understanding the neural basis of language processing could help us resolve the debate about whether human and nonhuman cognitive processes are fundamentally different. Work in cognitive science has shown that a network of brain areas seem consistently linked with processing of natural language. Pompe-Alama suggests that we could approach the question of whether human thought is primarily linguistic by determining with functional imaging whether these areas are consistently active during human propositional thought. This will not be determinative, for reasons I sketch here. Most importantly, even if we do see activity in these areas, it will not serve to answer the question of whether human thought is fundamentally linguistically-based. Suppose phenomenal inner speech typically accompanies our thought, and it is dependent on activity in these areas. This may be because our thoughts are fundamentally linguistic, but it could also be merely a causal consequence of the deeper thought processes, without constituting them or being a necessary component of them at all. Thus, if we consistently saw activity in language-relevant areas, it might not be reflective of the fundamental nature of our thought. Suppose, on the other hand, that we failed to see such activation (and suppose we knew that inner speech was dependent on activation of language areas). This could be due to the low signal-to-noise ratio of the methods, or to the fact that language pervades brain representation and is not restricted to the areas that we typically see "light-up" in a language task, or it could indicate the non-linguistic nature of thought. In this domain, negative results are not decisive. Thus, the question of whether language centers are always active during human propositional thought will not resolve the issue.

That said, significant progress is being made in understanding at least some aspects of the representational coding of thought contents. The object perception literature demonstrates

that cognitive neuroscience has achieved much in the last few years, due to work with both noninvasive fMRI in humans and invasive recording in humans and nonhuman primates. In particular, we have gained much greater insight into the representational coding of faces, with access to regional information about coding of representational aspects of face identity, similarity, expression, and so on (see e.g., [Haxby et al. 2014](#), and [Freiwald & Tsao 2011](#)). Other work suggests that the visual cortex represents semantic features in the form of a cortical map ([Huth et al. 2012](#)). Although this kind of work is in its infancy, novel analytical and modeling techniques promise to continue to yield a deeper understanding of how our brains represent semantic properties. An important result stemming from this kind of research is evidence of the extensive homologies between neural processes of visual representation in humans and nonhuman primates ([Sha et al. in press](#); [Kiani et al. 2007](#)). These homologies seem to extend in large part to complex cognitive processes such as decision-making ([Gold & Shadlen 2007](#)). At the neural level, we have no evidence of qualitative differences in neurological processing between humans and nonhuman primates, nor evidence that we and they possess radically different representational frameworks. Nonetheless, none of the work mentioned explicitly targets propositional contents, and very little extant work has looked at the combinatorial or structural properties of these mental representations. In my own view, answers to these difficult questions will not come from bottom-up approaches alone or even in large part. Only a high-level theory of brain function is likely to make real headway on this issue. It will be interesting to see whether new work in predictive coding (see [Clark this collection](#); [Hohwy this collection](#); [Seth this collection](#)) allows for new ways of approaching these fundamental questions.

4 Conclusion

Pompe-Alama seems to argue that Davidson's argument about the impossibility of animal thought is at base an argument based on the phenomenology of thought as inner-speech. I

don't see this. His is an argument about the process of interpretation, and the interpersonal nature of objective thought. While I disagree with Davidson's arguments, and in particular with the view that animals cannot have propositional attitudes, I am nonetheless sympathetic to the possibility that the ability to use language makes possible cognitive feats that are unavailable to nonlinguistic creatures (see e.g., [Roskies 2015](#)). These may only be quantitative differences, allowing us to represent contents that nonlinguistic creatures cannot represent, or they may be more qualitative leaps, such as giving us metarepresentational abilities that make possible culture, cross-generational learning, and science. Thus, whether Davidson is right or wrong, we are still left with the fascinating question: What does language or linguistic competence allow us to do that we otherwise couldn't do?

Bridging the Objective/Subjective Divide

Towards a Meta-Perspective of Science and Experience

Jonathan Schooler

In this paper I use the thesis that perspective shifting can fundamentally alter how we evaluate evidence as the backdrop for exploring the perennial challenge of bridging the divide between the subjective first-person perspective of experience, and the objective third-person perspective of science. I begin by suggesting that reversible images provide a metaphor for conceptualizing how the very same situation can be understood from two very different perspectives that appear to produce seemingly irreconcilable accounts of their contents. However, when one recognizes that both views are different vantages on some deeper structure, a meta-perspective can emerge that potentially offers a vantage by which the opposing perspectives can be reconciled. Building on this notion of a meta-perspective, I outline a framework for conceptualizing how science can draw on individuals' first-person experience in order to explicate those experiences within the necessarily third-person perspective of science. I then show how this approach can illuminate one of the most private yet ubiquitous aspects of mental life: mind-wandering. Finally and most speculatively, I attempt to tackle the enduring ontological tensions that emerge from the disparities between the first- versus third-person perspectives. Specifically, I suggest that the present prevailing third-person perspective of material reductionism fails to adequately account for the first-person experience of subjectivity, the flow of time, and the present. While I argue that these differences are an intrinsic property of each perspective, and thus irreconcilable from the vantage of either, I raise the possibility of a meta-perspective in which these clashes might be better accommodated. Toward this end, I speculatively suggest that experience, the flow of time, and the unique quality of "now" might be accommodated by the postulation of a subjective dimension or dimensions of time.

1 Introduction

I am the proud owner of a philosopher's stone. Although it does not hold any of the mysterious powers (e.g., turning lead to gold, providing endless youth) that the alchemists attributed to its namesake, I nevertheless feel its title fitting, as it offers some rather deep insights into the importance of perspective in defining what seems true. What distinguishes my stone from

an ordinary river rock is that it has engraved upon it the statement "Nothing is written in stone." In pondering its irony, I've come to realize that my philosopher's stone can be viewed in at least three ways, each leading to a different accounting of its merit. From one vantage the statement on the stone is self-evidently false, as clearly revealed by where it is carved.

From another it is demonstrably true, as the word “nothing” is written in stone right there. Finally, the fact that the presentation of the stone’s message simultaneously reveals it to be both true and not true enables the stone to clarify the paradoxical essence of its meaning. Nothing is definitive because a change in perspective may shift what is seen as factual. However, the stone further illustrates that when one recognizes how the perspectives that one takes influence the conclusions that one draws, one gains a larger meta-perspective that can accommodate them both.

Figure 1: From one perspective, as evident from the place onto which it is carved, “Nothing is Written in Stone” is a contradictory statement. However, from another perspective, “Nothing” is in fact written in stone, making the statement true. Thus, “Nothing is Written in Stone” illustrates that when one recognizes how the perspectives that one takes influence the conclusions that one draws, one gains a larger meta-perspective that can accommodate them both.

Although it is relatively straightforward to describe the manner in which my philosopher’s stone conveys how shifting perspective can alter what is seen as true, such descriptions do not do justice to the impact the stone has when one actually encounters it. The stone not only conveys its message, it embodies it. Its message thus speaks not only to one’s capacities of logic but also viscerally, physically, through one’s senses. Indeed this difference between the third-person *account* of something and the first-person *experience* of it is perhaps the ultimate ex-

ample of the manner in which perspective can alter how we understand the world.

In this paper I attempt to nudge the field towards a rapprochement between the subjective first-person perspective of experience and the objective third-person perspective of science. My efforts are divided into three somewhat distinct sections; all united by the goal of illustrating how the divide between the subjective and objective might begin to be bridged by a broader perspective that acknowledges that while neither can be reduced to the other, they may be alternative vantages of a larger meta-perspective.

In the [first](#) section, I use the analogy of reversible images to emphasize the importance of perspective shifting in recognizing that views that seem one way from one perspective may seem quite different from another. However, when one recognizes that both views are different vantages on some deeper structure, a meta-perspective can emerge that potentially offers a vantage by which the opposing perspectives can be reconciled. I propose that the relationship between the first-person perspective of subjective experience and the third-person perspective of objective science can be conceptualized in this manner, and that at least some of the heated debate between scholars on this topic may stem from their exclusively favoring one vantage over the other.

In the [second](#) section, I illustrate how the third-person perspective of science can both draw on and elucidate first-person experiences, and in particular the ubiquitous internal state of mind-wandering. I argue that although people’s self-reports of private internal experiences such as mind-wandering necessarily rely on a re-representation of the experience to themselves (meta-awareness), we can nevertheless draw inferences about their underlying experience by examining the relationship between self-reports and physiological and behavioral measures. Triangulation between these measures has highlighted both the strengths and limitations of people’s meta-awareness of their drifting minds: although people frequently fail to notice that their minds are wandering, when queried they are quite accurate at reporting whether

or not their minds were on task. This analysis thus reveals the value of using empirical third-person science to clarify the nature of first-person experience.

In the [final](#) section I consider how first-person experience may inform our understanding of objective reality. Current views of science offer no way of accounting for the existence of subjective experience, the flow of time, or the privileged present, leading mainstream science to marginalize these essential elements of consciousness as irrelevant or illusory. However, from my vantage these aspects of existence are at least as certain as physical reality itself. It seems nonsensical to characterize experience as an illusion, because even an illusory experience (i.e., where the contents have no bearing on physical reality) is still an experience. Moreover, experience exclusively resides in an ever-changing present. A characterization of reality that has no place for subjective experience, the flow of time, or importance of the present seems devoid of the core aspects of my existence. In keeping with others who have speculated that theories of physical reality will need to be expanded to accommodate subjective experience, I conjecture that consciousness may correspond to movement in an additional subjective dimension (or dimensions) of time. Although this hypothesis is highly speculative, it provides an example of the kind of meta-perspective that may be necessary to successfully accommodate subjective and objective views.

Clearly I have my work cut out for me. However, before embarking on the more ambitious aspects of this journey, let us first step back and consider the nature of perspective and the impact that it can have on understanding.

2 Applying perspective shifts to conceptualizing human experience from the first- versus third-person perspective

The striking parallels between perceptual and conceptual perspective shifts exemplify the embodiment of mental capacities in physical experience ([Schubert & Semin 2009](#)). Colloquially, when we talk about dramatic shifts in concep-

tual understanding, we routinely use perceptual metaphors ([Schooler et al. 1994](#)). We speak of “thinking out of the box,” or of “stepping back and looking at the bigger picture.” Even the term that we use for gaining a fresh perspective on an old problem, i.e., “insight,” directly alludes to the parallels between perceptual and conceptual perspective shifting. It is no coincidence that the Gestalt psychologists who pioneered research on visual perspective shifting ([Wagemans et al. 2012](#)) also were the first to investigate the processes of conceptual insight ([Duncker 1945](#)). And indeed, research in our lab ([Schooler & Melcher 1995](#)) reveals a strong correlation between people’s ability to make perceptual insights (e.g., recognizing out-of-focus pictures) and conceptual insights (e.g., solving insight word problems). Thus, in order to explore how perspective may constrain our conceptual understandings, it is helpful to start by briefly considering the ways in which perspective can influence perceptual experiences. As will be argued, the manner in which alternative first-person perceptual perspectives constrain our experiences, provides a compelling metaphor for the broader contrast between first- and third-person perspectives that individuals face in reconciling their personal subjective experiences with objective reality.

One of the greatest challenges of visual perspective is recognizing how fluid it really is. Typically, when we view an object or a scene, we apprehend it from a particular vantage and rarely consider the possibility that it may be seen in a different way. If and when a shift occurs, the experience is typically characterized by a marked surprise that the very same view could afford such a different understanding. The Gestalt reversible figures are a quintessential example of images that startle us with their alternative perspectives. At first when we encounter them we often perceive them from only one perspective; that is, although there are several possible interpretations of the image, we assign one set of perceptual properties to the elements of the image (front or back, figure or ground), and one conceptual interpretation of the object (e.g., duck or rabbit, young woman or old hag).

When presented with an image of a duck/rabbit as a duck, those unfamiliar with the image may initially see only a duck. However, if alerted to the possibility of another embedded image, suddenly a rabbit may virtually pop out. Other classic examples of reversible images include: a Necker cube facing one way or another, a vase or a pair of faces, a young woman or an old hag. A particularly compelling recent addition is the spinning dancer illusion, where a perceptual shift not only changes one's perspective of her orientation but also the direction in which she appears to be spinning.

Figure 2: The duck-rabbit illusion is a classic example of a perspective-dependent reversible image. When presented as a duck, those unfamiliar with the image may initially see only a duck. However, if alerted to the possibility of another embedded image, suddenly a rabbit may pop out. McManus, I. C., Freegard, M., Moore, J., & Rawles, R. (2010). Science in the making: Right hand, left hand. II: The duck-rabbit figure. *Laterality*, 15, 167.

Figure 3: The Necker cube is a reversible image that, depending on the perspective taken by the observer, appears to be facing one way or another. Shifting one's perspective allows the observer to view the cube either from slightly above or slightly below. Necker, L.A. (1832). Observations on some remarkable optical phenomenon seen in Switzerland; and on an optical phenomenon which occurs on viewing a figure of a crystal or geometrical solid. *London and Edinburgh Philosophical Magazine and Journal of Science*, 1 (5), 329–337.

There are several notable aspects of all the aforementioned visual perspective shifting examples. First, before one knows that there are multiple interpretations, it is common to only perceive one or the other. Second, once one is aware of both perspectives, one can experience an oscillation between the two, shifting from one perspective to the other, and back again. Third, at any one moment in time, it is impossible to simultaneously see both interpretations. The Necker cube is either seen facing one way or the other; the spinning dancer only rotates in one direction at a time. Finally, although one can only perceive one interpretation at a time, one can nevertheless know that multiple perspectives exist, and this knowledge provides a *meta-perspective*, whereby we appreciate that what we

perceive one way at one moment can be perceived in a very different way in the next.

Figure 4: Rubin's vase (sometimes referred to as "The Two Face, One Vase Illusion") depicts the silhouette of a vase in black and the profiles of two inward-looking faces in white. The figure-ground distinction made by the brain during visual perception determines which image is seen. Ittelson, W. H. (1969). *Visual Space Perception*, Springer Publishing Company, LOCCCN 60-15818

A particularly remarkable class of perceptual shift that enables us to switch to a meta-perspective comes from "Magic Eye" stereograms that can reveal a full holographic three-dimensional realm that is not initially perceptible at all. These stereograms entail images that first are viewed as a two-dimensional pattern. However, if one stares at the image long enough in just the right way (this requires a little eye crossing) and believes that it is possible to actually see into it, an entirely different and fully three-dimensional image emerges. What is so striking about these "Magic Eye" stereograms is that the embedded three-dimensional images have absolutely no resemblance to the two-dimensional images from which they emerge. There is of course a sophisticated algorithm (based on principles of stereopsis) that enables the three-dimensional perception to arise from the two-dimensional

image, but the experiences of the two images are wholly of a different sort. Those who have not gotten into a Magic Eye image can have no idea what the underlying image looks like, and even if they are shown what the form is, they cannot appreciate what it is like to actually witness the two-dimensional page miraculously open up into a three-dimensional world that is somehow residing within it. However, those who have experienced this transformation gain a wholly different appreciation for the image, recognizing that it affords two entirely different vantages, even while appreciating that only one can be apprehended at any particular time.¹

The lessons learned from perceptual perspective shifting are relevant to the long-standing tension between conceptualizing human experience from the first- versus third-person perspective. Not unlike the shifting perspectives of a reversible image, the field of psychology has vacillated back and forth between focusing on people's self-reported internal experiences (the first-person perspective) and their observable behaviors (the third-person perspective). Moreover, just as the spinning dancer can move in one direction for a while, then flip back and forth in direction, and then carry on in the opposite direction, the field has had periods of relative steady focus on one or the other vantage and other periods in which the vantage was more variable.

¹ A possible objection to the Magic Eye stereogram as an illustration of a shifting perspective is that it can be enabled merely by a musculature action (the crossing of the eyes). One reviewer suggested that the new representation that emerges from these images may be no "more interesting than the muscular action of opening a closed eye which also allows the appearance of a suddenly unseen picture." While a worthwhile observation, I do not think it challenges the relevance of the example. First, closing one's eyes is not a different vantage of an image; it is a lack of a vantage at all. Second, like other reversible images whose shifting interpretation can be enhanced by movement of the eyes, the muscular adaptations required for seeing the alternate image of a Magic Eye stereogram is a necessary but not sufficient condition for its reinterpretation. This is illustrated by the fact that many people, despite all efforts of eye crossing, are incapable of entering them and that those who do have the good fortune to be of being able to experience them typically must engage in sustained cognitive effort to unpack the image once they begin to get into them. The central point of the Magic Eye example is that it illustrates how changing vantages on what one is looking at can profoundly influence what one believes to be true about it. The fact that this changing vantage may require a little eye crossing does not, in my view, lessen this observation.

Figure 5: The young girl-old woman illusion (otherwise known as “My Wife and My Mother-in-Law”) is a reversible image in which the viewer may either observe a young girl with her head turned to the right or an old woman with a large nose and protruding chin, depending on one’s perspective. Wright, E. (1992) The original of E. G. Boring’s Young Girl/Mother-in-Law drawing and its relation to the pattern of a joke. *Perception*, 21, 273–275.

The inception of psychology was marked by a concern with the inner experience of the individual (Schultz & Schultz 1992). Introspection was the tool of choice, and research entailed asking participants to scrutinize the components of their experiences. In short, psychology began with a fixed first-person perspective. In fact, it was during this time that psychology created some of its most robust laws of psychophysics demonstrating strikingly rigorous relationships between changes in various perceptual estimates (e.g., perceived brightness, weight, volume) and changes in the physical stimuli themselves (for a history, see Murray 1993). Then, concerns about the value of introspection arose, and researchers began to vacillate regarding the value of introspection relative to more “objective” third-person perspectives. Although

some researchers (notably the Gestalt psychologists and other researchers in the domain of human perception, e.g., Katz 1925/1989) continued to maintain a concern with inner experience, for a significant period of time the behaviorist reign caused a shift toward disregarding people’s first-person perspectives. Internal experience was a taboo topic. In short, psychology switched to a fixed third-person perspective. Then, with the rise of information processing and the cognitive era, the field again began to vacillate back and forth between considering people’s internal experiences and focusing on their behavior.

Figure 6: The spinning dancer illusion, or silhouette illusion, depicts a woman spinning in a circle. The direction of the dancer’s spinning (clockwise or counterclockwise) is dependent on the perspective taken by the observer. Kayahara, Nobuyuki (2003). Silhouette Illusion. *ProCrea*. Retrieved from <http://www.procreo.jp/lab0/lab013.html>

While psychology again finds itself in an age of flipping perspectives about first- versus

third-person accounts, much consternation still arises from this fact. Science in general (Wilber 1998) and psychology in particular (Wallace 2000) still find it challenging to fully integrate subjective experience into their accounts. Just as it is impossible to see a Necker cube simultaneously facing in its alternative directions, so too psychology has struggled to reconcile its vacillation between first- and third-person perspectives. On the one hand, ignoring the inner realm of experience seems to leave out much of “what it is like” to be human (Nagel 1974). On the other hand, researchers are rightly concerned about the validity and meaning of people’s first-person reports (Wilson 2003). With no alternative window into people’s minds, how can we know that their reports accurately correspond to their inner experience? After all, science necessarily relies on mutually agreed-upon observations. So how can we evaluate the first-person perspective that by its very nature eludes such consensus? The challenge is how to translate these first-person experiences into third-person data that can be scientifically investigated. The most straightforward answer of course is simply to ask people about their experience; their observable verbal statements thus become the third-person window onto their first-person experiences. But here we run up against the challenge that caused psychology to abandon the first-person perspective in the first place: How do we know if self-reports line up with first-person experiences without some independent measure of people’s internal states (Bayne this collection)?

Fortunately, self-reports are not the only third-person window into people’s inner experience. We can also examine other behaviors as well as measure physiological and brain activity in order to make reasoned inferences about what individuals are genuinely experiencing. In this manner, we can begin to discern when people are accurately characterizing their internal experience, and when they may be overlooking or distorting key aspects. The approach that I am advocating here is very much in keeping with Dennett’s notion of heterophenomenology (2003) that takes at its starting point the premise that people’s self-reports do not neces-

sarily reflect what they are actually experiencing but rather “*what the subject believes to be true about his or her conscious experience*” (Dennett 2003, p. 2). Although such an approach refrains from necessarily taking people’s first-person reports on face value, it does not abandon the prospect of making inferences about what people are actually experiencing.² Rather it posits that we must evaluate people’s self-reports in light of other third-person measures. As Dennett (1993) puts it:

My suggestion, then, is that if we were to find real goings-on in people’s brains that had enough of the ‘defining’ properties of the items that populate their heterophenomenological worlds, we could reasonably propose that we had discovered what they were really talking about—even if they initially resisted the identifications. And if we discovered that the real goings-on bore only a minor resemblance to the heterophenomenological items, we could reasonably declare that people were just mistaken in the beliefs they expressed, in spite of their sincerity. (p. 95)

As will be argued there are at least some situations in which external observers may have better knowledge of a person’s internal state than does the person in question. Moreover, there are some mental states (e.g., mind-wandering) for which the crucial bottleneck in people’s introspective awareness stems not from their capacity to classify the experience, but rather from the fact that people only intermittently take stock of what is going on in their own minds.

In the following section, I review some of the insights about first-person experience that can be gained when it is assessed from a third-

2 In the past (Schooler & Schreiber 2004) I characterized Dennett as dismissing the notion of underlying experience altogether, noting that he has written “Nobody is conscious... we are all zombies” (Dennett 1993, p. 406). Although I still find his views on this issue somewhat slippery, I now believe that he endorses the existence of genuine phenomenal experience that can be validated with third-person evidence. For example Dennett (2003) argues that evidence about briefly presented stimuli could help to inform subjects about their actual conscious experience observing “Subjects would learn for the first time that they were, or were not, conscious of these stimuli” (p. 9).

person perspective. By adopting a “trust but verify” approach to first-person reports, we not only gain a more objective understanding of subjective states, but also potentially glean a more astute perspective of our own experience.

Figure 7: “Magic Eye” stereograms can reveal a holographic three dimensional realm that is not initially perceptible at all. Consisting of abstract visual patterns constructed from an algorithm based on the principles of stereopsis, “Magic Eye” illusions require the viewer to blur their vision for a period of time, thereby revealing a three-dimensional imprint once perspective has shifted. Image provided by eyetricks.com. Additional examples can be found at <http://www.magiceye.com/3dfun/stwkdsp.shtml>.

3 Gaining a third-person perspective on people’s first-person experience

On some occasions we simply have experiences, but at other times we reflect on those experiences; that is, we intermittently take stock of our ongoing experience and re-represent it to ourselves. This distinction between having an experience (experiential consciousness) and explicitly re-representing it to ourselves (meta-awareness) is illustrated by the example of mind-wandering while reading (Schooler 2002). All of us have had the experience of reading along and suddenly realizing that, despite our best intentions, our eyes have been moving across the page but our minds have been entirely elsewhere. Indeed this has likely happened

to a goodly proportion of the readers whom have made it this far. The immediate question that this common experience raises is: why do we continue to simultaneously read and mind-wander even though we know that it is impossible to fully do both at the same time? The answer I suggest, and I’ll offer more evidence for this contention shortly, is that we routinely lose track of the contents of our own minds. People continue mind-wandering while reading because once they begin to mind-wander they often temporarily fail to notice (i.e., become meta-aware of) the fact that their minds are thinking about something unrelated to the text.

Figure 8: The three-dimensional image is a three dimensional yin-yang which the original Magic Eye image would not have revealed without a shift in perspective. The embedded three dimensional image has absolutely no resemblance to the two dimensional image from which it emerges. Image provided by eyetricks.com.

The notion that people routinely shift in perspective (from simply experiencing to attempting to re-represent their experience to themselves) provides the foundation for a framework for scientifically investigating first-person experience. Specifically, the distinction between experiential consciousness and meta-awareness raises the prospect of two types of dissociations between these vantages that are empirically tractable (Schooler 2002). *Temporal dissociations of meta-awareness* involve situ-

ations in which individuals engage in an experience without explicitly realizing that they are doing so. The example of temporarily failing to notice that one is mind-wandering is an example of a temporal dissociation. *Translation dissociations of meta-awareness* occur when one distorts or otherwise mischaracterizes their experience to themselves. Shouting “I am not angry” at the top of one’s lungs is an example of this latter dissociation. In the following discussion I briefly outline the empirical approach for exploring these two types of dissociations.

3.1 Temporal dissociations of meta-awareness

Although failing to notice that one is mind-wandering is a particularly apt example of a temporal dissociation of meta-awareness, there are numerous other examples of experiences that can temporarily go without being explicitly noticed, including unnoticed emotions (Lambie & Marcel 2002; Schooler & Mauss 2010) suppressed thoughts (Baird et al. 2013), and various mindless behaviors (Schooler et al. in press). Temporal dissociations of meta-awareness readily lend themselves to empirical investigation. Two approaches have proven effective in delineating situations in which people temporarily fail to notice a particular mental state: self-catching versus probe-catching and retrospective measures (Schooler et al. 2011).

The self-catch/probe-catch methodology pits two common self-report techniques against one another. Participants are asked to indicate every time they notice a particular mental state (e.g., mind-wandering). If an individual reports that they have just noticed themselves engaging in that mental state, then this is by definition a demonstration that the mental state has reached meta-awareness. Thus, self-caught episodes provide a straightforward measure of mental states of which individuals have become meta-aware. However, within this methodology, participants also periodically receive experience-sampling probes (Hurlburt & Heavey 2001) in which they are asked whether, at that particular time, they had been engaging in that mental state. If people are caught engaging in the state

before they notice it themselves (via self-catching), this provides a metric of episodes of that state that have eluded meta-awareness. As will be detailed later, this approach has proven effective in documenting temporal dissociations of a variety of different mental states including both mind-wandering (Schooler et al. 2004; Sayette et al. 2009; Sayette et al. 2010) and unwanted thoughts (Baird et al. 2013).

A second approach for identifying temporal dissociations of meta-awareness is to rely exclusively on experience sampling probes (i.e., probe-catching) but to additionally query people when they are caught in a particular state (e.g., mind-wandering) regarding whether or not they had been previously aware of that fact. Again, as will be seen, this strategy routinely reveals that people can be caught engaging in mental activities that they were previously experiencing but were not explicitly aware of. Intriguingly, the findings with this measure of temporal dissociation align with those revealed by the self-caught/probe-caught methodology to reveal consistent systematic differences between mental states associated with meta-awareness and those that lack it.

3.2 Translation dissociations of meta-awareness

Translation dissociations correspond to situations in which, while in the process of re-representation, one omits, distorts, or otherwise misrepresents one’s mental state to oneself and/or others. The basic strategy for assessing translation dissociations is to examine the correspondence between individuals’ self-reports of their mental states and indirect measures that might reasonably be expected to correspond to that state (Schooler & Schreiber 2004). If the correspondence is high, there is good reason to think that individuals are accurately reporting their internal state. If the correspondence is low, one needs to at least be suspicious that people are mischaracterizing their mental state.

Emotions are likely to be a particularly common source of translation dissociations. For example, when individuals report experiencing anxiety, a host of physiological measures (includ-

ing heart rate and galvanic skin response) typically become elevated (Marks 1987). Such correspondence gives us confidence that people are accurately characterizing their internal state; in other words, there is no translation dissociation. However, there is a class of individuals, referred to as repressors, who show the standard physiological changes when put in situations that would cause most people to experience anxiety, but who fail to report any change in anxiety (Asendorpf & Scherer 1983). In these cases, it seems reasonable to speculate that the repressors are misrepresenting their internal experience to themselves; they are experiencing anxiety but not acknowledging it (Lambie & Marcel 2002; Schooler et al. in press). As another example, consider that when males experience sexual arousal they typically show changes in their penile tumescence (a technical way of saying they become erect). Intriguingly, men who reported disgust for homosexual activity were shown to actually exhibit greater increases in penile tumescence when witnessing males engaging in sex, than men who did not report aversive feelings toward homosexuality (Adams et al. 1996). One reasonable account of these findings is that these so-called homophobics experience a translation dissociation, such that they are unable to acknowledge the arousal that they feel towards men, and instead misattribute the experience to a feeling of disdain.

A final example of translation dissociations involves situations in which individuals analyze why they feel the way they do about an affective experience. For example, in one study (Wilson et al. 1993), participants viewed various art posters and then both rated the posters and selected one to take home with them. Prior to engaging in this assessment, some participants were further asked to analyze why they felt the way they did about the posters, whereas others were not. When contacted several weeks later, people who had attempted to reflect on the basis of their preferences were less satisfied with their choice and were less likely to have hung the poster on their wall than those who had not analyzed their reasons. The disruptive effects of analyzing reasons, which have been conceptually replicated in a variety of contexts (Wilson & Schooler 1991), suggest that sometimes self-

reflection may be a source of translation dissociations. That is, in the process of trying to understand why people feel the way they do, they may construct a faulty meta-conscious representation and thereby lose touch with their feelings.

3.3 Investigating temporal and translation dissociations of meta-awareness in the context of mind-wandering

In recent years, a growing body of research has addressed the nature of mind-wandering as it pertains to the occurrence of temporal and translation dissociations of meta-awareness. This research suggests that mind-wandering is highly susceptible to temporal dissociations of meta-awareness; that is, individuals routinely fail to notice that their minds are wandering despite the considerable disruption to performance that such unnoticed lapses often incur. This claim is supported by various strands of evidence revealing the frequency with which participants are routinely “caught” mind-wandering before they notice it themselves. In contrast, mind-wandering appears to be relatively resistant to translation dissociations of meta-awareness. Although individuals regularly fail to notice when their minds are wandering, when meta-awareness is directed toward the current state of thought, they are generally quite accurate in characterizing whether or not their minds were on-task. This latter claim is supported by numerous demonstrations of systematic differences in performance and neurocognitive activity as a function of individuals’ self-classifications of their mental state as on-task versus mind-wandering.

3.3.1 On the veracity of self-reports of mind-wandering: How susceptible is mind-wandering to translation dissociations?

A fundamental challenge to the investigation of mind-wandering is its necessary reliance on self-report. Mind-wandering is, by its very nature, defined in terms of internal mental states. Given psychology’s long suspicions about introspective evidence (Nisbett & Wilson 1977), this reliance

on self-reports likely contributed to why, until recently, consideration of this important topic was largely limited to a few stalwart researchers (Antrobus 1999; Klinger 1999; Singer 1988; Giambra 1995). However, accumulating evidence suggests that when individuals are directly queried regarding whether they are mind-wandering, their self-reports accurately reflect their internal mental state. Evidence for this claim is largely based on the logic of triangulation (Schooler & Schreiber 2004). Accordingly, if self-reports of mind-wandering consistently co-vary with behavior and neuro-cognitive activity in a manner that might reasonably be expected to be impacted by mind-wandering, then we can have increased confidence that such introspective evidence accurately reflects the underlying mental state. In the following review, I detail at some length numerous findings in support of this relationship from a host of paradigms in which potential behavioral or physiological proxies of mind-wandering are related to individuals' responses to randomly timed queries regarding whether they were just mind-wandering. This review provides a review of the extensive literature on mind-wandering and evidence for the general contentions that: 1) the concordance between behavioral and physiological measures and self-report data indicate that people's self-reports of mind-wandering correspond to actual instances of this mental state; and 2) while people are routinely able to recognize mind-wandering after the fact, they often fail to notice it while it is occurring. Readers willing to take my word on these two points may want to scan or skip this section and jump ahead to its *Summary* (on page 16) or to the *Implications of this approach for the more general enterprise of the science of first-person perspective* (on page 18) if the general topic of mind-wandering is not of primary interest.

3.3.1.1 Behavioral measures

Reading comprehension

Although long overlooked as a source of reading comprehension failure, Schooler et al. (2004) found a strong correlation between the frequency of mind-wandering reports in response

to experience sampling probes and comprehension accuracy. Subsequent work demonstrated that mind-wandering specifically disrupts the development of a detailed situational model (Smallwood et al. 2008).

Another way in which the absence of reading comprehension following mind-wandering has been documented is through the examination of people's capacity to detect when the text becomes gibberish. In one study (Zedelius et al. 2014) participants were asked to read simple children's texts and report every time they noticed that the sentences no longer made any sense (some of the sentences were constructed so that the nouns of the sentences were rearranged in a nonsensical manner, e.g., "This sense makes no sentence"). The results revealed that participants sometimes continued reading for a number of sentences before noticing that the text had become gibberish. Moreover, participants who received thought probes after several sentences of gibberish were more than twice as likely to report mind-wandering without meta-awareness, relative to those who were probed at random times.

Eye-movements

If individuals' self-reported mind-wandering episodes during reading correspond to genuine mental lapses, then we might also reasonably expect to see differences between the patterns of gaze durations following periods in which individuals report reading attentively versus mind-wandering. These predictions were confirmed in an experiment in which subjects read the entirety of Jane Austen's *Sense and Sensibility* while their eye movements were recorded (Reichle et al. 2010). Relative to eye movements obtained during intervals of normal reading, the fixations measured during intervals that preceded reports of mindless reading were both longer in duration and less modulated by variables that are known to influence fixation durations (e.g., word frequency, Rayner 1998). These results suggest that the fairly tight coupling between the mind and eye during normal reading (Reichle 2006) becomes disengaged during self-reported mind-wandering.

Sustained Attention to Response Task (SART)

Another paradigm that has proven effective in documenting the validity of mind-wandering reports is the SART task. The SART is a simple go/no-go task in which participants are asked to refrain from responding to an infrequent no-go target (Manly et al. 1999; Robertson et al. 1997). Studies have documented that the brief lapses associated with this task share important features associated with reports of off-task thought. For example, individual difference measures such as cognitive failures (Smallwood et al. 2004), depression (Carriere et al. 2008; Farrin et al. 2003; Smallwood et al. 2007), and poor executive control (McVay & Kane 2009) have been associated both with greater mind-wandering reports and more errors on the SART. Similarly, both off-task reports and errors in this task share similar information processing features in terms of measures such as reaction time (RT) and evoked response potentials (ERPs; Smallwood et al. 2008, 2004, 2007).

3.3.1.2 Neurocognitive measures

Evoked Response Potential

When the brain faces situations in which it toggles between alternative perspectives, it routinely temporarily inhibits one perspective in favor of the other. This dampening of the non-dominant perspective is shown in reversible figures, where brain activation of one interpretation is inhibited while the other is consciously experienced (Tong et al. 2006). This same process of dampening the nondominant vantage also appears to operate when people favor their internal train of thought over external events. Accordingly, reports of mind-wandering should be associated with a dampening of attention to external stimuli. Indirect support for this “decoupling hypothesis” comes from studies demonstrating that participants are more prone to errors during periods associated with self-reported attentional drifts (e.g., Carriere et al. 2008; Smallwood et al. 2004; Weissman et al. 2006) and that they are less likely to recollect

external events during these periods (Smallwood et al. 2003, 2007, 2004).

More direct support for a relationship between self-reports of mind-wandering and dampened external processing comes from several ERP studies. In one study (Smallwood et al. 2008), participants intermittently received experience sampling probes while performing a simple target discrimination task. Analysis of the ERP responses to the targets revealed that the amplitude of the P3 ERP component elicited by the targets was significantly reduced for targets associated with “off-task” relative to “on-task” reports. Given that the P3 component reflects the degree to which external events are cognitively analyzed (e.g., Donchin & Coles 1988), these initial data support the proposal that mind-wandering reports are associated with an attenuation in stimulus processing at relatively late, post-perceptual processing stages.

A more recent ERP study examined whether mind-wandering might also attenuate sensory-level cortical processing (Kam et al. 2011). Participants again performed a simple discrimination task (at fixation) while being prompted at random intervals to report on their attentional state, but this time we also included task irrelevant probes in the visual periphery. The results revealed that the initial sensory-evoked response to probes was significantly attenuated prior to reports of “off-task” attentional states, as measured via the visual P1 ERP component. A second experiment that included irrelevant auditory probes similarly revealed that sensory-level auditory processing in the cortex is also dampened during self-reported “off-task” states, as measured via the auditory N1 ERP component. Another recent study from our lab (Baird et al. 2014) replicated the finding that mind-wandering reduced the P1 ERP, and further revealed that mind-wandering was associated with decreased phase-locking of electroencephalograph (EEG) neural oscillatory activity to sensory stimuli, suggesting that mind-wandering disrupts the temporal fidelity with which the brain responds to a stimulus.

Taken together, the collective ERP and EEG evidence demonstrates that self-reports of mind-wandering correspond to attenuated sens-

ory processing and cognitive appraisals of external stimuli. This finding further confirms the validity of self-reports of mind-wandering and suggests that a central feature of the mind-wandering state is an attenuation of the processing of external stimuli.

Functional magnetic resonance imaging (fMRI)

One of the challenges facing the burgeoning discipline of cognitive neuroscience is making sense of the observation that several brain areas, including the posterior parietal cortex and the precuneus, the medial prefrontal cortex, and the medial temporal lobe (which are collectively known as the default mode network (DMN), Raichle et al. 2001), all exhibit high levels of activity when participants have no external task to perform. One candidate process that the DMN could serve is the generation of the stimulus-independent thoughts that occur during the mind-wandering state, a hypothesis that is supported by a growing body of evidence. For example, McGuire et al. (1996) used the technique of retrospective thought sampling to demonstrate that reports of mind-wandering were associated with activity in the medial prefrontal cortex. More recently, several studies have documented that situations associated with greater mind-wandering reports (as assessed outside of the scanner) also lead to greater activity in many of the key elements of the DMN (Mason et al. 2007; McKiernan et al. 2006).

While activity in the DMN is correlated with high probability of retrospective reported mind-wandering, it was originally unclear whether particular episodes of self-reported mind-wandering are linked to recruitment of the DMN. To assess whether this was the case, we conducted a study in which experience sampling was combined with fMRI to assess the neural activity that occurred during particular episodes of mind-wandering (Christoff et al. 2009). This study revealed that, in addition to the activation of several core structures in the DMN, areas normally observed in controlled processing (including the dorsolateral prefrontal cortex and the dorsal

anterior cingulate) were also engaged during self-reported off-task thought. This pattern of brain activation suggests that executive and default network resources are jointly recruited during episodes of mind-wandering. One possible account explaining this joint activation is that executive network resources play a role in transforming the self-referential content supported by the DMN into the internal train of thought that we experience when the mind wanders. Further support for this hypothesis is provided by evidence that the ability to engage in autobiographical planning (such as “how do I get out of debt?”) requires cooperation between the DMN and a system involving attentional control (Spreng et al. 2010).

Christoff et al. (2009) also compared the pattern of activations associated with introspective reports of mind-wandering, on the one hand and the pattern of activations associated with behavioral errors, on the other hand. Although a variety of factors are known to contribute to behavioral errors during the SART, mind-wandering is believed to be one important source of such errors. Consistent with this view, SART errors (Figure 9) and the introspective reports of mind-wandering (Figure 10) were associated with similar patterns of brain recruitment, providing further validation for the use of introspective experience sampling reports for the study of mind-wandering.

Figure 9: Activations preceding reports of mind wandering (off-task versus on-task). Upward green arrows: default network regions; downward blue arrows: executive network regions. Regions of activation included (A) Dorsal ACC (BA32); (B) Ventral ACC (BA 24/32); (C) Precuneus (BA7); (D) Left temporoparietal junction (BA 39); (E) Bilateral DLPFC (BA 9). Height threshold $P < 0.005$, extent threshold $k > 5$ voxels (from Christoff et al. 2009).

Figure 10: Activations preceding SART errors (interval prior to incorrect versus correct targets). Upward green arrows: default network regions; downward blue arrows: executive network regions. Regions of activation included: (F) Ventromedial PFC (BA10/11); (G) Dorsomedial PFC (BA9). Height threshold $P < 0.005$, extent threshold $k > 5$ voxels (from Christoff et al. 2009).

3.3.2 The intermittent meta-awareness of mind-wandering: How susceptible is mind-wandering to temporal dissociations?

Although when queried individuals are quite reliable in their capacity to self-report whether or not they were mind-wandering, a variety of strands of evidence suggest that people routinely fail to spontaneously notice when mind-wandering takes place. Two paradigms, reviewed earlier, have documented the intermittent meta-awareness of mind-wandering.

3.3.2.1 Self-caught/probe-caught methodology

One approach for documenting mind-wandering in the absence of meta-awareness is combining self-catching and experience sampling measures into a single paradigm. Recall that the self-catching measure asks participants to press a response key every time they notice for themselves that they have been mind-wandering. This measure provides a straightforward assessment of the mind-wandering episodes that have reached meta-awareness. The experience sampling measure, on the other hand, randomly probes people regarding whether they were at that particular moment mind-wandering. When used in conjunction with the self-caught measure, experience sampling can catch people mind-wandering before they notice it themselves.

A number of studies have effectively used the self-caught/probe-caught methodology to illuminate the relationship between mind-wandering and meta-awareness. This approach was initially used to examine mind-wandering while reading (Schooler et al. 2004) and revealed that whereas participants regularly caught themselves mind-wandering, they nevertheless were often caught mind-wandering by the probes. Strikingly, and in support of a fundamental difference between mind-wandering episodes that are accompanied by meta-awareness and those that are not, there was a strong correlation between probe-caught mind-wandering and comprehension performance but no such relationship between self-caught mind-wandering and comprehension.

Additional studies have examined the impact of two mind-altering experiences hypothesized to undermine individuals' meta-awareness: alcohol intoxication and cigarette craving. In one study (Sayette et al. 2009), social drinkers consumed a moderate dose of alcohol or a placebo beverage and then performed a reading task (implementing a self-caught/probe-caught mind-wandering assessment methodology). Compared with those who drank the placebo, participants who drank alcohol were more likely to report that they were “zoning out” when probed. After accounting for this increase in mind-wandering, alcohol also lowered the probability of catching oneself zoning out (i.e., self-catching). These data suggest that alcohol increases mind-wandering while simultaneously reducing the likelihood of noticing one's mind-wandering.

In another study (Sayette et al. 2010), smokers, who were either nicotine-deprived (crave condition) or non-deprived (low-crave condition), performed the same mind-wandering task used in Sayette et al. (2009). Smokers in the cigarette-crave condition were significantly more likely than the low-craving smokers to acknowledge that their mind was wandering when they were probed. When this more-than-threelfold increase in zoning out was accounted for, craving also lowered the probability of catching oneself mind-wandering. Similar to the alcohol consumption findings, it appears that ci-

garette craving simultaneously increases mental lapses while reducing the metacognitive capacity to notice them.

3.3.2.2 Retrospective classification of mind-wandering episodes

A second methodology that has been used to examine fluctuations in meta-awareness of mind-wandering entails combining the experiential sampling methodology with a judgment of participants' immediately prior state of awareness. Recall that, in the experience sampling procedure, participants are intermittently queried regarding whether or not they were mind-wandering; in this combined approach, if they report mind-wandering to the probe, then they are also asked to indicate if they were aware that they were mind-wandering. In response to such queries, participants routinely indicate that they had been unaware of their mind-wandering up until the time of the probe. Moreover, when participants classify mind-wandering episodes as unaware, their performance and neurocognitive activity systematically differ from when they report having realized they were mind-wandering.

Consistent with findings using the self-caught/probe-caught methodology, retrospective classifications of unaware mind-wandering episodes (termed zoning out) and aware episodes (termed tuning out), indicate that the former are more associated with comprehension failures than the latter (Smallwood et al. 2008). By contrast, reports of zoning out seem to be most closely linked to failures in response inhibition (Smallwood et al. 2008, 2007) and to poor mental models during reading (Smallwood et al. 2008). Together these results suggest that while maintaining streams of stimulus-independent thought interfere with the integrity of external attention, the absence of awareness of mind-wandering is especially damaging to task performance.

Neurocognitive measures also reveal differences in the degree of activation between mind-wandering episodes that have been classified as aware versus unaware. In the combined experience sampling/fMRI study conducted by Christoff et al. (2009), mind-wandering with awareness activated similar brain regions to those observed

during mind-wandering without awareness. These brain regions, however, were more strongly activated when mind-wandering occurred without awareness (see Figure 11). The anterior prefrontal cortex (BA10) was one of the brain regions significantly more strongly recruited during unaware episodes of mind-wandering. Notably, anterior prefrontal cortex (PFC) recruitment has been directly linked to engagement of cognitive meta-awareness (McCaig et al. 2011). The observation that this same brain region became specifically more recruited during unaware episodes of mind-wandering may seem surprising at first. However, the anterior PFC may be involved in mind-wandering through its role in the maintenance of thought. As discussed further below, its recruitment during mind-wandering in the absence of awareness may make it more difficult for meta-awareness to be implemented.

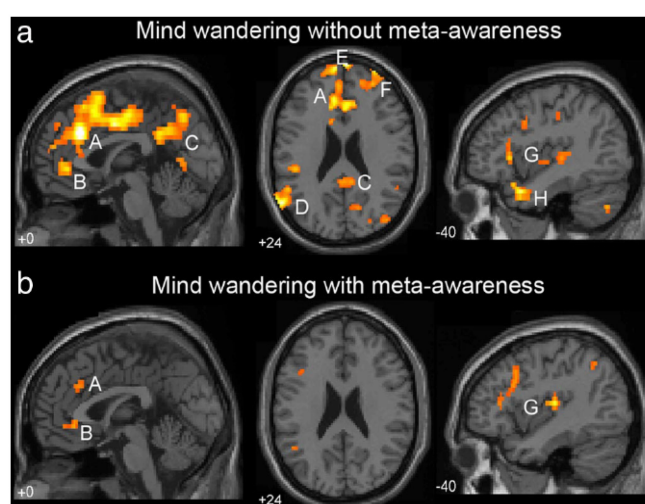

Figure 11: Mind-wandering in the (a) absence and (b) presence of meta-awareness. (a) Regions of activation associated with mind-wandering in the absence of awareness (off-task unaware versus on-task): (A) Dorsal ACC (BA32); (B) Ventral ACC (BA32); (C) Precuneus (BA7); (D) Posterior Temporoparietal Cortex (BA39); (E) Dorsal Rostromedial Prefrontal Cortex (BA10); (F) Right Rostrolateral Prefrontal Cortex (BA10); (G) Posterior & Anterior Insula; (H) Bilateral Temporopolar Cortex; (b) Similar regions were activated during mind-wandering with awareness (off-task aware versus on-task comparison) but to a lesser degree, including: (A) Dorsal ACC (BA32); (B) Ventral ACC (BA24/32); (G) Posterior & Anterior Insula. Height threshold $P < 0.005$, extent threshold $k > 5$ voxels (from Christoff et al. 2009).

3.3.3 Summary

In sum, the investigation of mind-wandering from the vantage of the distinction between having an experience (experiential consciousness) and explicitly realizing that one is having an experience (meta-awareness) has provided a fertile ground for developing a third-person understanding of first-person experience. This research has begun to chart the stream of consciousness, demonstrating that individuals regularly vacillate between the outer realm of perception and the inner realm of thoughts and feelings. This fluctuation routinely evades explicit meta-awareness, enabling people's minds to move on to a new topic without explicitly realizing this fact. Nevertheless, when directly queried, people are remarkably capable of introspecting and noticing whether or not they were mind-wandering. The fluctuation of perspectives on the mind that this approach affords raises numerous questions. Here, I address three: 1) If people are so competent at recognizing that they are mind-wandering when queried, then why do they find it so difficult to notice this fact on their own? 2) Are there ways of enhancing the capacity to catch one's mind in flight? 3) What are the implications of this approach for the more general enterprise of the science of first-person perspective? I consider these questions in turn.

3.3.3.1 Why is mind-wandering so easy to report but so difficult to catch?

The observation that meta-awareness is so effective at discerning mind-wandering when queried about it, yet so poor at catching it on its own, raises the natural question of why this discrepancy exists. Two potentially interrelated explanations may contribute to this striking discrepancy.

Like mind-wandering, meta-awareness appears to be associated with rhythms of attentional flux (Schooler et al. 2011). Sometimes we are explicitly aware of our mental states, and other times we are not. Such vacillations in meta-awareness could readily contribute to individuals' frequent tendency to overlook episodes

of mind-wandering, as this mental state may only be notable when the explicit spotlight of attention is metaphorically turned on itself. Indeed the tendency to only notice mind-wandering after the fact may similarly apply to other mental states that routinely curtail the occurrence of meta-awareness. Like mind-wandering, other subjective states such as sleep, anesthesia, dreaming, and flow states are typically not noticed while they are occurring, but are readily acknowledged after the fact. Sleep (in the absence of dreaming) and anesthesia are typically lacking conscious experience entirely and so clearly are not candidates for meta-awareness. The mental states associated with gradually drifting off to sleep and dreaming do have phenomenal content but typically lack meta-awareness. This is why people routinely don't notice that they are falling asleep (a grave danger for driving) or dreaming (except in the case of lucid dreaming, LaBerge 1980). Another example is that of flow states (Csikszentmihalyi 1988), during which people engage in highly demanding tasks at close to their optimum level of performance. In such cases, people lack the additional resources to take stock of their experience, which may be why meta-awareness of a flow state often leads to its sadly premature termination. Nevertheless, as in the other cases, after a flow state has ended, individuals are quite able to acknowledge its occurrence. In all of these cases, the common denominator may be that these various states (for one reason or another) curtail the occurrence of meta-awareness, and thus are only noticed after the fact once the opportunity for meta-awareness reoccurs.

One reason why mind-wandering may undermine meta-awareness may stem from its reliance on the very same brain regions that may be necessary for noticing its occurrence. A striking aspect of the brain regions associated with mind-wandering is that they involve many of the systems that might be expected to contribute to the monitoring of the state. For example, elements of the medial prefrontal cortex are recruited both during mind-wandering and in tasks that require theory of mind (Gallagher & Frith 2003). As mental state attribution involves the application of meta-cognitive pro-

cesses to information of a stimulus-independent nature (e.g., inferences about the mental state of another individual), the engagement of these brain regions during mind-wandering could prohibit their utility in the service of catching the wandering mind. Similarly, in the combined fMRI/experience sampling study conducted by [Christoff et al. \(2009\)](#), periods of mind-wandering engaged regions such as the dorsal ACC, involved in error-detection and conflict monitoring, and the anterior PFC, involved in cognitive meta-awareness. If mind-wandering engages both meta-cognition and error-detection systems in the service of generating a coherent stream of stimulus-independent thought, the fact that these systems are already engaged may make them less capable of detecting a mind-wandering episode. The observation that mind-wandering and meta-cognitive processes both engage the same systems does not necessarily establish a causal relationship between these two. Nevertheless, it remains an intriguing speculation that our persistent failure to catch ourselves mind-wandering may occur because mind-wandering hijacks the precise meta-cognitive brain regions that are necessary for noticing it. Future research might profitably explore this hypothesis by examining whether mind-wandering episodes that are experimentally induced to emphasize meta-cognitive reflection are particularly likely to evade detection.

3.3.3.2 Are there ways of enhancing people's awareness of their mind-wandering?

One of the clear findings of research on mind-wandering is that it can be extremely disruptive to performance. Reading ([Smallwood et al. 2008](#)), working memory ([McVay & Kane 2009](#)), vigilance ([Cheyne et al. 2009](#)), and general intellectual functioning ([Mrazek et al. 2012](#)) can be seriously disrupted by mind-wandering, especially when it occurs without awareness ([Smallwood et al. 2008](#)). This raises the natural question of whether enhancing people's meta-awareness of their minds can help to curtail the disruptive consequences of mind-wandering.

Of course, just because episodes of mind-wandering routinely end with a moment of meta-awareness ("shoot, I drifted off again") does not mean that the meta-awareness necessarily was responsible for its ending ([Schooler et al. 2011](#)). Meta-awareness could be a consequence rather than the source of the termination of a mind-wandering episode. According to this view, the intuition that meta-awareness terminates mind-wandering episodes is another example of an over-reach of the attribution of deliberate intention ([Metzinger 2013](#)). While this remains a viable possibility, it is also the case that mindfulness techniques aimed at enhancing awareness of one's internal states can curtail the negative effects of mind-wandering.

In one study ([Mrazek et al. 2013](#)), participants were randomly assigned to one of two interventions that they were told were expected to enhance their performance: two weeks of training either in mindfulness meditation, or in good nutrition practices. Both interventions involved similar time commitments, expectations, and homework (either daily meditation or a nutrition journal). Before and after the intervention, participants were given both reading comprehension and working memory tasks, and their mind-wandering during each was assessed. Compared to the nutrition control, the mindfulness intervention significantly reduced mind-wandering, improved performance on both tasks, and these benefits were mediated by the reduction in mind-wandering for those who were high in mind-wandering to begin with. These findings dovetail with other recent studies indicating that the general tendency for mindfulness (being present in the moment) is negatively correlated with mind-wandering ([Mrazek et al. 2012](#)), and that even a simple mindfulness exercise conducted with non-meditators (focusing on one's breath for eight minutes) can temporarily reduce mind-wandering ([Mrazek et al. 2012](#)).

Although research on the impact of mindfulness training in dampening mind-wandering is consistent with the notion that part of its efficacy is due to enhancing meta-awareness, there is one finding that does not completely square with this account. Specifically, [Mrazek et al. \(2012\)](#) found that mindfulness training re-

duced people's tendency to spontaneously notice mind-wandering episodes. However, this reduction in self-caught mind-wandering could have occurred because the mindfulness practice enhanced people's awareness of the focus of their attention, thereby preventing them from initiating mind-wandering episodes in the first place. Consistent with this speculation, another recent study (Baird et al. in press) demonstrated that a similar mindfulness program can enhance at least one meta-cognitive skill, namely, the ability to assess the accuracy of memory recognition judgments. Although more research is clearly needed, it remains quite plausible that one mechanism by which mindfulness training reduces mind-wandering is by increasing people's meta-awareness of when their minds are beginning to wander.

3.3.3.3 What are the implications of this approach for the more general enterprise of the science of first-person perspective?

The program of research outlined above demonstrates the insights into first person experience that can be gleaned by assessing it from a third-person perspective. In many respects, the approach described here exemplifies the program of heterophenomenology that Dennett advocates. We are systematically assessing people's reports about their conscious experiences while explicitly acknowledging that those reports correspond to people's beliefs about their experience (i.e., their meta-awareness) and not necessarily their actual experience. However, by using various reasonable markers of people's internal states we have been able to examine the conditions under which people's reports are more or less likely to be aligned with their experience. In this regard, we find that when people are explicitly asked whether they were just mind-wandering, their self-reports align with a host of behavioral and physiological measures that should co-vary with mind-wandering. These findings suggest that people are quite accurate in retrospectively assessing whether or not they were just mind-wandering. In other words, by triangulating between people's retrospective self-re-

ports of mind-wandering (following experience sampling cues) and both behavioral and physiological measures, we have identified situations in which all evidence suggests that people's opinions about the content of their private experience is generally quite accurate.

At the same time, by introducing the self-caught procedure in combination with retrospective assessments of people's awareness of prior states of mind-wandering, we have also documented critical lacunae in people's knowledge of their mental states. Specifically we find that people routinely fail to spontaneously notice when their minds have wandered. When tasked with reporting mind-wandering whenever they become aware of it, people routinely demonstrate behavior indicative of mind-wandering while failing to report it. If they are probed during periods in which these measures suggest they are mind-wandering, they routinely indicate that they now realize that they were mind-wandering, but they had not noticed this state until the time of the probe. We are thus also able to identify situations in which all evidence suggests people are routinely lacking in their current knowledge of their ongoing mental state.

By triangulating between people's first-person reports and multiple other third-person measures we have begun to reveal the relationship between people's beliefs about their experience and empirical indices of their underlying mental states (for related approaches, see Hurlburt & Heavey 2001; Jack & Roepstorff 2002; Lambie & Marcel 2002; Lutz & Thompson 2003). Moreover, the theory of the intermittent and imperfect nature of meta-awareness as a representation of experience (Schooler & Schreiber 2004; Schooler 2002; Schooler et al. 2015) provides a scaffold for conceptualizing the situations in which beliefs and underlying experience converge and diverge. Of course, one could always counter that we cannot be sure that the variety of behavioral and physiological measures that correlate with self-reported mental states such as mind-wandering are necessarily indicative of those states. Perhaps there is some third variable that is responsible for both mind-wandering and the host of measures that

we find to be correlated with people's self-reporting of it. But it seems a stretch to suggest that this entirely unknown third variable could account for why, when people say they were mind-wandering, their performance on primary tasks is impaired, their eye movements become less sensitive to what they are looking at, their physiological measures indicate a dampening of attention to external processes, and their brain activation corresponds to that which occurs when they are unoccupied. In short, a strong case can be made for the value of using empirical third-person science to inform not only our understanding of people's beliefs about their experience, but also to discern when those beliefs are likely to be accurate and when they may be inaccurate or incomplete.

It seems likely that those with strong allegiances to either an exclusively first- or third-person account of experience will balk at the notion that third-person empirical indices can be used to corroborate people's first-person accounts. Traditional phenomenologists (e.g., [Husserl 1963](#)) may contend that first-person experience is privileged and so, when discrepancies arise between it and third-person data, that the former should invariably be favored. Those with a behaviorist bent may argue that making claims about underlying subjective states remains a dead end because ultimately they can never truly be verified. Personally I find myself sympathetic to both of the vantages; however, I argue that the striking disparity of these views, both from each other and from the one promoted here, stems from the incongruence that naturally arises from shifting perspectives.

From the vantage of one perspective of a Necker cube, the alternative perspective makes little sense. When the spinning dancer is moving in one direction, it is hard to imagine how she could possibly shift directions. Those who have never entered the third dimension of a Magic Eye image could reasonably doubt that such a perspective could possibly exist. But once one realizes that there are distinctly different perspectives to be had on a situation, and that these alternative perspectives each offer their own valuable vantage, then that knowledge can be held even as one remains incapable of experi-

encing both at the same time. I believe this is the case with interpreting scientific third-person accounts of first-person experience. If one is capable of recognizing both the strengths and limitations of each perspective, then they can use each to inform the other. If, however, they solely look at a problem from one or the other perspective, then this may lead to a logically consistent view, but one that omits an important vantage. I turn now to a consideration of this larger issue: namely, conceptualizing a meta-perspective that can accommodate the vacillating manner in which first-person experience is both that which we know best and understand least.

4 Toward a meta-perspective for considering the metaphysics of first-versus third-person perspective

It is my contention that debates about how to reconcile the first- and third-person perspective on reality arise in part from the distinct vantages that different scholars take on the issue. The problem in a nutshell is that while the prevailing third-person perspective of science (material reductionism) does an admirable job of accounting for all aspects of reality that are revealed from its vantage, it robustly fails to accommodate several self-evident aspects of existence that are uniquely apparent from a first-person perspective. If one simply dismisses those aspects of the first-person perspective that are incongruent with the third-person perspective, (as most scientists and many philosophers do), then there is no problem. However, here I will argue that there exist self-evident observations derived from the first-person perspective that are as compelling as any objective fact. Such observations should not be simply dismissed as irrelevant or illusory but rather suggest the need of serious revision to current accounts of physical reality (for related arguments see [Chalmers 2002](#); [Nagel 2012](#)). In the following section, I first review the material reductionist account suggested by the prevailing third-person perspective view. I then consider several elements of existence revealed by a first-person perspective that seem to have no place

in this account, most notably subjective experience, the flow of time, and the distinctiveness of the present. Finally, I offer some speculative remarks about the nature of a meta-perspective that might be able to accommodate both vantages.

4.1 Ontological third-person perspective—Material reductionism

When reality is conceived of strictly from the vantage of a third-person perspective, it quite naturally leads to the premise of material reductionism, namely that everything including the arising of subjective experience can be accommodated on the basis of physical principles that do not themselves make any appeal to consciousness. This account is arguably the prevailing view among both scientists (e.g., [Crick 1994](#); [Bloom 2009](#); [Graziano 2013](#)) and philosophers (e.g., [Dennett 1993](#); [Churchland 1989](#); [Metzinger 2004](#)). Its strength comes from its remarkable record of success. Having abandoned the superstitions and spiritual whimsies of the past, hard-nosed science has an amazing track record for explaining everything it has been directed toward with purely physical constructs. Aspects of reality that were once thought to be beyond the ken of the third-person perspective of science, for example the notion of some sort of mystical force of life, *élan vital*, have been reduced to rigorous formalisms (e.g., DNA code). Admittedly, we do not currently have a full accounting of how it is that we experience a first-person perspective on reality, but given science's track record, it is presumed to be merely a matter of time before these experiences are explained with precisely the same type of accounts that have been used so successfully to explain so much so far ([Churchland 1989](#)). People may feel as if they have some type of privileged perspective, as if the view from within their own minds could never be reduced to and explained by the machinations of atoms, but this is just shortsightedness, perhaps fueled by some evolutionary advantage to view mind and matter as different ([Bloom 2009](#)).

There is much to be said for material reductionism, as it draws on the very assumptions

that have led to the remarkable progress of science. To appeal to the existence of some other distinct realm of reality beyond the objectively physical smacks of ghosts and fairy dust (e.g., [Jackson 1982](#)). To date, while the previous analysis has revealed the marked advances to our understanding that emerge when we consider people's first-person perspectives, no *explanation* in science has required abandoning an exclusive reliance on mutually verifiable third-person observations. In other words, although I will soon suggest cases that may challenge this tradition, to date there are no third-person accounts of physical phenomena that have been undermined solely because they conflict with first-person experience. Given the track record of third-person accounts, it may seem hard to justify why one scientific question (the arising of conscious experience) should challenge an ontological perspective that is not problematic for anything else.

4.2 Ontological first-person perspective—What material reductionism leaves out

Although material reductionism provides an outstanding vantage for accounting for the physical world, it comes up wanting when the mind is inspected from a first-person perspective. The essential challenge is that even if a materialistic explanation is able to account for how the mind functions, this does not explain how it is that there is a subjective experience associated with it, or why that experience is as it is. As [Jackson \(1982\)](#) puts it:

Tell me everything physical there is to tell about what is going on in a living brain, the kind of states, their functional role, their relation to what goes on at other times and in other brains, and so on and so forth, and be I as clever as can be in fitting it all together, you won't have told me about the hurtfulness of pains, the itchiness of itches, pangs of jealousy, or about the characteristic experience of tasting a lemon, smelling a rose, hearing a loud noise or seeing the sky. (p. 127)

Jackson introduces the canonical example of Mary the color scientist to illustrate this point. Imagine that Mary is a color scientist who has been brought up in a black and white room and has never experienced red; nevertheless, she knows all there is to know about the physical processes relevant to color vision. Jackson's point is that if she later experiences red firsthand, she will learn a new fact (the experience of red) that all of her physical knowledge was insufficient to provide. Complete physical knowledge about a subjective experience is insufficient to entirely know all there is to know about that experience. One has to actually have the first-person experience to fully understand it.

A second criticism of material reductionism involves its inability to explain the arising of conscious experience. It is quite straightforward to imagine how physical processes could account for the structure and function of the mind in much the same way that they can explain the structure of computer hardware and the functions of computer software. But such an account would not explain how subjectivity itself arises or what it is like from the vantage of the experiencer. Similarly, even if we were to create a computer that perfectly emulated a conscious being, we could not know whether it was genuinely conscious, and if it were, "what it is like to be" (Nagel 1974) a computer.

The inherent difficulty of conceptualizing how material objects enjoy subjective experience is further illustrated by a third criticism of material reductionism, namely that it is possible to conceive of a system that has all of the physical characteristics of a conscious being, but nevertheless lacks consciousness. Philosophical zombies (Chalmers 1995) are hypothetical human beings who have no internal experience but are otherwise identical to normal people in all other physical measurements and behaviors (including claiming that they are conscious). Although there is no way of demonstrating that such creatures could ever exist, there is also no way of demonstrating that they couldn't. Finding the neural correlates of consciousness helps not an iota, as even a zombie who reported consciousness in certain brain states would still not be actually enjoying a genuine experiential

state. If zombies that are physically indistinguishable from experiencing humans could in principle exist, then there is nothing inherent in what is known about physical systems that speaks to the arising of consciousness. This presents a major problem to the prevailing material reductionist view because it offers no way to distinguish between philosophical zombies and the non-zombies.

The essential problem of the exclusively third-person perspective of material reductionism is that it is forced to ignore all aspects of experience that cannot be reduced to a third-person perspective. A thought experiment may help to provide a further "intuition pump" (Dennett 2014) for illustrating just how special that extra something might be. Consider the following science fiction variant on the classic Faustian bargain (Goethe 1867). One day, to your amazement, a flying saucer lands in front of you and a member of a clearly more advanced species emerges and says that he/she (it's unclear) has been enjoying our debates about the mind-body problem, which his/her civilization has solved. If philosophical zombies are logically³ possible, you can be turned into one. He/she offers you all the gold you can imagine (they've also mastered alchemy) if you are willing to accept the risk of becoming a zombie. If a zombie is a logical possibility, you will be transformed into one. From everyone else's perspective (i.e., the third-person perspective), you will be exactly as you were before (just much richer). However, you will not actually have any experience at all; you will simply seem to others as if you do. Would you take the bargain? Hard-nosed material reductionists say they would (D. Dennett, personal communication, 7/15/2014; M. Graziano, 6/10/2014, personal communication), but many of the rest of us might not. What is the value of untold wealth, if there is no inner experience by which it can be enjoyed?

The *Zombie Faustian Bargain* serves as a useful intuition pump for illustrating the im-

³ Let's just assume, for the sake of argument, that the aliens had solved the tricky issue of moving from logical to nomological possibility, that is that if it is possible for a philosophical zombie to exist in any conceivable universe, that it would be possible for you to become one.

portance of the extra something that is left out of the third-person material reductionist perspective. Nevertheless, it is clearly a fanciful proposition and material reductionists might reasonably argue that there is not much to worry about if the only cost to adopting their view is not knowing how to respond to such an unlikely scenario. However, there are numerous other examples closer to home where the limits of a third-person accounting of consciousness become relevant. Issues surrounding the nature and existence of consciousness in other species, fetuses, and computers all revolve around inferences about first-person experiences that gravely exceed all known or conceived ways of reconciliation.

A less obvious domain for a clash between the current prevailing third-person perspective of science and first-person experiences arises in, of all places, physics. Although there has been some speculation, now largely disregarded by the mainstream, that consciousness could have something to do with the collapse of the wave function in quantum physics (Wigner & Margenau 1967), in general, consciousness is assumed to have little relevance to physics. However, there are two current assumptions in physics that seem to squarely contradict first-person experience. Specifically, physicists believe that the flow of time is an illusion and that there is nothing special about the present. Before considering why these claims are so problematic for the existence of subjective experience, let us first consider why physics makes this claim.

4.3 Why physicists dismiss the flow of time and the privileged present

In considering the nature of time, physicists often “spatialize” it. In other words, they attempt to place it on a similar footing to the traditional three dimensions of space (see Figure 10). Though differing from spatial dimensions in important respects (Einstein 2001), the notion of time as similar to a spatial dimension is a key feature of the prevailing Einstein/Minkowski interpretation of special relativity theory. Space and time are combined in this theory into one concept: space-time. The spatialization of time

allows the depiction of a “block universe” in which the traditional spatial dimensions are reduced (for purposes of visual illustration) to two dimensions from three, and time is added as a third dimension. Such a depiction can be thought of as a space-time “loaf of bread,” where each narrow cross-section of the loaf (“slice”) constitutes a moment in time of the entire universe. According to the block universe view (widely held by today’s physicists), all slices—past, present, and future—already exist. This arises from the relativity of simultaneity, which means that “now” is different for different observers. It is simply that each individual observer is privy to only one moment (slice) at a time. From the vantage of a block universe, the only thing that seems to actually move in time is consciousness itself (i.e., the observer). This means that from the vantage of the prevailing view of physics, the flow of time is not a part of objective reality but simply an artifact of subjective experience. As Stanford physicist Linde (2004) notes: “Thus we see that without introducing an observer, we have a dead universe that does not evolve in time” (p. 25). What is more, once we conceive of the temporal dimension as the equivalent of another spatial dimension, then there are not enough degrees of freedom for the observer to move in time; that is, movement requires a rate in time, but time in the block universe is already represented as a spatial dimension, and thus cannot also be used as the metric that establishes the rate of movement through time. As the physicist Paul Davies (2002) puts it:

Nothing other than a conscious observer registers the flow of time. A clock measures durations between events much as a measuring tape measures distance between places; it does not measure the ‘speed’ with which one moment succeeds another. Therefore it appears that the flow is subjective, not objective. (p. 36)

The upshot of this reasoning is that the flow of time is an illusion, an artifact of consciousness. Again, as Davies (2002) puts it: “From the fixed past to the tangible present to the undecided

future, it feels as though time flows inexorably on. But that is an illusion” (p. 32).

Figure 12: Although the conventional view derived from experience is that the present is real and moves through time, current views in physics say this is erroneous. According to the standard block universe view in physics, all moments—past, present, and future—are equally real. The flow of time and the privileged present are seen as illusions of consciousness (from [Davies 2002](#)).

The characterization of reality as a block universe, with the flow of time as an illusion of consciousness, also leads to the conclusion that the privileged present is an illusion. One of the most pronounced aspects of consciousness is its extension in time. Consciousness extends in time and thereby gains the “now” in which it resides. First-person observers may remember the past or imagine the future (as often happens during mind-wandering) but ultimately mental time travel always takes place in the present. The observer perpetually and exclusively resides in the present. In this sense, it seems intuitively self-evident that the “now” is privileged. But not so from the current vantage of the block universe in physics, where the present is treated exactly the same as the past and the future. As Einstein himself observed, “The past, present and future are only illusions, even if stubborn ones” (quoted in [Hoffmann & Dukas 1972](#), p. 258). Again, the problem is that the only thing that defines the present from the vantage of a block universe is that it is where the observer perceives itself to be at any particular moment in time. But from the vantage of a block universe, all moments of time exist simultaneously.

The notions that the flow of time and the privileged present are merely illusions of consciousness are less problematic from a third-person

perspective than the first-person perspective. If there is no ultimate reality to subjectivity, then there is no problem making claims that are directly in opposition to subjective experience. At a recent public lecture, I asked the noted physicist Brian Greene how he reconciled physics’ static view of nature with the self-evidently dynamic experience of consciousness. His reply was that he “sees a psychiatrist,” that consciousness is capable of all sorts of illusions, and that the flow of time is just another example of the artifacts of consciousness.

While as detailed in the earlier section of this paper, I am the first to concede that our first-person reports can be fallible, as consciousness is capable of all sorts of illusions, it is hard for me to conceive of how consciousness could create an illusion of the flow of time, or the privileged present. There are several reasons why I am skeptical of this claim. First, just as matter must have extension in space in order to exist, so too it seems that consciousness must have extension in time. If consciousness had no “thickness” in time, then I simply do not understand how it could exist any more than an object could exist without some extension in space. Time is the dimension in which consciousness extends. Although the objective duration of the specious present ([James 1918](#)) may be rather modest ([Pöppel 1997](#)) without at least some extension in time I do not see how there can be any consciousness at all. Second, my experience is defined in terms of the flow of time and a privileged present; the stream of my consciousness is essentially a succession of “nows,” with the present always entailing the bridge between the past now and the future now. In a nutshell, from my first-person perspective I find the reality of the flow of time and the privileged present as compelling as the existence of physical reality itself (which also could in principle be an illusion, [Descartes 1641/1996](#)).

4.4 Reconciling first- and third-person perspectives of reality

Those who subscribe to a strict material reductionist perspective insist that when first-person experience suggests characteristics of reality

that are not readily handled by a third-person account, that those aspects must be rejected. From a strict materialist perspective, the seemingly privileged knowledge afforded by subjective experience, the flow of time, and the unique significance of the present all must be disregarded as illusions of consciousness. But herein lies the rub. The third-person perspective on reality is adequate as long as it provides constructs that correspond to the core aspects of the first-person perspective. However, when that perspective requires me to abandon absolutely fundamental aspects of my experience, then I am forced to question the assumptions that impose that requirement.

Whether we acknowledge it or not, all of us must discern for ourselves what aspects of existence to take as axiomatic. By definition, axioms cannot be empirically proven or logically deduced, rather they are self-evident truths that must be taken as givens. Perhaps the most fundamental of all such axioms is that physical reality exists; i.e., that I am not residing in a solipsistic mirage. Ultimately, while I grant the ontological reality of the physical world, in an important sense I am less epistemologically certain of it than I am of partaking in subjective experience. Ultimately, the only thing that I can know with absolute confidence is that I am currently enjoying a first-person experience (Descartes 1996). Physical reality could be a dream, I could be a brain in a vat or the matrix, indeed even my past could be an illusion, but there is simply no question but that I am currently having an experience. It might be an illusory experience⁴, but even an illusory experience is still experienced. Thus, although it is conceivable that physical reality could be an illusion, it is inconceivable (at least to me) that the occurrence of my subjective experience could be entirely baseless. This leads me to conclude that the existence of subjective experience and all premises that necessarily underpin its existence must be treated on equal ontological grounds to that of physical reality. Accordingly, if we grant subjective experience an ontological status equivalent to that of

objective reality then we must seriously question any characterization of objective reality that challenges the essential qualities of subjective reality. While much of our subjective experience may be an illusion, it is very difficult to see how the privileged vantage of subjective experience, the flow of time, or the unique status of the present could be such. To quote the philosopher David Ray Griffin (2007): “The reality of time is a more fundamental and stubborn fact than the alleged facts on which its denial is based” (p. 119).

A variety of approaches has been offered to accommodate the seeming limitations of a purely physical accounting of consciousness. Idealism (Berkeley 1878; Goswami 1993; Hoffman 2008) responds to the seemingly superior ontological status of subjective experience (i.e., its existence is more certain than an inferred external reality) by suggesting that if one must be reduced to the other, then it should be physical reality that is seen to be an outgrowth of subjectivity, rather than the other way round (as the material reductionists contend). Although difficult to refute, idealism (at least in the macro sense of conscious beings creating reality with consciousness) appears to discount the independent existence of a natural world, and thus seems at odds with a scientific vantage.

Another approach for reconciling the seemingly incommensurate existence of the subjective and objective is to pose that they both exist as two interacting yet distinct realms. This approach (substance dualism) was favored by Descartes, but it has a serious logical deficiency (at least as originally formulated): if two realms are truly incommensurate and distinct, then there seems to be no way for them to interact. To posit a “ghost in the machine” (Ryle 2009) is to assume that the ghost can affect the machine, which means that they share some common ground and therefore are not entirely distinct realms. This difficulty has proven a major problem for substance dualism (Armstrong 1999), although see Chalmers (2002) for arguments as to why the challenge of understanding the causal nexus between the mental and physical is not unlike similar issues of causality observed within the physical realm.

⁴ An illusory experience being defined as an experience that does not correspond to actual reality, such as a hallucination. Note that a philosophical zombie does not have an illusory experience of being conscious, it has no experience at all.

In my view, the seeming impasse between the third- and first-person perspectives of reality strongly suggests the existence of some other meta-perspective that can accommodate them both. Like the reversible images that can initially invoke one of two entirely opposed interpretations, but that can subsequently be reconciled from a vantage that recognizes the reality of both, (even if they cannot be both apprehended simultaneously) so too it seems there must be some meta-perspective for reconciling first- and third-person vantages on reality. In other words, it seems likely that there exists a higher order outlook that simultaneously acknowledges the manner in which neither perspective can simply be reduced to the other, yet still offers a mode of resolution. It is clearly easier to recognize the need for a meta-perspective than to identify precisely what such a view might be. Nevertheless, it seems a goal well worth pursuing.

Over the years, a number of scholars have tried their hand at envisioning a vantage that neither tries to reduce the subjective to the physical, nor the physical to the subjective, but rather conceives of some common ground or property that may be reflective of both. This approach, often referred to as neutral monism (Chalmers 2002; Feigl 1958; James 1904; Russell 1927), though with close affinities to dual aspect theories (e.g., Jackson 1982; Nagel 1986; Spinoza 1677/1985; Velmans 2009), attempts to identify a neutral realm of existence that can be alternately characterized as mental, physical, or neither.

The ever-changing present represents a core element of the common ground between subjectivity and objectivity that is invoked in several accountings of neutral monism. For William James, the neutral realm was the present:

The instant field of the present is at all times what I call the ‘pure’ experience. It is only virtually or potentially either object or subject as yet. For the time being, it is plain, unqualified actuality, or existence, a simple that. (1904, p. 23)

For Bertrand Russell, the neutral realm was the event: “Everything in the world is composed of

‘events.’... An ‘event,’ as I understand it ... is something occupying a small finite amount of space-time.” For Alfred North Whitehead (1929), the present also served as the nexus of conjunction between the objective and the subjective. In Whitehead’s panpsychic characterization of reality, the interface between first- and third-person perspectives occurs in the “creative advance” of the present in which time marches forward in a continual alternation among all elements of reality between subjective and objective states (for further discussions of Whitehead’s account, see Griffin 2007; Hunt 2011).

Information represents a second element that unites several efforts to find the neutral realm from which both subjectivity and objectivity arise. As Chalmers (1996) observes:

Perhaps, then, the intrinsic nature required to ground the information states is closely related to the intrinsic nature present in phenomenology. Perhaps one is even constitutive of the other. That way, we get away with a cheap and elegant ontology, and solve the two problems in a single blow. (pp. 304–305)

Sayre (1976) similarly argues that “the concept of information provides a primitive for the analysis of both the physical and the mental.” The notion that information somehow serves as the interface between the subjective and the objective is also a central component of Tononi’s (2008) recent suggestion that consciousness arises when matter produces “integrated information,” which is defined as “the amount of information generated by a complex of elements, above and beyond the information generated by its parts” (p. 216). The basic idea is that complex systems that integrate information, even potentially non-biological ones, will experience some minimal amount of consciousness: something it is like to be that system (see also Koch 2012, 2013).

In sum, although there is considerable variability in the manner in which scholars have conceptualized the common ground of reality from which both the objective and subjective emerge, two common elements are 1) that the

interface occurs within the ongoing march of the present, and 2) that it is constituted within the shared informational properties entailed in both objective and subjective states. A final shared aspect of many of these approaches is that subjectivity represents a fundamental attribute of the universe that either permeates all aspects of matter (panpsychism), or exists as a potentiality of matter that emerges when certain conditions are met (protopanpsychism; Chalmers 2002). Drawing on these general observations, I turn now to offering my own highly speculative conjectures regarding a meta-perspective on reality that may provide the shared foundation for first- and third-person perspectives.

4.5 The possibility of a subjective dimension of reality

Many scholars who posit that subjectivity is an essential aspect of reality argue that ultimately physics may need to be expanded to include constructs corresponding to subjective states. As the philosopher David Chalmers (1995) observed:

I propose that conscious experience be considered a fundamental feature, irreducible to anything more basic. ... In the 19th century it turned out that electromagnetic phenomena could not be explained in terms of previously known principles. As a consequence, scientists introduced electromagnetic charge as a new fundamental entity and studied the associated fundamental laws. Similar reasoning should be applied to consciousness. If existing fundamental theories cannot encompass it, then something new is required. (p. 96)

Eminent physicist Andrei Linde (1990) has also speculated that consciousness may some day be recognized as part of our understanding of physics:

Could it be that consciousness is an equally important part of the consistent picture of our world, despite the fact that so far one could safely ignore it in the description of

the well-studied physical processes? Will it not turn out, with the further development of science, that the study of the universe and the study of consciousness are inseparably linked, and that ultimate progress in the one will be impossible without progress in the other? (p. 27)

The critical question, of course, is: What in the physical universe might correspond to the arising of consciousness?

To recap, the physical realm as currently construed offers no place for subjective experience, the flow of time, or the uniqueness of the present. In order to bridge the gap between physical reality and subjectivity, scholars have posited the existence of a neutral realm that gives rise to both. Though varied in their emphasis, two elements have emerged as likely components of this neutral ground: the evolving present and information. Together these considerations suggest that a conjoined first-person/third-person meta-perspective will likely conceptualize subjectivity, the present, and the flow of time within an architecture that closely links information to an ever-changing now. Toward this end I offer the following conjecture: *consciousness arises via the changing informational states associated with an observer's movement through objective time relative to a currently unacknowledged dimension or dimensions of subjective time.*

Although speculative and highly underspecified, the above account has intuitive appeal. The sense of moving through time from one informational state to the next is clearly central to experience. Indeed it could well be said that it is the defining aspect of our existence. It is difficult to conceive of experience without invoking movement in time and change in informational state. Recall however that the current block universe portrayal of time provides no way to conceptualize moving through time, as movement in time would require change in time at a rate that could never be specified. As the Physicist Paul Davies observes:

But what meaning can be attached to the movement of time itself? Relative to what does it move? Whereas other types of motion relate one physical process to another, the

putative flow of time relates time to itself. Posing the simple question ‘How fast does time pass?’ exposes the absurdity of the very idea. The trivial answer ‘One second per second’ tells us nothing at all. (2002, p. 8)

subjective dimension (or dimensions) in which the observer moves relative to physical space-time (e.g., Smythies 2003). Noting the inability of current theories of physics to account for the flow of time or the existence of subjective experience, physicist Linde speculates that dimensions of consciousness may be required to provide the necessary degrees of freedom. Linde (2004) observes:

Thus to move in time requires movement in relationship to some dimension other than time itself. The postulation of an additional temporal dimension allows observers to change information states in objective time relative to subjective time. Indeed, it seems possible (and perhaps even a mathematical necessity) that in order to extend in and move through space-time (i.e., the block universe), there needs to be at least one additional dimension to provide the degree of freedom necessary to enable such movement (Schooler et al. 2011). In other words, if we accept the block universe model⁵ of reality, then in order to move through objective time, we have to move relative to something, and that something cannot itself be time because all time exists simultaneously in the block universe. A seemingly reasonable solution is to posit an additional dimension (or dimensions) of time. Although the postulation of additional dimensions of reality should not be taken lightly, it is not without precedent. In physics, string theory has postulated seven additional spatial dimensions beyond the three dimensions of space and one dimension of time that are customarily acknowledged (Greene 2004). If there can be multiple dimensions of space, then might there not also be additional dimensions of time? Indeed, some physicists have argued that an additional dimension of time might be very useful for conceptualizing various issues in physics (Bars et al. 1998). If the postulation of an additional dimension (or dimensions) of subjective time could also resolve the paradox of time and provide a realm for subjectivity, then surely that would also warrant its consideration as a possibility.

I am not the first to suggest that the failure of objective time (as it is currently conceptualized) to afford the flow of time or inner experience may require the postulation of an additional

Is it possible that consciousness, like space-time, has its own intrinsic degrees of freedom, and that neglecting these will lead to a description of the universe that is fundamentally incomplete? What if our perceptions are as real (or maybe, in a certain sense, are even more real) than material objects? What if my red, my blue, my pain, are really existing objects, not merely reflections of the really existing material world? Is it possible to introduce a ‘space of elements of consciousness’....? (p. 451)

I remain agnostic regarding precisely how many additional dimensions may be required in order to provide the degrees of freedom necessary for time to flow and consciousness to have extensions in the present. Indeed, I am not even committed to the notion that such a realm must necessarily be thought of as possessing all of the mathematical formalities of spatial dimensions. My point is simply that the current material reductionist model of reality has left no room for time to flow or now to exist. It is as if physics has built a pendulum clock but left no space for the pendulum to swing. In statistics, there always must be one more degree of freedom than the total number of subjects and conditions so as to leave the freedom for variables to vary. I believe that such degrees of freedom are similarly required to enable experience to flow through time.

A dynamic depiction of the value of adding a second temporal dimension is illustrated in the following three examples depicting a simple event of bottles breaking. The first (Figure 13; see video clip in its description) depicts the event as it would unfold from the first-person perspective, a dramatic shattering of initially intact colored bottles. The second example (Figure 14) transforms this event into a

⁵ Another possible way of reconciling the challenges of the flow of time and the present is to discard the notion of the block universe. While this vantage is the prevailing view in physics (Greene 2004), some have suggested that it needs revising (Hunt 2014; Smolin 2013).

block universe depiction in which objective time is spatialized, and each slice corresponds to a separate moment of the event. Notice that in the block universe representation there is no motion (and hence no video clip), and no singular frame (i.e., slice) corresponds to “now.” However, in the third example (Figure 15; see video clip in its description), an additional temporal dimension is introduced so that the observer can move through the block universe. Frame by frame a moving “now” marches through the block universe. By adding a second temporal dimension to the block universe, the dynamical experience of events unfolding is once again achieved.

A spatialized depiction of the notion of observers moving through subjective time relative to physical space and objective time is presented in Figures 16–18. As previously, noted, in the standard presentation of the block universe the three dimensions of space are, for graphical depiction, reduced down two dimensions (Figure 16). Here, in order to provide room to depict an additional dimension, physical space is further reduced to one dimension (Figure 17). Within this characterization, it is possible to see how the introduction of an additional dimension of subjective time (Figure 18) provides the necessary degree of freedom to enable an observer to move through time, as they can now move through physical time via a succession of moments in subjective time.

Figure 13: An event of breaking vases as it would be experienced from a first-person perspective. See http://open-mind.net/videomaterials/schooler_bootle_loaf5.mp4/view.

Figure 14: The breaking vases event is depicted as a block universe, with the temporal dimension spatialized, and each moment corresponding to a separate “slice.” Notice that there is no way to depict “now” and no way to move through it.

Figure 15: The breaking vases event is again depicted as a block universe, with the addition of a second temporal dimension. The moving present is represented as successive illuminated slices that progress from moment to moment through the block universe. Notice that witnessing movement through the block universe requires an additional dimension of time as the standard dimension of objective time is already dedicated to spatializing the block universe. See <http://open-mind.net/videomaterials/schooler-bottles-loaf-1.mp4/view>.

An interesting implication of this characterization is that observers can vary in the granularity (i.e., extent) of their moments. Notice how in Figure 17, the observer with the smaller spatial extent also occupies smaller successive moments in time.⁶ Intriguingly, there is evidence to support this view: recent findings suggest that smaller vertebrates may have a different “temporal grain size” relative to larger verteb-

⁶ Although subjective agents may move in subjective time relative to objective time in varying sized steps, it does not appear that there is necessarily a single temporal grain size for the processing of all sensory stimuli. Specifically, Pöppel (1997) finds that the duration of what constitutes a single moment (as assessed by temporal discrimination of successive sensory events) varies between sensory modalities. This observation seems potentially consistent with the suggestion that even within a single individual there may be multiple distinct conscious systems (Schooler et al. 2011; Zeki 2003) corresponding to different sensory levels and systems.

rates. Specifically, Healy et al. (2013) report a negative correlation between vertebrate size and the highest rate at which they can detect the flickering of a light (the flicker fusion rate). From the vantage of the current discussion, these findings suggest that the consciousness of smaller animals may move through subjective time relative to physical time at a faster rate than larger animals. This may be why it is so hard to swat a fly: from its vantage, we are moving in slow motion.

Figure 16: The observer depicted in the standard block universe with two dimensions of space. In the standard block universe, the observer is static and exists simultaneously in all locations. There is an insufficient number of degrees of freedom for the existence of a genuine now or movement in time.

Figure 17: The observer depicted in a standard block universe with one dimension of space. As with the standard convention of depicting the block universe in two spatial dimensions instead of three, the reduction to one spatial dimension is useful for illustrative purposes.

A critical question that arises in postulating an additional subjective dimension (or dimensions) of time is: what are the properties of this dimension? I have left the answer to this question intentionally vague as I believe under-

specification leaves greater room to flesh out the rudimentary idea in various possible ways. With that said, it seems plausible that the subjective temporal dimension(s) could correspond to subjective informational states in the same way that objective informational states correspond to different moments of objective time. As noted, subjective informational states are aligned with but not identical to objective informational states (recall Mary, the color scientist). Moreover, current theories of neutral monism posit information as being one of the core potential interfaces between the objective and the subjective. Thus, characterizing subjective time as corresponding to distinct subjective informational states that are aligned with but not identical to objective informational states seems a promising characterization of the nexus between the objective and the subjective.

Figure 18: The observer depicted moving through a dynamic block universe with one dimension of physical space and the introduction of an additional subjective temporal dimension. In this model, there are a sufficient number of degrees of freedom to enable the observer to move in objective time relative to subjective time. The present can also be depicted as a series of moments extending in subjective time, objective time, and physical space.

A further potential benefit of the conjecture that experience emerges from movement in a subjective temporal dimension relative to objective time is that it provides a potential way of conceptualizing the nature of experience in the universe. Many scholars throughout history, and particularly those sympathetic to neutral monism, have articulated some type of panpsychic vision of nature, where all elements of

matter are seen as partaking in some rudimentary experience or proto-experience. Advocates of some version of panpsychism include [Spinoza \(1677/1985\)](#), [Leibniz \(1989\)](#), [James \(1909\)](#), [Bergson \(1896/1912\)](#), and [Whitehead \(1929\)](#). More recent adopters of this view include [Hameroff & Powell \(2009\)](#), [Chalmers \(1995\)](#), [Hunt \(2011, 2014\)](#), [Koch 2013](#), [Schooler et al. \(2011\)](#), [Skrbina \(2005\)](#), and [Strawson \(2008\)](#). The notion that the flow of time emerges by virtue of movement in a subjective temporal dimension relative to an objective one provides a potential way of conceptualizing how all of matter may partake in experience at varying levels of complexity. Accordingly, if experience emerges by movement through a dimension of subjective time relative to objective time, then it seems quite plausible that elements associated with all of matter may be on a shared trajectory through these two (or more) temporal dimensions, and thus may be enjoying some form of experience. In other words, if consciousness emerges from something as potentially ubiquitous as movement through an additional time dimension, then it seems plausible that all matter could enjoy some modicum of experience.

Figure 19: Two observers depicted moving through a dynamic block universe. Notice how this account enables varying temporal grain sizes between observers.

Although the present view provides a way of conceptualizing how matter might partake in at least some rudimentary form of experience, it need not suggest that all objects—collections of matter—are themselves sentient beings. To use [Nagel’s \(1974\)](#) terminology, there need be nothing “that it is like to be” a rock, for example.

Rather, the claim is that at some level, the constituent elements of a rock (and all other material objects) partake in at least some very rudimentary kind of experience, what the physicist/philosopher [Alfred North Whitehead \(1929\)](#) referred to as “actual entities”. In other words, according to the panpsychic tradition, matter is constituted of collections of individual elements each of which partake in some minimal experience. The subjective state of these individual experiential elements (or “actual entities”) is presumed to be extremely simple, and for the most part, when they combine, it is assumed that they form “mere aggregates” that do not entail a higher-order experience. However, under some circumstances, and in particular when present in certain organic structures, these simple actual entities may combine to form higher-order actual entities corresponding to the conscious agents that we typically acknowledge as such.

The notion of observers moving through objective time relative to a subjective temporal dimension may offer a possible direction toward solving the perennial “combination problem” of panpsychism, namely discerning how rudimentary proto-experiences of individual elements can combine to form the larger higher-order experiences that we enjoy ([Hunt 2011](#)). Accordingly, it seems possible that experience may correspond to oscillations in objective time relative to subjective time. As depicted in [Figures 18 and 19](#), I have speculated that observers may move in subjective time relative to objective time in discrete steps. The precise timing of these steps from one moment to the next could potentially provide the foundation for a unified experience among elements (i.e., an approach to the combination problem). When elements oscillate in synchrony (i.e., when they all jump from one moment in subjective time to the next), this may produce a unity of conscious experience. Nervous systems may provide an organizational structure that enables material elements to oscillate in synchrony and thereby produce larger, more organized fields of subjective experience. In this sense, the combination problem may be addressed by, and our holistic experience may result from, the common wavelength of oscilla-

tion through objective time relative to subjective time that constituent elements of a singular experience partake in. Put colloquially, each of us may have our own unique wavelength moving through subjective time relative to objective time.

Importantly, these speculations are presented as an example of the kind of meta-perspective that might enable an acknowledgement of the reality of both first- and third-person vantages. This is far from a formal model, and leaves much unspecified. For example, although I believe it could be possible to formalize the relationship between subjective time and informational states, this remains a major conjecture. Other elements of the framework, such as the notion that observers move in discrete steps in subjective and objective time, and that the pattern of oscillation may provide a way of addressing the “combination problem,” also are merely conjectures. I suspect that there are potentially a great variety of ways of conceptualizing how observers might move in a dimension of subjective time relative to objective time. My goal in attempting a rudimentary depiction of this notion is simply to fuel the conversation.⁷

Even if scientists resist the suggestion of an additional temporal dimension of reality, characterizing how experience can reside in a physical world will require explicating how observers move in physical time relative to changes in subjectively apprehended information. In other words, to be an observer in reality is arguably to reside in a now that corresponds

to a “location” within continually changing information states. Thus, conceptualizing the experience of the observer requires understanding how that observer moves between informational states over time. Given that the present prevailing view of physics does not afford the degrees of freedom to actually move in time, understanding how an observer changes informational states relative to time seems to require at a minimum the postulation of a virtual dimension of subjective time. Whether that dimension is given ontological status as a genuine aspect of reality depends on one’s perspective, but that of course is precisely the point.

For those who are willing to entertain the possibility of the kind of meta-perspective that I am envisioning, there are a number of possible ways forward. Perhaps, and most dramatically, it seems plausible that the existence of an additional temporal dimension may have empirical consequences. Although received with understandable skepticism, evidence continues to accumulate for precognition (i.e., that the mind is sensitive to events that have not yet occurred). There is a long tradition of research in this area (Honorton & Ferrari 1989). For example, Bem (2011) recently published a series of nine studies in a highly respected journal that seem to suggest evidence of genuine precognition and a subsequent meta-analysis of 90 additional findings appear to further substantiate these findings (Bem et al. 2014). Not surprisingly, these claims have been met with considerable skepticism (e.g., Ritchie et al. 2012; Wagenmakers et al. 2011). Given their profound challenge to our current scientific understanding of reality, claims of this sort will require studies that offer highly tangible evidence that cannot be attributed to artifact or statistical anomaly, e.g., taking advantage of people’s alleged precognitive capacities to make consistent future predictions of real world events, such as the future outcome of roulette wheel spins or the stock market (Franklin et al. in press). Nevertheless, the demonstration of robust findings of precognition might provide the type of data that could inform theories of how consciousness interfaces with time in a manner not currently considered in modern science.

⁷ Several years ago, I presented the idea that consciousness entails movement through a subjective dimension of time using the depiction in Figure 15 and illustrated at the site: <http://open-mind.net/videomaterials/schooler-bottles-loaf-1.mp4/view>. One of the attendees, Robert Forman (see his description of the event, Forman 2008), suggested that although he was intrigued by my depiction, that it did not square with his intuitions. In my model, the block universe is fixed and consciousness marches through it. He suggested that his intuition was the opposite: namely that the field of the observer remains fixed and time passes by, or changes within it. This alternative vantage in which time evolves through a fixed observer seems a worthy alternative perspective for conceptualizing the ever-changing now that may be closer to approximating several other neutral monist vantages (e.g., Whitehead 1929, and Hunt 2014). While I think this alternative viewpoint is worthy of consideration, I also think it is likely that the two vantages are logically equivalent—it is simply a question of which one is taken as the fixed frame of reference. Nevertheless the manner in which we construe the movement of time relative to the individual may have important psychological consequences (Casasanto & Boroditsky 2008).

Other approaches for fleshing out the kind of meta-perspective suggested here may include quantitative reconceptualization of existing findings. Although quantum theory is one of the most precisely predictive theories ever conceived, its explanation remains a mystery. In particular, the manner in which measurement seems to affect outcomes, and the theoretical relationship between measurement, consciousness, and the collapse of the wave function are not at all understood (Chalmers 2002). It seems possible that the postulation of an additional subjective dimension of time might lead to alternative ways of conceptualizing current formalism.⁸ Indeed it seems possible that once psychological constructs (such as a dimension of subjective time) are integrated with physical principles, that new psycho/physical laws of nature may emerge (Chalmers 2002; J. N. Schooler 2010). Alternatively, the notion that subjective experience emerges from movement through another dimension of time may resist empirical documentation, but may nevertheless remain a conjecture that appeals to some intuitions but not others.

Even if ultimately there is no conclusive ways of determining whether there exists an ad-

ditional subjective dimension of time this does not mean that the consideration or rejection of this view should be arbitrary. There are many judgments in life that rely on leanings that are not purely objective in nature. From ethics to art we routinely favor some views over others for reasons besides purely objective facts. Indeed the adoption or rejection of views close to those under discussion here are often based on subjective considerations. For example some physicists embrace string theory because of the elegance of its mathematics, whereas others reject it because there is no physical evidence to support it. Similarly there is great debate on how far down the phylogenetic scale we should postulate the existence of consciousness. Most of us have an opinion on this matter, but it remains entirely unclear whether there will ever be a purely objective way to resolve it. In the absence of objective evidence, our positions on these issues are far from arbitrary, rather they are based on the same sorts of sensibilities and intuitions that underpin many of our most heartfelt convictions.

In a final further effort to appeal to readers' intuitions, let me introduce one last metaphor for the meta-perspective I am striving for: consider the allegorical tale of *Flatland*, written by Edwin Abbott (1885) more than a century ago. Flatland depicts a two-dimensional world that is visited by a three-dimensional being (a sphere). The sphere takes a citizen of Flatland (a square) on a journey through the third dimension, offering the square a vantage on his reality that he never had before. The story of Flatland offers a number of useful lessons for the present discussion. First, it provides a powerful metaphor for thinking about the existence of additional dimensions of reality. Long preceding relativity theory, which treats time like a fourth dimension, or string theory, which currently posits the existence of up to seven additional spatial dimensions (Greene 2004), Abbott's tale introduces us to the concept of higher-order dimensions. Flatland describes how additional dimensions can be both embedded in and yet simultaneously transcend what we know. The parallels to consciousness are also striking: when the square is taken through the

⁸ Although not a mathematician it seems plausible to me that existing mathematical formalisms might be adopted to accommodate some of the present conjectures. Most speculatively, a quantitative characterization of additional dimensions of time might correspond in some manner to the many worlds account of quantum mechanics (Everett 1957) that postulates that every potential alternative outcome of quantum events entails a different branching parallel universe. It strikes me as possible that these so called "many worlds" could correspond to different coordinates in additional temporal dimensions. From this vantage, the block universe might be better conceived of as a block multiverse, with innumerable distinct temporal projections. Several multi-dimensional theories of objective time might (e.g., Bars et al. 1998; Craig & Weinstein 2008) also be relevant. Also potentially pertinent are various existing quantitative efforts to reconcile experience and physical matter. For example, the magnitude of a conscious observer's extension in subjective time might correspond to Tononi's (2008) quantitative assessment of Φ (pronounced "fi") which he characterizes as corresponding to the amount of integrated information that a conscious observer apprehends at any particular moment. Other potentially relevant formal approaches for reconciling consciousness with physical matter include: Hameroff & Penrose's (2014) efforts to explain how consciousness may "consists of a sequence of discrete events, each being a moment of 'objective reduction' (OR) of a quantum state" (p. 73), and Tegmark's (2014) suggestion that "consciousness can be understood as a state of matter, 'perceptronium', with distinctive information processing abilities" (p. 1). The relevance of these various approaches is highly speculative, and indeed given their disparities it is unlikely that they could be mutually accommodated. My point in mentioning them is simply to point the way towards some more formal approaches that might hold potential for advancing this discussion.

third dimension, he suddenly sees inside the objects of Flatland. Like consciousness, movement in an additional dimension in Flatland enables the perception of an inside where none could otherwise be possible. Like consciousness's relationship to reality, an additional dimension intersects with the lower dimensions and yet is distinct from them. And like the recognition of an additional dimension in Flatland, positing consciousness as moving through objective time relative to a dimension (or dimensions) of subjective time provides an example of a meta-perspective that potentially offers observers a new way of conceptualizing their relationship with physical reality. Although I make no claims as to having fleshed out this meta-perspective, it is my hope that my arguments have persuaded at least some readers that it is a vantage worth considering.

5 Summary and final conclusions

In this paper I used the thesis that perspective shifting can fundamentally alter how we conceive and evaluate evidence as the backdrop for exploring one of the most perennial and challenging of all perspectives shifts: namely, between the subjective first-person perspective that provides each of us with a unique window onto reality, and the objective third-person perspective that serves as the consensual foundation for science. My arguments were divided into three sections, which though admittedly distinct in their focus, all converge in attempting to elucidate a rapprochement between the subjective and objective perspectives on human experience.

In the [first](#) section I introduced the notion of perspective shifting in the context of classic reversible images. Here I argued that reversible images provide a context for conceptualizing how the very same situation can be understood from two very different perspectives that appear to produce seemingly irreconcilable accounts of their contents. However, once this juxtaposition is recognized, a meta-perspective emerges that enables the appreciation of both perspectives even if they cannot be apprehended simultaneously. The perspective shifting and meta-perspective that arise from reversible images

provide a metaphor for conceptualizing the tension between the first- and third-person perspective for understanding human experience. Both researcher and the field of science itself have been divided on whether to take perspectives on human nature that emphasize inner experience or external behaviors. While historically this has been a debate on which researchers have been forced to take sides, I argue that we should strive towards a meta-perspective in which the two vantages can inform one another.

In the [second](#) section I sought to show how the third-person perspective of objective science can elucidate our understanding of first-person experience. Towards this end, I introduced the distinction between having an experience (experiential consciousness) and one's explicit understanding of that experience (meta-awareness). Historically when researchers have sought to understand people's actual experience they have relied on people's self-reports about what they believe they were experiencing. This has led some to argue that it is impossible to gain insight into underlying experience. However, I argue that through triangulation between self-reports and behavioral and physiological measures, it is possible to make reasoned inferences about people's actual experience; identifying both situations in which meta-awareness overlooks experience (temporal dissociations of meta-awareness) and cases in which it distorts them (translations dissociations of meta-awareness). This framework was fleshed out within an extensive review of research on mind-wandering that, because of its inherently private nature, provides an ideal testing ground for developing a third-person science of first-person experience. By assessing the relationship between people's behavioral and physiological measures and self-report this review concludes that while people's self-reports of mind-wandering routinely correspond to genuinely experienced instances of this mental state, they nevertheless often fail to notice mind-wandering while it is occurring.

In the [final](#) and most speculative section of this paper, I turned the tables around. Instead of asking how third-person science clarifies first-person experience, I asked how first-person experience may inform third-person science. Here I ar-

gued that there are certain aspects of first-person experience that are so fundamental that they may reasonably serve as axioms of existence that any construal of physical reality must be able to accommodate. As detailed in the [prior](#) section it is clear that many aspects of experience may be illusory but several can reasonably be construed as unassailable, including: the occurrence of experience, the flow of time and the privileged present. Notably, current accounts of physical reality offer no way of accommodating these inherent aspects of first-person experience. This conflict between seemingly self-evident aspects of personal experience and current accounts of physical reality leads me to posit that, like the reversible images that can only be accommodated by recognizing a larger meta-perspective in which they both reside, so too there must exist some meta-perspective that can accommodate both objective scientific facts and personally experienced ones. Towards this end I introduced a highly speculative conjecture about the larger framework in which both objective and subjective perspectives might reside. Namely that consciousness involves a fundamental aspect of the universe that arises via the changing informational states associated with an observer's movement through objective time relative to a currently unacknowledged dimension or dimensions of subjective time. Although highly speculative, I offer this account as an example of the kind of meta-perspective that may simultaneously accommodate extant objective observations and certain aspects of subjective experience that I find as compelling as the existence of physical reality itself.

In my view, bridging the objective/subjective divide will require adopting a meta-perspective in which the two points of view are viewed as alternative vantages on an underpinning reality that corresponds to both but can be fully accommodated by neither alone. As I attempted to illustrate at the outset, it is quite possible to hold inaccurate or incomplete beliefs about one's experience, and third-person science can help to illuminate such errors. However, from my vantage there are certain elements of subjective experience that are as axiomatic as any aspect of the physical realm. Nevertheless, I recognize that not all will see it this way. Some will remain exclusively

fixed to the third-person perspective of objective science, while others will conceive of reality exclusively from their own personal first-person point of view. In conceptualizing this breadth of perspectives, it is important to remain mindful of an essential insight of Bayes' theorem of probability. Bayes' theorem states that in calculating the probability of something one must integrate new evidence with one's *a priori* probabilities. From a Bayesian perspective, for those who believe that something is impossible (i.e., infinitely unlikely) there is no amount of evidence or argument that should sway them. The ontological reality of first-person experience seems very much to fit in this category. My arguments on this point will likely remain wholly unpersuasive to those who cannot conceive of subjective experience as offering an epistemological authority that rivals science. However, for those open to the possibility that science will need to find a way to accommodate the reality of both the subjective and objective perspectives, I hope my discussion offers some glimmers as to what such a meta-perspective might be like.

Acknowledgements

The writing of this paper was possible with the support of grants from the Templeton Foundation, the Institute of Educational Studies, and the Fetzer Franklin Fund. I am grateful to numerous individuals who commented on earlier versions of this manuscript, including Ben Baird, Robert Bernstein, James Broadway, Ashley Brumett, Michael Franklin, Tam Hunt, Jack Loomis, Ben Mooneyham, Michael Mrazek, Brett Ouimette, John Protzko, Claire Zedelius, and two anonymous reviewers. This work has also benefited from conversations with David Chalmers, Daniel Dennett, Daniel Gilbert, Mark Laufer, Wolfgang Lukas, Merrill McSpadden, Brianna Morseth, Dawa Tarchin Phillips, Daniel Povinelli, Carmi Schooler, Lael Schooler, Nina Schooler, Rachel Schooler, Edward Slingerland, Jan Wallecezk, Dan Wegner, Timothy Wilson, Sid Zagri, and many others too numerous to mention. Though they aided in the project and/or influenced my thinking, none of these individuals or organizations should be viewed as endorsing the sentiments presented here.

Bridging the Gap

A Commentary on Jonathan Schooler

Verena Gottschling

In my commentary on this rich paper, I will focus on the methodological approach proposed by Schooler. The main goal of this commentary is to introduce an improved and more detailed interpretation of Schooler's distinction between experiential consciousness and meta-awareness. I will address four issues. After summarizing Schooler's main ideas, I will discuss some general problems regarding the proposed distinction between experiential consciousness and meta-awareness. I will relate the distinction to the more general debate. I then discuss some conceptual claims to which Schooler seems to be committed to making, and show how they relate to one another. I point to some tension between them. As I will argue, the central issue has to do with the underspecified notion of "reflection". Different kinds of reflection are required for Schooler's "pure experience" and for meta-awareness. I will try to get a better grasp on the author's underlying position by discussing the main empirical evidence motivating the account, namely mind-wandering, in section two. I argue that the evidence does not support the distinction as introduced, but does give us some insight into the complexity of the required meta-cognitive processes. I will suggest some conceptual changes in the underlying framework, which I believe make the main project stronger and help to avoid some of the problems we have encountered. Specifically, I want to introduce a taxonomy of different kinds of reflection and show which kinds of reflections might required both for Schooler's "pure experience" and for his meta-awareness. In the third section, I turn to the author's main claim, which is the existence of a new meta-perspective. According to Schooler, this is the central proposal of his paper, and it follows from his initial perceptual-perspective-shifting analogy and the distinction he proposes. Schooler claims that the meta-perspective helps us to overcome the limitations of both perspectives: the first person perspective and the third person perspective. In effect, by introducing the meta-perspective we can bridge the gap between self-reported experiences and observable behavior, and get a completely new perspective on the mind-body problem. As I will argue, this ontological element is relatively independent of the rest of his methodological project. Moreover, it is an unnecessary strategic move.

Keywords

Accessibility | Cognitive | Consciousness | Higher-order accounts | Phenomenal | Reportability | Stream of consciousness

1 Introduction

Starting from perceptual perspective shifting, Schooler focuses on the gap between self-reported experiences (the first-person perspective) and observable behavior (the third-person perspective). So consciousness versus self-awareness of being in a certain state, and the relationship of both of these to observable behavior is at the heart of the project. The main goal of the tar-

get paper is to introduce a new methodology for studying conscious versus unconscious states and processes. Although this is a very rich paper, we are not given too much information about the conceptual framework and the way in which Schooler's proposal relates to the contemporary philosophical debate about consciousness, reportability, and accessibility. This aspect

will be my focus: the relationship between philosophical theories of consciousness and Schooler's account.

Schooler's ([this collection](#)) project uses the combined strategy of self-reports, observable behavior, and physiological measurements of the body: a "trust but verify" (p. 8) approach to reports of subjects' experience. He is interested in:

the relationship between people's belief about their experience and empirical indices of their *underlying mental states*. [...] Moreover, the theory of the intermittent and imperfect *nature of meta-awareness as a re-representation of experience* [...] provides a scaffold for conceptualizing the situations in which *beliefs and underlying experience converge and diverge*. (p. 19, emphasis added)

Though it sounds at the beginning as if Schooler is making a claim about internal states in general in general, it quickly becomes clear that he indeed makes a claim about the personal-level, or conscious internal states. In so doing, he transitions from internal states to a certain kind of internal state—a conscious one. Later in the paper we find similar transitions: first we find a statement that can be interpreted as talking about all internal states, or verbally reportable knowledge of one's states, but then he immediately makes a statement about the underlying experience. For example, he informs us that in mind-wandering we can "identify situations in which all evidence suggests people are routinely lacking in their current *knowledge of their on-going mental states*" ([Schooler this collection](#), p. 19, emphasis added). A little later we find a statement about experience, thus knowledge or beliefs about *conscious* states:

In short, a strong case can be made for the value of using 3rd person science to inform not only our understanding of people's beliefs about their experience, but also to discern when those beliefs are likely to be accurate and when they may be inaccurate or incomplete. ([Schooler this collection](#), p. 20, emphasis added)

A similar transition from a statement about internal states to a statement about conscious internal states, which as a result can be reported, can also found slightly earlier:

by using various reasonable markers of people's internal states we have been able to examine the conditions under which people's reports are more or less likely to be aligned with their experience. ([Schooler this collection](#), p. 19, emphasis added)

To summarize, it seems that "what is going on in someone's mind", in Schooler's terminology, refers to the conscious mind. His approach locates him in a group of thinkers¹ who challenge the notion of accurate reportability, or who challenge access as the main criterion for conscious experience. There is a very active contemporary dispute between defenders of what have been dubbed cognitive accounts of consciousness and proponents of non-cognitive accounts ([Overgaard & Grünbaum 2011](#)). Opponents of cognitive approaches associate consciousness with cognitive functions like controlled processing, working memory, selective attention, or some network of different cognitive processes.² Because of this association, these functions can be used to study consciousness from a third-person perspective. In contrast, non-cognitive approaches assume that consciousness cannot be operationalized in terms of cognitive function. Consequently, these accounts dissociate consciousness from cognitive capacities. Which leaves us (typically) with just subjective criteria as acceptable for studying consciousness. Obviously Schooler's account is an example of a cognitive approach. In my opinion, this general dispute cannot be resolved by empirical evidence because neither of these approaches can be empirically falsified, or at least the empirical evidence can in principle be explained both ways—in essence we have a clash of intuitions, and the evidence can be interpreted as supporting opposing views.³ However, the approach one favors

1 See for example [Seth et al. \(2005\)](#), who presented a proposal close in spirit.

2 See [Overgaard & Grünbaum \(2011\)](#); [Block \(2011\)](#); [Cohen & Dennett \(2011\)](#); [Kouider et al. \(2010\)](#).

3 See the debate about alternative explanations of the findings of atypical perceptual conditions (for example of the Sperling paradigm) in the references above.

will obviously determine one's criteria of consciousness, the experimental methodology used, and, consequently, one's findings. Nonetheless, I do not want to go too much into this very wide dispute, partly because I think it would be rather fruitless.⁴ So for the purposes of this commentary, I will focus on issues *within* cognitive approaches alongside Schooler's cognitive account. But the objections against cognitive accounts of consciousness in general are issues that Schooler, given his introduction of a cognitive methodological approach for studying consciousness, potentially needs to address.

By using mind-wandering as his main example, Schooler then proposes a list of criteria that—so the idea goes—might help us to get a better grasp on the conscious experience, and not just conscious states to which we attend or states of which we are meta-aware. This underlying conceptual distinction turns out to be essential for Schooler's overall project.

One way of interpreting Schooler's account is to see it as a combination of a number of claims, which is evident in the quote above. He himself, right after introducing the distinction, argues that the two cases come apart in mindreading, and the fact that “people routinely shift perspective (from simply experiencing to attempting to re-represent their experience to themselves) provides the foundation for a framework of scientifically investigating first person perspective” (Schooler [this collection](#), p. 9). The implicit *main argument of the paper* can be reconstructed in the following way:

(1) Schooler introduces a conceptual distinction between *experience* and *meta-awareness* as a re-representation of experience.

(2) He then presents empirical evidence that this conceptual distinction corresponds to reality, in mind-wandering and other cases.

(3) He then uses this evidence to suggest a general list of testable features for those interested in the empirical investigation of conscious-

ness. The last issue is particularly important: in effect, Schooler suggests replacing the classical testable criterion for consciousness, (oral) reportability, or accessibility to introspection, by several criteria, which are testable and available from the third-person perspective.

(4) He claims that this gives us a principled new way of reconciling the tension between the first- and third-person perspective by introducing a higher meta-perspective, an ontological claim; in essence, this meta-perspective allows for a new strategy to solve the mind-body problem. We are promised the above-mentioned new “framework for scientifically investigating first-person experience” (Schooler ([this collection](#), p. 9) resulting from the analogy of perspective shifting.

2 The revised view

There is much more in the target paper than I have mentioned here. For the purposes of this commentary, I will focus on four issues related to the general issue of consciousness, which then result in the presentation of a revised version of the author's account. Now that I have summarized what I take to be the author's most important ideas, I will discuss some general problems the underlying distinction seems to bring with it. This section receives my main attention. I will try to localize the distinction within theories of consciousness. I then discuss some underlying conceptual claims to which Schooler is committed to making, and show how they relate to one another. I will point out that there is serious tension between them. In the second section, I will discuss in more detail the main empirical evidence that motivates the account—mind-wandering—and introduce the proposed criteria. My epistemic goals in the commentary are, first, to determine the exact relationship between the initial distinction, the evidence presented, and the proposed list of criteria. Second, to discuss of how we should evaluate certain criteria, and what they tell us about underlying concepts of meta-awareness, access, and reflection. Third, to gain some insight into the relationship between one's position regarding the mind-body problem and the suggestion

⁴ By this I mean that the evidence does not allow us to rule out the whole class of cognitive versus non-cognitive accounts. I think however, that certain accounts within these classes are vulnerable to evidence; for example, explicit accessibility accounts (Prinz 2012) seem to have a lot less room to maneuver. But as a debate between cognitive versus non-cognitive accounts, the possibilities for interesting general insights seem limited.

the author draws from his perceptual perspective shifting analogy. According to Schooler, this is the central proposal of his paper; he claims the existence of a new-meta-perspective, which helps to overcome the limitations of both perspectives and thereby solves the mind-body problem. As I shall argue, this element is relatively independent from the rest of the project. Moreover, I think it weakens the main project.

As a positive contribution, I will suggest some conceptual changes of the underlying framework. The changes I will suggest include giving up some claims and revising others. I think these changes make the main project, which I take to be a methodological strategy for studying consciousness, stronger. They also help to avoid some problems we encountered in the discussion of the main argument. I also suggest a finer-grained specification of different kinds of reflection and taking stock. This will help to give us a better understanding of meta-cognition in general as well as of consciousness and awareness of being in a certain state as distinct phenomena. I take this to be a driving idea in Schooler's initial distinction.

3 The category of “conscious but unaccessed” states

Traditionally, we find a distinction in the literature between two categories: on the one hand conscious experiences, states, and processes to which subjects have access, and on the other hand unconscious processes to which they do not have access (Cohen & Dennett 2011). According to this general picture, access to these states and processes then includes in many cases accurate reportability, which is the reason why reportability, or accessibility to introspection, is central to any judgment about conscious states. But access can also be understood more broadly: not all access is conscious itself, and not all access results in behavioral or verbal reportability.

In general, if we have a conscious state and a corresponding unconscious state, there are two possibilities for how the two can differ.⁵

⁵ Of course hybrids are possible, so we might have combinations of functional differences and differences in content. I take Tye (1995) to defend such an account.

The first option is that the representational content of a state determines the experience, at least in part, so that both states differ in content. My conscious belief that my partner is cheating on me has a different representational content than the corresponding unconscious belief. These accounts are first-order accounts. The second option is that the states have identical representational content, but there is a difference in kind in the way in which they are embedded in the system—in philosophical jargon, the functional role that each state plays differs. According to this position, my conscious and unconscious suspicious beliefs that my partner is cheating on me are two states with the same content—expressed in the *that*-clause—but the conscious belief causes different internal states and different behavior to my unconscious belief. For example, in the conscious case, I will have the conscious thought that he is not treating me respectfully, and I might verbally confront him right away; in the second, unconscious case, neither of these activities will happen.

The first option is consistent with the standard view of what determines a difference in experience. However, it has a disadvantage: we cannot explain why the two states “correspond” unless there is some significant semantic overlap between them. The functional role view has the advantage that it can explain the similarity between the two states, but the disadvantage that we need an explanation of what exactly it is that makes a state conscious, and we have to show *why* this difference results in a difference in experience.

Schooler seems to opt for the content or representational view. Picking up Dennett's idea⁶ that people can be inaccurate about their own mental going-ons and internal states, Schooler concludes that, at least in some situations, external observers can have better insight into a subject's experience than the subject themselves (p. 8). However, as we saw in the quotes above, Schooler seems to interpret the internal states in question as conscious internal states.

This is consistent with the idea that the access to internal states changes the content of

⁶ See Schooler (this collection), p. 8.

the state, i.e., the content view: accessing a state changes the content of the state. Since the content determines the experience, the experience of a non-accessed and an accessed state differ. Understood this way, Schooler's criteria give us opportunities to know *better* than the subject himself what he consciously experiences. Access and the reports of subjects about their experience, and the experience itself can come apart. If this is right, it would be unexpected and not what the commonsense understanding of conscious states predicts. As for the first aspect, Schooler believes that mind-wandering gives us an empirical case, where accessing (in the sense of attending to) a process or state changes that very state.

3.1 The general distinction between conscious experience and meta-awareness

I will start with a discussion of the motivation for the distinction (see p. 3), and some general problems we seem to invite if we accept this distinction. Schooler, and with him others, presuppose that conscious experience and accessibility can come apart; moreover, there is an experience *before* it is accessed. In other words, we postulate a third category, besides conscious and unconscious states: there are now “conscious but not accessed” states. These thoughts seem to be in line with other considerations in this debate, which propose a new category of phenomenal consciousness with no access (Block 2011; Lamme 2003).

Schooler distinguishes between simply “having experiences”, which he calls that *experiential consciousness*, and explicitly “taking stock” or re-representing this experience, which he calls *meta-awareness* or *meta-consciousness* (Schooler 2002, p. 339). Meta-consciousness then, is “defined as the intermittent explicit re-representation of the contents of consciousness” (2002, p. 339), while a later he says it is “knowing that one is having that experience” (2002, p. 339). So meta-awareness is about a certain kind of access.

Because we can clearly distinguish both, mind-wandering seems an excellent empirical

candidate for the study of consciousness. At one point we notice our mind-wandering; but *what* we notice, the mind-wandering itself, occurs earlier. In the meta-aware case, we re-represent the former state; in order to do this, we access it by re-representing it, and we “take stock”. Then the subject becomes meta-aware of the state, and we know that we are in this state, but this very process changes the content. Our experience of mind-wandering is different once we become meta-aware that we are mind-wandering.

But this seems conceptually puzzling. Access and (verbal) reportability are clearly not the same, such that missing (verbal) reportability cannot not be equated with general lack of access, especially at the subpersonal level. With knowledge, reflection, re-representation and meta-awareness, as well as meta-consciousness, we get additional and differing concepts. First, often “knowledge” is used as something that is itself conscious. Is the idea that we are aware only of the mind-wandering, or also of our knowledge that we are mind-wandering? The author alternates between both phrases. But both claims differ. I can be aware of an experience without being aware of my knowledge that I have this experience. The latter includes a meta-level of a different kind. While the first contains a meta-process regarding the experience, the second is a meta-process referring to a propositional state, knowledge, *of* the experience. As a result I am aware of being in the state and not just of the experience. Moreover, reflection is a vague term. How exactly do we reflect on a state, process, or content of a state? What exactly does this entail? So the question is: what is meta-awareness and what distinguishes it from simple awareness? Finally, re-representation is mentioned, yet another concept used to characterize meta-awareness. Without further explanation, re-reflection seems a very broad and vague concept that would include all kinds of re-represented contents. Do most of these occur unconsciously, as certain kinds of functional accounts, higher-order accounts, predict (Jackendoff 1987; Rosenthal 2005)? How is something re-represented? How exactly

do the representation and the re-representation relate to one another?

The question of which types of neural processes might be sufficient for awareness is highly controversial in current debate, as is whether there can be any awareness of a state without access (see the exchange between [Fahrenfort & Lamme 2012](#) and [Cohen & Dennett 2011, 2012](#)). Relatedly, the status of local recurrences is debated. Block and Lamme argue that there are perceptual cases in which subjects do not attend to a stimulus (in change blindness, inattention blindness, and attentional blink) and as a result are not able to report the presence of the stimulus. They might nonetheless be phenomenally conscious of the stimulus because it induces local recurrence in perceptual brain regions. As a result, a subject's reports are not to be trusted in all cases: subjects could be conscious of stimuli even when they themselves deny it. This sounds very close in spirit to Schooler's idea. However, Schooler doesn't tell us how his account, and pure mind-wandering versus meta-awareness of mind-wandering, relates to this debate.

Despite these unclear aspects, the underlying intuitive idea is clear: Schooler wants to distinguish phenomenally-conscious experience from a meta-level of consciousness, in the literature also referred to as meta-awareness, and sometimes as reflective awareness, reflexivity, or reflexive consciousness. But what exactly characterizes this meta-level remains unclear. We are simply not told, the used concepts seem vague, and, without further explanation, underspecified. But, of course, this does not imply that the main idea is not helpful, or that it is not possible to specify them.

However, Schooler seems to sympathize with Cohen and Dennett, so I take it that he thinks (like them), that awareness differs from behavioral reportability. However, Cohen and Dennett explicitly state that they do not see many reasons to think such conscious information exists before it is accessed ([Cohen & Dennett 2012](#), p. 140). So they reject the very option, the third category, that Schooler wants to postulate. There seems to be a sharp tension between Schooler's distinction and his agree-

ment with Cohen and Dennett's general approach: Whereas Cohen and Dennett argue that theories postulating inaccessible conscious states are intrinsically off-limits to investigation, Schooler not only defends an account along those lines, but also argues that his account gives us a solution strategy to overcome the tension between the first- and third-person. Obviously, there is a need for conceptual clarification of this highly original idea.

However, I think we can learn a few interesting things from this. First, we can rule out a very general understanding of reflection or meta-cognitive processes. Most theorists agree that part of what it is to be in a conscious state is to have a unified perspective on the world. So the possibility of distinguishing between me and the world, or a self, or some kind of self-consciousness is required as an indispensable part of conscious experiences of many kinds. One way of describing this is to say that experience includes some kind of categorization. In other words, it is a kind of meta-cognition on this highest and most general level. At least, we as humans keep track of this interdependence of action and perception/experience at the personal level. To mention a classical example, it seems very hard to experience pain if one doesn't classify something as painful, or without seeing it as painful *for me*. Indeed, some kind of evaluation, conscious or not, seems to be required for something to classify as pain; just as, in order to see something visually as a cow, we have to classify or categorize it as a cow ([Dretske 1993](#)).

At first glance, an account like Schooler's cannot allow for this because the standard view requires meta-cognition for conscious experience. Experience is cognitively penetrable, such that knowledge about categories influences how we experience an object. In contrast, Schooler distinguishes both, and wants to allow for experience before (any?) meta-level involved. At least he talks sometimes as if meta-cognition in general is the issue when it comes to meta-awareness of mind-wandering. When he talks about theory of mind and the areas involved in meta-cognition ([Schooler this collection](#), p. 17), he suspects that because certain meta-cognitive

processes and mind-wandering occupying both engage the same systems, specially the dorsal ACC and the anterior PFC, this might explain why it is so hard to catch oneself mind-wandering, i.e., to gain meta-awareness of mind-wandering. However, he notices that identity of brain regions does not imply a causal relationship, and that further research is necessary.

However, it would be hasty to conclude that Schooler cannot concede that meta-cognition can be involved in experience on his account. Though he talks frequently as if the issue were meta-cognition in general, he is not committed to excluding *any kind of* meta-cognitive process. But what is needed is a differentiation between different kinds of meta-reflection or re-representation. Schooler needs to address the question of whether we see the same kind of meta-cognitive processes in different kinds of experiences, and how exactly this changes the experience. Interpreted this way, only a certain *kind* of meta-reflection or meta-cognition might establish meta-awareness. As I will show, this move avoids a number of other problems.

We know that experience depends on background knowledge, and that our knowledge and our classification processes change our experience in many cases. This seems to be the case not just in mind-wandering, Schooler's favorite example, but also in many other cases. What matters is not just how I classify a state or process; many other internal states and contextual factors influence experience. Let's assume that I am a big fan of Baroque music, but cannot stand twelve-tone music. I happen to blunder into a concert with music by Penderecki, and of course do not like what I hear. Simply by gazing at the program and learning that I am listening to Penderecki's Saint Luke Passion, which uses references to motives by Johann Sebastian Bach and is in a sense a homage to a well-known Bach piece, how I experience this piece of music might change. Chances are that I am still not able to hear the references to Bach and the coded references to passages in Lucas in the middle of all the dense tone clusters. But my belief that it is a homage to my beloved Bach will change my experience in general. Other states, beliefs, and emotions in-

fluence my auditory experience and make it, in this case, somehow more enjoyable.⁷ It is also well known that crossmodal influences change experience: one's taste experience changes with conflicting visual experience. So a pure strawberry juice tastes less like strawberry to us if it is colored blue, even if the juice itself is not altered.⁸ How we experience a certain wine depends on knowledge about price, how famous the winery is, and many situational aspects. In these examples, the real question seems to be how exactly our experience changes, and how do particular internal and external factors contribute to the change. What changes in how we re-represent, and how fundamental is this change? And what is meant by these terms?⁹

So Schooler's meta-awareness can come in many forms. "Meta-cognition" includes a broad range of phenomena. What they have in common is that subjects have some insight into their own cognitive functioning. It is not clear to me that it is an all-or-nothing affair between pure experience and meta-awareness or reflection. So a specification of what exactly is meant by meta-awareness, re-reflection, and access seems necessary. We also need to answer the question of how the two categorically differing states differ in content, and which *exact kinds of meta-processes* are relevant. "Reflection" and "re-representation" are notoriously vague terms. Some kind of reflection at least seem indispens-

7 Bayne & Montague (2011) provide a nice overview of the complex cognitive phenomenology debate in his introduction to his volume. One might think that other contents causally influence the phenomenology of a state. A second option would be that "what it is likeness" is not a useful conceptual distinction at all (Lycan 1996, p. 77; Papineau 2002, p. 227). A third option would be that there are several meanings of "what its likeness"—indeed, in the literature different distinctions have been suggested. I will go into more detail in a later section, when I introduce elements of an improved taxonomy.

8 See further discussion in Grush (this collection).

9 Regarding visual perception Siegel (2005) has argued that that learning to recognize an object can change the way that it looks—in the phenomenal sense of "look", which is taken to imply that the cognitive components of such states are necessary for explaining the change in phenomenal character. In contrast, one could argue that the phenomenology does change, but the change can be explained in sensory terms instead of in terms of cognitive components. Either a subject's concepts do not directly constitute the subject's phenomenal states, such that they can have a causal influence on their phenomenology (Carruthers & Veillet 2011), or the contrast between both is the result of differences in the way that one processes the information within the sensory system (Tye & Wright 2011). For my purposes here, what matters most is *that* the phenomenology differs, and that we need an explanation for it.

able for a state to be conscious. But that doesn't mean the distinction above is not justifiable. We just need to determine and specify the kind of reflection and/or re-representation. I will make some suggestions later in this paper (see p. 15).

To be fair, while Schooler does not distinguish between different kinds of reflections, he indirectly assumes that there are differences. But in his view the phenomenon dictates what the criterion for introspective awareness is. He distinguishes classification under the concept of "taking stock": "there are some mental states (e.g., mind-wandering) for which the crucial bottleneck in people's introspective awareness stems not from their capacity to classify the experience, but rather from the fact that people only intermittently take stock of what is going on in their own minds" (Schooler [this collection](#), p. 8).

This obviously implies that for other phenomena the crucial difference does stem from their capacity to classify an experience. As a result, we in effect have different criteria for introspective awareness and for mind-wandering and visual perception. I believe a more promising route is to allow for dimensions of reflection and complexity of experience along multiple dimensions, but to try to find as uniform criteria as possible. The experience and phenomenology in cases of thought and sensory states (broadly construed) might be different.¹⁰ But some properties or property clusters have to bind instances of introspective or meta-awareness together.¹¹ Otherwise, what would justify classifying them as the same, if both the phenomenon and the properties associated with the phenomenon differ? We would just be talking about different things. I have already ruled out two kind of meta-cognitive processes the author cannot use for a more detailed characterization of the difference between conscious states and meta-aware states: categorization under concepts is one kind of meta-cognitive reflection that itself is unconscious, but necessary for con-

scious experience. Distinguishing between self and world is another dimension of reflection, at the highest level, that seems necessary. Meta-cognition always requires representational use (of some kind), because within it we find monitoring of cognitive affordances. But there are several *ways* in which this monitoring can take place. As I argue below, meta-cognition, the ability to monitor and control one's own cognition, and the ability to attribute mental states to oneself and others can occur in different ways; and both the self-other distinction, and self-awareness can occur in a number of ways.

3.2 Meta-cognitive accounts of consciousness: Content vs. function

A core idea in the target paper is the claim that there is a difference between an experience and an experience one is aware of having. Both states are experienced, but the idea seems to be that reflection could potentially change an experience in a certain way, because it focuses on the content of the intentional formerly un-reflected state. Interpreted this way, Schooler seems to defend the content view, though I do not think he is committed to it. He doesn't explicitly subscribe to it, but it seems implicit in what he says when he talks about the content of states and frequently switches back and forth between content talk and talk of experience. He seems to think that these are related. And he doesn't say much about the functional role that the states in question play in other states, or how cognitive processes use them—something one would expect if he held the functional view. So it is tempting to interpret him as having the view that content determines experience (Block 2005). For example, in writing that there are "some situations in which observers might have better knowledge about a person's mental state than does the person in question" (Schooler ([this collection](#), p. 8), what he must mean is that observers have better insight into the *content* of people's states. A little later, he claims, regarding misrepresentations, "while in the process of re-representing, one omits, distorts or otherwise misrepresents one's mental state to oneself and/or others" (Schooler [this collection](#),

¹⁰ As the complex debate about the possibility of a phenomenology of thought suggests.

¹¹ At the very least we would need to insist that there is a family of co-occurring properties playing an explanatory role within theories (Boyd 1999).

p. 10). Again, what we misrepresent is obviously the *content of the state*.¹² If he has a content view, than his view is that (at least in some cases) I have an experience first, and then, when I reflect on it, that very process changes the content of the initial intentional state. That then is the reason why the experience differs between mind-wandering as “purely experienced”, and mind-wandering experienced with awareness. The phenomenon of mind-wandering indeed introspectively changes after we reflect upon it, and become aware that we are mind-wandering.

But I think there is a larger issue here. Interpreted this way, it is tempting to judge that accounts claiming that what makes a state a conscious state is its functional role are inconsistent with Schooler’s account. Again, I think this would be too hasty. Let me explain. Assuming a representational theory of phenomenal consciousness,¹³ there are accounts that provided in purely first-order terms and accounts that implicate higher-order cognition of one sort or another (see below) with conscious experience. If we accept Schooler’s distinction, a state is conscious before we are aware of it, or know that we are in this state, and, when we become aware of it, this changes the state, or its content, to be more precise, as Schooler seems to suggest. Thus, Schooler seems to defend a first-order account, namely an account in which it is claimed that the consciousness of a state is partly (or entirely) determined by its representational content, or sometimes the format of its representational content, not primarily at first the function it plays (Byrne 2001; Dretske 1993; Kriegel 2009).

In the class of functional¹⁴ accounts we find a great range of different accounts, including second-order accounts, accessibility accounts (Prinz 2012), and global workspace accounts (Baars 1988). Many of these are close in spirit to Dennett’s. Though they differ, they have one thing in common: it is a certain functional relationship the states in question have to other states or within the system, which makes these states conscious states.

Second-order accounts, for example, would claim that what makes a state a conscious state is that the state is (or is disposed to be, in some versions) the object of a higher-order representation of a certain sort. This state is a meta-level state, a mental state directed at another mental state. Higher-order accounts differ on how exactly this higher-order representation is characterized and what the exact relationship between both states is. In some versions the higher-order representation is a higher-order thought (Rosenthal 1986, 2005), in others a higher order-order perceptual or experiential state (Lycan 1996), yet other versions see the higher-order state as dispositional (Carruthers 2000). There are also differences concerning the question of whether the higher-order state should be understood as entirely distinct from its target state (Rosenthal), or whether the higher-order thought is better viewed as intrinsic to the target state, which would imply that we have a complex conscious state with parts. There exist different versions of the intrinsic view, which all have in common the idea that instead of a separate higher-order state there is a global meta-representation within a complex brain state (Gennaro 1996; Van Gulick 2000; Metzinger 1995). For the purposes of this commentary, I will focus on Rosenthal’s higher-order thought theory, but my considerations generalize to many of the higher-order accounts. The existence of the higher-order state and the right connection between both (one is the object of the other) makes the lower level one a conscious state. The higher-level state, however, is itself unconscious, unless there exists a third-level state—the existence of which would result in awareness of being in a conscious state. In effect, the existence of a certain kind of meta-cognition is what makes the lower level state a conscious state, or even a state that we are aware of being in. In this framework, Schooler’s meta-awareness would require a third-order state.

Accessibility accounts, for example that of Jesse Prinz’ (2012), would claim that attention is both necessary and sufficient for states to be conscious. In global availability accounts¹⁵ it is

¹² See also, for example Schooler (this collection), pp. 16-17.

¹³ For the purposes of this commentary I neglect biological state theories.

¹⁴ On a very broad reading of “functional”.

¹⁵ Initially introduced by Baars (1988, also 1996). More modern proponents would be, for example, Dehaene et al. (2006).

claimed that the functional role is the global availability, or the workspace. The idea is that there is competition among neural coalitions; the winning coalitions are the conscious ones. There are a lot of similarities between higher-order theories and the neuronal global-workspace theory, but we should not see them as theories of the same type. According to the neuronal global-workspace theory, a state is conscious due to the global availability of its content, whereas higher-order theories see a state's being conscious as "consisting of one's being aware of oneself as being in that state" (Rosenthal 2012, p. 1433). If one interprets Rosenthal's reference to "oneself" as Metzinger's phenomenal self-model (2003), then a higher-order theory requires the integration of an individual state in a coherent representation or inner model of oneself, in contrast to a global-workspace theory, in which all that is required is availability of the content. Both aspects, the kind of meta-representation (the number of higher-order steps) and a certain identification of the original state as *my* state are dissociable, and they are examples of what I mean by different dimensions of reflection.

I think Schooler's account stands in natural alliance with both kinds of accounts, in contrast to what one might initially think. It is the vagueness of the term "meta-awareness" that is causing this unjustified reluctance. For example, higher-order thought accounts seem a natural way to specify what Schooler might have in mind when he talks about meta-aware states. According to Rosenthal, there can be unconscious pain states, if these are accompanied by the thought that I am in pain, I am experiencing pain, but the thought itself is unconscious. Only if there is a third-order state, the thought that I have the thought of being in pain, am I aware that I think that I am in pain. To me, this sounds close to Schooler's meta-awareness of taking "stock of our ongoing experience and re-present[ing] it to ourselves" (this collection, p. 8). However, there is an important difference: for Rosenthal there are only conscious and unconscious states; the presence of the third-order state gives us what Schooler might call meta-awareness. However, Rosenthal

denies the very possibility Schooler claims exists, that one can be in a conscious state but not aware of it. "No mental state is conscious if the individual that is in that state is in no way aware of it" (Rosenthal 2012, p. 1425). Due to the existence of a third-order state with the right content, we get introspective awareness of a conscious state: a third-order awareness that makes one aware of the second-order awareness. Rosenthal expects such cases, in which we "are aware of focusing attentively on that state" (2012, p. 1427), to be rare. It seems to me that there is a natural fit between Schooler's meta-aware states, in which we know that we are having a certain experience and Rosenthal's introspective awareness of a conscious state. In Rosenthal's framework, meta-awareness necessarily requires a third-order representation.

In addition, Schooler's suspicion that "meta-awareness appears to be associated with rhythms of attentional flux" (this collection, p. 17) relates nicely to accessibility accounts.¹⁶ But as I will claim in the next section, global availability accounts stand in another obvious alliance with Schooler. Again, it seems that it all depends upon our understanding and further specification of "reflection" or the "meta" in Schooler's meta-awareness. Is reflection itself necessarily a conscious process? Is it a thought, or just any kind of representation for the purposes of monitoring one's own cognition or an explicit higher-order classification? Unfortunately, Schooler does not describe his meta-awareness in more detail.

It seems to me that we should concede that some kind of "reflection" might be required for something to be an experience. This leaves still plenty of room to specify different kinds of reflections, some of which might constitute more than awareness, namely meta-awareness. This becomes the real question. Is this reflection itself unconscious or even necessarily conscious? Is it a re-representation of some kind? If that is the case, what kind of re-representation is required? Schooler's meta-awareness might require a rather demanding kind of reflection, and the

¹⁶ However, in the end accessibility accounts will not be Schooler's best bet—after all, I interpreted him above as agreeing that access and awareness differ.

relationship Rosenthal describes seems a good candidate. But perhaps what we have instead of a simple dichotomy between pure experience and meta-awareness is a full spectrum of dimensions of meta-representation. Then the question is, what are the dimensions of reflection required for Schooler's "pure experience" and those for meta-awareness, and which other reflections are there? This search for a proper taxonomy of "reflection" seems the most pressing need. It will hence be my main focus, and I will suggest some building blocks for such a taxonomy (p. 15). Rosenthal's introspective awareness of a conscious state as an possibility for characterizing Schooler's meta-awareness will be one element of this.

3.3 A general concern for scientific practice and a conceptual worry

This brings us to another and more problematic issue. I find the general line of thought behind a rigid distinction between pure experience and meta-awareness of this experience problematic. First, it presupposes that we accept the distinction between access-consciousness and phenomenal consciousness—a distinction not everybody (to say the least) is happy to accept.¹⁷ Second, and more fundamentally, such a new category would have to be motivated. How do we distinguish "conscious processes, which are not accessed" from unconscious activity? Are they *de facto* not explicitly re-represented, or is it impossible to re-represent them? What does it then mean to say that something is "conscious"? One might suspect that this new concept of "conscious" is not compatible with our common-sense intuitive understanding of the term. Moreover, the stronger reading of Schooler's position might invite further problems. If we claim that access to a state would necessarily change the status of its content (or the content itself), it would be impossible to address whether it was of a phenomenal or unconscious nature prior to this conscious access. If

such an "observer-effect" exists, it could potentially render the whole issue completely immune to scientific investigation (Kouider et al. 2012).

Another open question is how Schooler's account relates to others that seem close in spirit. Dehaene et al. (2006) have presented a more modern and updated version of Freud's concept of preconscious activity. They introduce a proposal with a carefully defended taxonomy of three categories: subliminal, preconscious, and conscious activity. According to Dehaene and Changeux's workspace model developed a little later, dominant neural coalitions involving the workspace are *accessed*. In contrast, existing other weaker activations in the workspace, such as a connection that *could be activated*, for example by a shift of attention, are only *accessible*. Processes that are potentially accessible, but are not accessed at the moment because of sufficient top-down attentional amplification, are "preconscious" phenomenal conscious processes in Dehaene et al.'s terminology (2006, pp. 206-207). I am not sure whether what Schooler is proposing is another version of Dehaene et al.'s "preconscious" phenomenal consciousness. This is consistent with what he writes. In debates on the third category of phenomenally conscious but not accessed states, their distinction between cognitive access and cognitive accessibility is often used to defend the possibility of the aforementioned third category (see for example Block 2011). My own suggestion is related, although I will suggest more closely specifying different kinds of access (see p. 11) and multiple levels of representation, instead of just distinguishing between accessibility and access.

I think Schooler's account would profit from directly relating his terminology to other concepts already in use in the debate. However, there are problems looming: Dehaene et al. defend a version of a functional account, which Schooler seems to explicitly reject when he seemingly advocates a first-order account. But if Dehaene's taxonomy is *not* what the author has in mind, what is the difference between the Schooler's phenomenally conscious but unaccessed activities and Dehaene's preconscious activities?

¹⁷ However, one might be able to resist the distinction between access-consciousness and phenomenal consciousness and at the same time allow for Schooler's distinction between experienced consciousness and meta-awareness if one claims that access is *not* what characterizes the meta-level in Schooler's meta-awareness.

Let us take stock. I have argued so far for three closely related points. The basic distinction between being experientially conscious of a state and being meta-conscious of being in a state needs further conceptual clarification. Moreover, the combination of a first-order account of consciousness (the content view) and this very distinction might not be the optimal strategy. In fact, a functional or hybrid account seems to provide a more natural strategic alliance for Schooler's main project. Finally, it seems there is no strict dichotomy between experiential consciousness and meta-awareness; we rather face a difference in many dimensions. From my perspective, both higher-order accounts as well as global workspace accounts might be helpful regarding this issue. They connect nicely with Schooler's main project, and would help to clarify his basic distinction. But we might very well end up with a more complex understanding of different meta-cognitive dimensions and differentiations instead of a simple conceptual dichotomy. This is what I will provide later in this paper. In order to do this we need to take a closer look at Schooler's second step; his argument that his conceptual distinction is something we find in cognitive capacities.

4 Mind-wandering—and noticing it. The bundle of criteria

On the basis of the former considerations he presents, Schooler argues that in many capacities we actually find a difference between being in a certain state and noticing that one is in a state (meta-awareness). So he moves onto his second claim, the claim that his conceptual distinction is empirically supported (see p. 3). According to Schooler, there are two forms of dissociations, *temporal dissociations* on the one hand and *translation dissociations* (misinterpretations) on the other. Let me begin with temporal dissociations. Examples of temporal dissociations are mind-wandering vs. noticing one's mind-wandering, but also mindless behaviors, suppressed thoughts, and unwanted emotions. Schooler mostly uses mind-wandering, however, characterized as situations, in which

we “lose track of the contents of our own minds” (Schooler [this collection](#), p. 9). This is the starting point for the introduction of Schooler's new “framework for scientifically investigating first-person experiences” (Schooler [this collection](#), p. 9).

I find this focus on mind-wandering a little puzzling, because I am not sure why this is an example supporting the general claim that the content of individual states changes in the specific intentional states. Why is it an individual intentional state that changes? Mind-wandering (at least intuitively) seems to be a complex process, and involves a number of states. In mind-wandering the issue is creature consciousness, not the experience or phenomenal character of an individual state, i.e., state-consciousness. Mind-wandering is about a train of thoughts, often accompanied by emotions, and autobiographical memories. In mind-wandering, we mostly think about issues related to our own life. For example we consider our “to-do” lists for today, what to have for dinner, our relationship to people close to us, telephone calls we need to make, and even our next lecture. At least the phenomenal character we experience during mind-wandering seems to include these the associated sensory states—broadly construed to include feelings of emotions, images, moods—which have a distinctive “phenomenal character” or “what it's likeness”. But the stream of consciousness also contains episodes of conscious thought.¹⁸ If we use this standard understanding of mind-wandering, it would rather be a bundle of thoughts, associations, or states, in other words a number of many more or less related thoughts, emotions, or other states and processes, not all of them necessarily fully specified in terms of content. And if so, it is not necessarily the content of individual states that changes—we seem to have multiple options for characterizing what changes once we

¹⁸ Schooler (2013) gives a good overview of the performance costs associated with mind-wandering (including reading comprehension, model building, and impairment of the veto-option to automatized responses) and suggests that mind-wandering may represent a pure failure of cognitive control. For this reason it is so useful to study consciousness. He argues that mind-wandering offers little benefit, though it might have a positive role in topics related to autobiographic episodes and information, for example in autobiographical planning and creative problem-solving.

are aware that we are mind-wandering. An alternative interpretation would be that the network of associated elements might change, or even the kind of associations involved. For a conceptual analysis, whether one should include these autobiographic sensory states in the phenomenon itself or just say the “train of thoughts in mind-wandering” causes them, is unclear. But it will determine how we analyze the experience of mind-wandering and the meta-awareness of mind-wandering, and its implications for theories of consciousness. There is also evidence that it has different functions and might itself be a heterogenic phenomenon (Northoff 2014, especially chap. 26; Metzinger 2013). For example, it is not clear whether mind-wandering is the same as day-dreaming, and if not, what the differences are.

Moreover, it is controversial whether thoughts even *have* a phenomenal character, and if so, how to analyze it (Bayne & Montague 2011). The orthodox view is that conscious thoughts themselves do not have a distinctive “phenomenal character”. They are either considered conscious without phenomenal character, or it is conceded that conscious thoughts might possess phenomenal character, but only in virtue of the sensory states with which they are associated (for example Braddon-Mitchell & Jackson 2007; Carruthers 2005; Nelkin 1989; Tyne 1995). However, recently, a number of authors introduced views according to which conscious thoughts themselves possess a “distinctive” phenomenology, but the phenomenal character differs from sensory states (Siewert 1998; Pitt 2004; Robinson 2005; Prinz 2004).

So there are a lot of further issues to consider, for a project like Schooler’s; we need to analyze the experience of mind-wandering and contrast it with meta-awareness or reflective experience in mind-wandering. However, Schooler gives some other examples for temporal dissociations, which can more obviously be explained in terms of individual states we do not notice or misinterpret. He doesn’t go into detail, but has mentioned mindless behaviors, suppressed thoughts, and unwanted emotions. The idea seems to be that we are not aware of an individual unwanted emotion, or a thought that

causes behavior. However, these case could also be explained as processes rather than individual states. Mindless behavior is in many cases caused by a bundle of connected states, unwanted emotions relate to other internal states (which make them unwanted), and suppressed thoughts are suppressed due to other internal states.

Nonetheless, if Schooler means by “state” the “general state of mind”¹⁹ rather than individual states, his examples become more convincing. But this seems inconsistent. Schooler takes inspiration from Dennett, who is interested in beliefs subjects have about phenomenal experience of individual states. Schooler switches between talk of phenomenal experience of individual states, and talk about the stream of consciousness the subject experiences. This is evident in the way he introduces the core distinction, namely in terms of the phenomenal experience of a state. At other times he talks about states of which I am aware, and sometimes about “what is going on in one’s mind”, which I take to refer to the stream of consciousness, or more precisely the sequence or combination of contents of individual states, rather than a classification of the experience of just one state. So the pressing question is really: what kind of reflection is “taking stock” exactly? How should we characterize what we do when we “take stock” and reach meta-awareness? In the following section I present more detailed suggestions for a taxonomy of different kinds of reflection. For now let me just say that one possible view would be that the content of these states (or the states) are accessed by other states, and maybe (unconsciously) evaluated. In that case, we should talk about complex processes rather than re-accessed individual states. Such a view would also be compatible with certain higher-order theories of consciousness.

Later in the paper, Schooler discusses examples of misrepresentation, in his terminology “translational dissociations”: emotions, or cases in which it is less controversial whether a phenomenal character is involved than in case of thoughts. He gives two examples of such misrep-

¹⁹ As formulations such as “take stock what’s going in their own minds” (Schooler this collection, p. 8) suggest.

resentations: emotions of anxiety, which are not reported, and reported disgust for homosexuality. In his first example we find a correlation with the inconsistent behavioral measures of heart rate and galvanic skin response, as indicators of existing unreported anxiety. In his second example we have a correlation with penile tumescence (an erection). In both cases we know the bodily aspects of the emotion well (or the caused bodily changes associated with the feeling on an emotion), and thus, so the argument goes, have evidence for the occurrence of the emotion. But in both cases there is also a discrepancy between the subject's reports (assuming the subject is honest) and its potential reportability. Schooler interprets the behavioral facts as indication of the real emotion the subjects experiences, but in the first case fails to acknowledge, and in the second misinterprets.

I am not so sure. First, the theory of emotion one feels committed to certainly plays a central role. Schooler seems to presuppose that unconscious emotions are not possible. Furthermore, it seems to me that both cases are open to a different interpretation, in fact the same interpretation I suggested for mind-wandering. Both unreported (or unreportable?), emotions of anxiety and reported disgust for homosexuality are complex cases. It might very well be that we do not have an individual content of a state that differs, but we rather simply struggle with a number of different but conflicting emotions, the reported one simply being in conflict with others. In both cases we have rather complex scenarios. And if one defends a multi-component account of emotions, it might very well be that the components of these emotions differ—it could be an element in a network that realizes the state, instead of the content of an individual state. This might seem like a minor point, but I think it is important. It undermines a central second part of the strategy, namely the empirical support for the theoretical distinction. Schooler needs more than a theoretical distinction (his first claim); he needs to show that this very distinction is helpful for understanding certain aspects of consciousness, mind-wandering, and other cases (his second claim; see p. 3). Otherwise the conclusion he draws, the new

methodological approach to studying consciousness, would not follow or would lose its plausibility. So undermining Schooler's second claim by showing that in the case of his examples related to emotions (as well as in case of mind-wandering) this evidence is not as clear as one might think, results in a problem for his view.

But there is another important issue here. The empirical evidence seems to be relevant to the stream of consciousness rather than to the experience versus meta-awareness of individual intentional states. The formulation of the main claims suggests that state consciousness is the issue. However, in other sections Schooler refers to the stream of consciousness (See quote above, p. 8). If this is correct, Schooler's empirical project, or more precisely the evidence he has gathered, is about a central aspect of *creature consciousness*. Philosophers distinguish creature consciousness from mental-state consciousness: the first is about a subject that is conscious (either in general or of something in particular), whereas state-consciousness is about conscious states of a creature that it is conscious. Though Schooler's project (especially claim (1)) is formulated in terms of *state consciousness*, the empirical support targets a different kind of consciousness. This also undermines Schooler's second claim by showing that the meaning of consciousness differs in claims (1) and (2). But, as I pointed out in section 1, the stream of consciousness claim would be compatible with a more functional interpretation of claim (1) as well. There is a way to revise claim (1) in a way that avoids this problem.

Using mostly the empirical evidence of mind-wandering, Schooler then suggest a bundle of criteria we might use for the third-person evaluation of what is actually going on in somebody's mind; in my analysis of his main argument this is the third step (see p. 3). These behavioral criteria include behavioral measures (eye-movements, reading comprehension, sustained attention to response) and neurocognitive criteria (ERP, fMRI, behavioral, neuroscientific, fMRI and others). His list is in the spirit of a cognitive account, and similar to others (Seth et al. 2005; Seth et al. 2008). For protagonists of non-cognitive accounts there seems

to be room for attack. But, as I have mentioned, this is not my project (see p. 2). In this commentary, I prefer to focus on conceptual issues *within* cognitive accounts, rather than the debate between cognitive vs. noncognitive accounts (See p. 2). As long as one commits to such a cognitive account, Schooler's list of criteria turns out to be very useful for our evaluation of the meta-components we need for a fined-grained understanding of reflection and re-representation. And this is the case independently of the worries I presented regarding his first two claims. However, I think there is a problem looming: Schooler is challenging both the reliability of first-person reports and the view that conscious states are accessible states. With a position that is in such sharp tension with our commonsense understanding, he needs to motivate this radical move: he needs to provide an answer to *why* we have this deep pre-theoretic entrenchment of the first-person accessibility of our own conscious states (Cohen & Dennett 2011).

5 A new taxonomy of different kinds of reflection

It's time for a positive proposal. I claimed that I would introduce suggestions for the building blocks of a new taxonomy of different kinds of reflections. As I argued, we need to further specify the kind of reflections required for Schooler's "pure experience" and for his meta-awareness, and to get a better grasp on what is meant by "taking stock" and "re-representation". I also argued that the difference between consciousness and meta-awareness should not be understood as a dichotomy. Rather, we should understand reflection itself as a hierarchical and multidimensional process. So, what exactly is the "taking stock" required for meta-awareness? According to Schooler, meta-awareness requires an explicit representation of the current contents of thought (2011, p. 321). But at least two of the terms involved in this characterization are used in several and distinct meanings: knowledge, and explicit representation.²⁰ Explicit rep-

resentation might be interpreted as being itself conscious, or as having symbolic or conceptual content. The notion of knowledge is also problematic, simply because knowledge is a factive verb. It implies that we cannot be wrong.²¹ As a result, Schooler built the impossibility of misrepresentation into his definition of meta-awareness. This might be consistent with his claim that the first-level perspective inhabits its own ontological realm. But it also creates a problem, because any view that understands introspection or reflection as an inner perception or re-representation automatically has to allow that this process can go wrong. In other words, it has to allow for misperception/misrepresentation. Moreover, Schooler himself want to allow for a certain kind of misrepresentation, in his terminology translational dissociations—cases in which at the personal level we misinterpret what we experience.

In my discussion of the distinction I claimed that we are able to rule out two kinds of reflections that are not helpful. First, categorization under concepts is one kind of meta-cognitive reflection that is itself unconscious, but necessary for conscious experience. Second, being able to distinguish between self and world is another dimension of reflection, at the highest level, that seems necessary for any conscious experience. Neither of these can be the kind of reflection that distinguishes Schooler's experience from meta-awareness. In addition I claimed that both the self-other distinction and self-awareness can happen in a number of ways. Different kinds of meta-cognition, the general ability to monitor and control one's own cognition, and the ability to attribute mental states to oneself and others, can as a result be further specified and characterized along those dimensions.

But again, what is the kind of reflection or "taking stock" required for meta-awareness? At the end of the last section I suggested that the kind of reflexion involved in "taking stock" could be characterized as a case in which the content of these states (or the states) are accessed by other states, and maybe (unconsciously) evaluated. So at issue are complex pro-

²⁰ For a more detailed discussion of the same issue see Metzinger (2013, p. 11).

²¹ Otherwise we would have a false belief, not knowledge.

cesses rather than re-accessed individual states. Such a view is compatible with certain higher-order theories of consciousness. And this would allow that misrepresentation is in fact possible. However, not only do authors like Rosenthal build several meta-representational levels into their theories, the content of the higher level thought contains an element of self, a reference to “oneself”. Self-awareness is built in the analysis, not just any kind of reflection, access, or re-representation. This interpretation uses a certain reading of creature consciousness. It requires that an organism is not only aware but also self-aware. This is a notion of creature consciousness that at first seems to be in tension with Schooler’s main distinction. However, as I argued, this is not necessarily the case. Self-awareness itself comes in degrees and varies along multiple dimensions. Creature consciousness in mind-wandering can than be understood as an intentional relation between the organism and some object or item of which it is aware, in our case a train of thoughts (and/or the sensory states associated with it). This is where the contrast between content theories and functional theories comes into play. As I have argued, pure content or representationalist theories, which claim that conscious states have their mental properties due to their representational properties, are not a good strategic partner for Schooler. In contrast, a certain class of functional accounts, especially higher-order theories, turn out to be a nice fit for his account. These accounts analyze consciousness as a certain form of self-awareness. As a result, we can grant that for the experience of mind-wandering without meta-awareness there is some self-awareness required, and for meta-awareness another more demanding kind of self-awareness is necessary. Rosenthal’s higher-order account would give Schooler this kind of distinction: meta-awareness would include a third-order state, in his terminology a re-re-representation, whereas the experience of mind-wandering would involve only a second-order state, a re-representation (see p. 10).

The literature on phenomenology offers more helpful distinctions of how we can further evaluate these different dimensions. Most of

these distinctions are orthogonal. Several authors claim that “what is likeness” comes in different forms. For example, Carruthers distinguishes the “what it’s likeness” of the world (or *worldly* subjectivity—what the *world* is like for the subject—from *experiential* subjectivity—what the *subject’s experience is like for the subject*; Carruthers 1998, 2000). Rosenthal uses a similar distinction. He distinguishes thin from thick phenomenality, whereby thin phenomenality is the occurrence of a certain qualitative character. Thick phenomenality is richer: “[t]hick phenomenality is just thin phenomenality together with there being something it’s like *for one* to have that thin phenomenality” (Rosenthal 2002, p. 657, emphasis added). So thick phenomenality includes a certain kind of reflexion or extra level; it includes an awareness of a richer kind. For Rosenthal this is identical with the existence of an appropriate higher-order representation. But it is a specific kind of meta-cognitive process, one that contains a representation of “oneself”, or in other terminology, a selfmodel (Metzinger 2003). But the self-model itself, our understanding of ourselves and of the difference between oneself and others, might itself come in degrees and on different levels. So the issue is not meta-cognition or reflexion in general, but different levels and involvements of self-awareness.

Instead of focusing on the differing phenomenology, one might also try to specify the notion of access in further detail (Kouider et al. 2010), a suggestion that I think helps us to better understand what is meant by states referring to other states or accessing them. In the workspace model discussion a simple distinction between cognitive access and cognitive accessibility is introduced to defend the possibility of the abovementioned third category, unaccessed but conscious states. Instead of just access vs. accessibility, I suggest that we distinguish different kinds of access (see p. 11). Rather than assuming a rich phenomenology and differing forms of consciousness, one could also propose that awareness itself might come in degrees and that something like partial awareness might exist (Kouider et al. 2010). Instead of distinguishing dissociable forms of consciousness or differ-

ent kinds of personal level phenomenal character like the above accounts, Kouider et al. (2010) use sub-personal descriptions explaining what awareness might be. More exactly, dissociable levels of access are distinguished and differentiated by a hierarchy of representational levels. In case of partial awareness, we have informational access at *some but not all representational levels*. The crucial idea is that information at other levels can remain inaccessible. Or, in some situations, information at these levels could be accessed, but plausible content is filled, which than potentially results in misrepresentation.

I prefer this line of thinking, and I believe it gives us an improved understanding of the sub-personal processes involved in the different levels of reflection and “taking stock” we want to characterize. This framework is very suitable for a revised understanding of Schooler’s main distinction. However, Kouider et al. (2010) postulate partial access as an alternative explanation for conscious visual perception,²² not for internal cases like mind-wandering. But I think the analyses might be useful for our purposes as well. According to this framework, accessible contents at each level of representation are seen as resulting from the integration of signals with contextual prior information, processes that are also influenced by other internal factors (for example attentional factors or vigilance); this integration is further assumed to be modulated by the degree of confidence of the subject. The result is a more fine-grained perspective on conscious experience; instead of simply conscious or unconscious, we can talk about different dimensions of experience. And this is done at the sub-personal level by a specification of access. This also avoids another problem. As I pointed out, Schooler’s account seems very close in spirit to modern versions of workspace accounts. However, these accounts typically assume all-or-nothing mechanisms for access. This is no prob-

lem for Schooler, who proposes his core distinction as a dichotomy. However, it is a potential problem for the revised view I suggest. But I think this can in fact be an advantage. We can indeed grant that representations *within* each level might be accessed in an all-or-nothing manner (as is assumed in workspace models), but none the less insist that the full set of all the representations associated with this process do not have to be conscious.

Different terminologies aside, I think this fits nicely with the spirit of Schooler’s general distinction, and his distinction between experience and meta-awareness. I admit that these are just first steps towards a better conceptual understanding. But interpreted this way, there is not just conscious experience of mind-wandering versus meta-awareness. The situation is more complex. Reflection comes in many forms and involves representations at many levels, as well as access at all these levels of representation. In addition, whether, and to what degree, self-awareness and a self-model is involved makes a difference as well.

6 Perceptual perspective shifting. The Analogy and the mind-body problem

Let me take stock. I have been through the claims made in Schooler’s main underlying argument (see p. 3) So far, I have discussed claim (1), the initial conceptual distinction between experiential consciousness and meta-awareness, a distinction Schooler sets up as a dichotomy. I then discussed his second claim that there is empirical evidence that this conceptual distinction is something we find in cognitive abilities in cases of dissociations, especially in temporal dissociations like mind-wandering and in emotional transitional dissociations. I then argued that his empirical criteria developed in claim (3) are useful for cognitive accounts in general, independently of the worries one might have about claims (1) and (2). Finally I suggested a finer-grained conceptual distinction between different levels of awareness, different kinds of reflection, and “taking stock”. I will turn now to the last issue we shall examine, which is Schooler’s last and main claim (see p. 3):

²² Like most authors, they focus for the most part on the discussion of conscious perception, and especially Sperling (Block this collection; Fink this collection) and Stroop’s paradigms (see Mroczko-Wąsowicz this collection) and what we can learn from them for consciousness. For a more detailed discussion of the pros and cons or an understanding of consciousness as graded within conscious perception see the debate between Cleeremans (2008), Sergent & Dehaene (2004), Seth et al. (2008), and Overgaard et al. (2006).

Schooler claims that this can be used for a new theoretical and ontological framework for studying consciousness, and this is the declared goal of the target paper. He claims that his perceptual perspective-shifting analogy, together with insights from the sections before, gives us a new ontological perspective on the mind-body problem, not just a new methodological strategy. I found this section of the paper surprising. In my opinion, it is relatively independent of the main project he undertakes. Schooler starts by describing the main thought experiments in the philosophical literature used to challenge reductive physicalism.²³ He concludes that the main problem with the reductive positions is that it needs to “reject” those aspects of first person experience “that are not readily handled by a third-person account” (Schooler this collection, p. 25).

I am not convinced that this is correct. It seems a viable alternative solution to me to just subscribe to the traditional reply, and point to some kind of epistemic gap between the third-person approach and the first-person approach instead of an ontological one. One can admit that there is a gap, but it is an explanatory gap between physical processes and conscious experience. One could even state that the gap may be uncloseable in principle, but that consciousness is nonetheless physical (Levine 1983). That is, there is an epistemological gap, but no ontological gap. That we intuitively see a gap might be true; it does not follow that there actually *is* a gap in what exists. All one can conclude is that, epistemologically, there is gap. In addition, our intuitions might simply be wrong: we might be “innate dualists” and that this is the reason why to so frequently slip back in dualist talk (despite knowing better; Papineau 2011). That is the real reason why commonsense intuition pumping thought experiments work so

well. According to this view, the feeling that some part of reality is “left out”, i.e., the “explanatory gap”, arises only because we simply cannot stop ourselves thinking about the mind-brain relation in a dualist way, though this is actually the wrong thing to do. One can be a reductive physicalist without having to reject the phenomenon of conscious experience, despite the fact that we cannot (yet) reduce it or have proper explanations available as to why we experience certain phenomena the way we do. We can experience a gap, have the intuition that something is “left out”, and nonetheless that very intuition might very well be wrong. I simply do not see the need for Schooler’s solution, the postulation of a new realm, that gives rise to both the physical and subjective reality.

I am also not sure about the meaning of the perceptual perspective-shifting analogy itself. Because it rests on a purely metaphorical use of “perspective”, the analogy does not go through. Perceptual perspective-shifting happens at a personal level, moreover, shifting *experience* at the personal level. The supposedly analogous case occurs at the level of theories or accounts, which emphasize either the first- or third-person perspective. But individual experiences differ in principle from the focus certain theories have. Schooler suggests that the resolution of the conflicting perspectives lies in a meta-perspective that acknowledges the existence and irreducibility of both, even though both are somehow equally valid, such that the solution to this tension is a new realm, a meta-perspective which gives us a “higher-order outlook” (Schooler this collection, p. 26). However, Schooler agrees “that [i]t is easier to recognize the need for a meta-perspective than to identify precisely what such a view might be” (Schooler this collection, p. 26). He admits the character of the introduced meta-perspective is “speculative and highly underspecified” (Schooler this collection, p. 28) but thinks that it has intuitive appeal. He also concedes that this is the most speculative part of the paper. I must admit that I struggle with the concept. I fail to see the intuitive appeal. Mostly because it eludes my understanding what the proposed meta-perspective might be and how it is help-

²³ However, this section of the target paper goes beyond the discussion of the well-known traditional arguments from the philosophical debate, including the explanatory gap argument, the Mary argument, and others. Schooler adds a section on the phenomenon of time experience and reductive accounts that explain time. I found the last example very inspiring, because in contrast to the other arguments it is not just based on thought experiments. However, the implications of this for my purposes here do not matter; they are used as a intuition pump to appeal to the necessity of a meta-level, so I cannot cover this aspect in this commentary.

ful despite acknowledging our commonsense intuition, not at an epistemological but an ontological level. As a result, I do not find it explanatory. Moreover, it does not follow from the analogy. For an argument by analogy one needs properties shared by both parts of the analogy. Even if we admit that in perceptual perspective-shifting both personal-level interpretations of an ambiguous figure are equally valid, it does not seem to follow that the first-person perspective and the third-person perspective in *strategies to study consciousness* require a meta-perspective not identical with either of these perspectives. Both the cases seem to have only one thing in common, “perspective shifting”. But “perspective” is used purely metaphorical in the second case. Moreover, bridging the first- and third-person perspectives seems to be an epistemic challenge. But from an epistemic observation or claim an ontological claim does not follow. Even if we admit an epistemic gap and agree that we cannot help but see an explanatory gap in all these cases, the postulation of an independent higher-order meta-level, an ontological claim, is not well supported. In addition, both of these issues, the ontological as well as the epistemological claim, differ from the methodological approach defended by Schooler. To summarize, in my opinion this section, and the preferences regarding solutions of the mind-body problem, are conceptually relatively independent from the main project, which I take to be the development of a useful strategy to study consciousness and mind-wandering. Schooler’s strategy might be helpfully independently of whether one is a reductive or non-reductive physicalist. I think that such a methodological reading of his approach strengthens the project, because it disassociates it from a completely different issue.

7 Conclusion

Having noted the initial plausibility of the general outline of Schooler’s account, I pointed out some problems and expressed some general reservations about its scope. First, I argued that the postulation of a third kind of

conscious but not accessed or reflected state is not justified. As a result, the account is too narrow, because one of the underlying general assumptions is not justified. This assumption causes a number of problems and a few misunderstandings. However, the assumption seems conceptually independent of the main project, which is to allow us to bridge the gap between first- and third-person criteria for consciousness. I suggested that the main distinction is underspecified and needs further clarifications of the elements involved: access, reportability, and levels of awareness.

Second, although it is tempting to attribute a first-order account to Schooler, a more convincing alliance would actually be certain functional accounts, especially higher-order accounts and global workspace accounts. And I argued that we should replace the introduced dichotomy by a finer-grained distinction of different kinds of meta-cognitive processes and meta-reflections in several dimensions.

In discussing support for the underlying conceptual framework, I then argued that the evidence offered is actually about complex cases. As exciting as the empirical results are, they seem not to be about individual states, but rather about the connection between many states or even the stream of consciousness. The project is about creature consciousness, not state consciousness—though the initial distinction suggests otherwise. This is the first result of my commentary.

I would suggest giving up the idea that the account offers a new meta-perspective, which for Schooler is a preferable alternative to reductive physicalist accounts. I do not think there is a need for this ontological element in his account, and it does not seem to fit with the rest of the methodological project. In addition, the claim seems independent of the rest of the project and there are reductive accounts available that fit very nicely with his project. This is the second result.

In essence I suggested a few conclusions and recommendations, mostly based on conceptual considerations, which clarify and strengthen the main project, with which I sympathize.

1. We keep many main insights of the paper:
 - a) The account is still be a cognitive account, and we allow that cognitive factors help to get a grasp on consciousness; the project is still to bridge the gap between the first- and third-person perspective.
 - b) We also keep the insight that further processing and certain kinds of further processes might either change the state itself and/or the state's content. But we acknowledge that we need to consider the embeddedness of the state to determine the experience. In other words, we focus on processes and phenomena, instead of individual states. This allows Schooler to associate his project with either a hybrid account or a version of a functional account, more specifically a workspace account or higher-order account. Which in turn helps to specify the dimensions of meta-processing in more detail and get a better grasp of the necessary conceptual clarifications. Nonetheless, we still see meta-awareness and consciousness as distinct phenomena. I take this to be the driving idea in his initial distinction.
 - c) The proposed list of potential criteria is still extremely useful, since it helps to determine these very reflective dimensions and factors, which determine both experience and the activities of the mind. For example, the behavioral criteria²⁴ will be caused by these very meta-processes, which we try to identify in more detail.
 - d) Finally, we keep the insight that factors accessible through the third-person perspective can give us insight into what is going on in the mind, as well as in conscious processes.
2. The remaining task, then, is to specify the aspects and dimensions that are relevant, and the kinds of meta-processes, access, or reflection in question. I suggested building blocks for an improved taxonomy of different kinds of reflections and "taking stock". I suggested that awareness itself might come in degrees and at different levels of representation. By

distinguishing dissociable levels of access differentiated at hierarchical representational levels, we allow for partial awareness. In effect, this allows for a fine-grained perspective on conscious experience. Instead of just unconscious, conscious, and a meta-reflective level of awareness, we have different dimensions of experience. And this is done at the sub-personal level by a specification of the term "access". But we should restrain from simply postulating a third category, namely a state that is unaccessed (or un-accessible) but conscious, thereby avoiding the problems associated with the postulation of this third category. The resulting finer-grained taxonomy allows an improved understanding of how exactly meta-awareness and conscious experience differ. Of course there is a price to pay if we accept this change of focus. While we can still claim that the criteria give an insight into what is going on *in the mind*, "the mind" includes unconscious states, conscious states, and several levels of re-representational processes.

There are a number of advantages of a view like this. First, it is not in conflict with some of the most promising candidates for philosophical theories of consciousness. Moreover, one can still account for the similarity of an unconscious state and its conscious counterpart. And third, one can keep the initial idea behind Schooler's distinction between the experienced state and a meta-reflective level of awareness of "knowing that one is in this state", but would substitute it with a finer-grained conceptual framework of multiple differences among several dimensions.

²⁴ For example in the the discussion of emotions p. 13.

Stepping Back and Adding Perspective

A Reply to Verena Gottschling

Jonathan Schooler

In this reply, I circumvent (some might say dodge) a number of Gottschling's fine-grained comments by stepping back and reviewing the key points of the three major sections of my target paper in light of her more general concerns. I first consider Gottschling's primary criticism of the first section of my paper, namely that insights that might emerge from considering the perspective shifting associated with reversible images do not apply in the context of differences between first and third-person perspectives. Although I concede there are differences in the meaning of "perspective" in conceptual and perceptual domains, I argue that the common element of a reliance on a frame-of-reference is sufficient to make the analogy helpful. I contend that a necessary element in overcoming the limitations of particular perspectives in both conceptual and perceptual domains is attempting to consider alternative vantages. This approach is then used to justify the tack of the next two sections: considering first-person experience from the vantage of third-person science and considering third-person science from the vantage of first-person experience. I note that Gottschling is largely sympathetic to the broad goals of the second section of my paper, and observe that her major concern with the construct of experiential consciousness emerges from her burdening it with unwarranted assumptions. I use her constructive suggestion for the need for further development of the notion of meta-awareness as a springboard for introducing a previously overlooked element (experiential monitoring) that may be useful for explaining how people can knowingly monitor performance without explicit verbal re-representation. Finally, I consider Gottschling's view that the third section fails to add to the value of the paper. Although I acknowledge that the arguments in the second section stand independently, I argue that discussion of how science can inform experience gains greater balance by also considering how experience informs science. I close by challenging the view that knowledge gained from science necessarily trumps that gained by experience, and conclude that it remains a worthy goal to seek a meta-perspective that accommodates both first- and third-person perspectives without reducing one to the other.

1 Introduction

Reviewing a commentary on one's work, even one as thoughtful as that provided by [Gottschling \(this collection\)](#), is much like viewing a close-up picture of one's face on a large high-definition screen; every blemish seems patently visible and appears to overshadow even the most genuine of expressions. The temptation is to pull out one's

metaphoric Photoshop and doctor up every imperfection. There is another option, however, and that is to step back and consider whether from a broader perspective the blemishes are really as disfiguring as they might initially appear.

Inspired by this analogy, I will not attempt to rebut all of Gottschling's consistently

incisive remarks about my paper. Rather I will use this essay as an opportunity to step back and review the broad strokes of my arguments in light of Gottschling's more general concerns. In so doing, I hope to demonstrate that while Gottschling offers a number of insightful suggestions for clarification and elaboration, the general logic of my arguments remain largely intact. Nevertheless, Gottschling's critique offers an excellent opportunity to clarify some points that may have been lost in the expanse of my initial paper.

2 Reflections on section 2¹: Applying perspective shifts to conceptualizing human experience from the first- versus third-person perspective

My paper opens with the contention that seemingly opposing arguments can often reflect alternative vantages of a larger meta-perspective from which both views can be understood. I illustrate this point using the example of reversible images that can be seen as corresponding to two entirely different objects depending on one's perspective. I argue that when one recognizes that both vantages are true from their particular perspective, one gains an understanding of the larger context (i.e., a meta-perspective). Although most of my examples are perceptual illustrations, I suggest that there is a close correspondence between the processes involved in perspective taking in perceptual and conceptual domains, and that an appreciation of meta-perspectives in the perceptual domain may help the formulation of meta-perspectives in the conceptual domain. In the spirit of this argument I suggest that the long-standing debate between approaches that emphasize the subjective first-person perspective of experience and those that emphasize the objective third-person perspective of science, may be akin to debating which direction the dancer is rotating in the spinning dancer illusion (see figure 6 in [Schooler this collection](#)). In both cases, it simply depends on your perspective. Taken from the perspective of

the individual, understanding consciousness necessarily invites a reliance on introspection and first-person analysis. Taken from the perspective of conventional third-person science, understanding consciousness necessarily requires objectively observable facts (e.g., behaviors, physiological responses) that can be derived independently of any single individuals' experience

I argue that both of these views have merit, that both researchers and schools of thought have debated (often vehemently) about which of these two vantages is more appropriate, and that part of the heat of this controversy may stem from people's disinclination to switch back and forth between perspectives and thereby gain a larger view that treats neither as decisively superior.

Gottschling rejects the notion that the alternative perspectives afforded by reversible images has relevance to conceptualizing the challenges of reconciling first- and third-person perspectives. Her difficulty with this analogy stems (at least in part) from her view that the meaning of "perspective" in these two contexts does not align. As she puts it: "Because it rests on a purely metaphorical use of 'perspective', the analogy does not go through" ([Gottschling this collection](#), p. 18). To be sure there are significant differences between the meaning of "perspective" in the context of perceptual experience, such as reversible images, and conceptual ideas, such as the difference between first- and third-person approaches to the study of consciousness. However, I argue that there are some deep parallels between the meanings of "perspective" in these two contexts that make the analogy a useful one. I'll begin by considering the broader issue of the parallels between perceptual and conceptual perspectives and then the more specific question of how these parallels might usefully apply to the conceptual distinction between first- and third-person perspectives.

Critically, in both perceptual and conceptual contexts "perspective" is defined by a frame-of-reference that determines how the constituent elements are understood and related to one another, as well as which elements are

¹ The paper begins with a very brief introduction that is numbered section 1. As a result the first major section of the paper is numbered section 2.

taken as central and which as more peripheral. In perceptual contexts, the frame-of-reference is defined in terms of the assignment of spatial arrangements; i.e., what is to the left and the right, what is in the foreground and background etc. In conceptual contexts, the frame-of-reference is defined in terms of the assignment of conceptual arrangements; i.e.; which elements are conceptually closer or further apart, which are more essential and which more peripheral. In both cases, frame-of-reference can have profound effects as evidenced by the reversible image research in perception (Chambers & Reisberg 1992) and research on cognitive framing (Tversky & Kahneman 1981) in cognition. A further striking parallel between perceptual and conceptual perspectives is that they both become easily entrenched. When one watches the spinning dancer (figure 6) it is very difficult to recognize that at any time she can be seen as facing in one of two different directions. In a very similar way, when one works on a conceptual problem it is very easy to interpret it in a particular way that creates a “mental set” that can impede its solution. There is even a common cognitive ability (Schooler & Melcher 1995; see also, Wiseman et al. 2011) for overcoming the mental sets associated with solving conceptual problems (e.g., insight problems) and perceptual problems (e.g., recognizing out-of-focus pictures). In short, perceptual reversible images elegantly illustrate a fundamental aspect of not just perception but of human cognition more generally; namely, that we routinely consider things (be they objects or ideas) within the context of a particular frame-of-reference (be that frame perceptual or conceptual), and we can have a very hard time reconsidering those things from a different perspective.

Even if it is appropriate to draw a parallel between the meaning of “perspective” in perceptual and conceptual contexts, it does not necessarily follow that the analogy can be extended to the particular conceptual problem of distinguishing between the first- and third-person perspective approaches. But I maintain that it is in fact particularly applicable in this context. The essence of the distinction between first- and third-person perspectives has to do with one’s

frame-of-reference. If one considers consciousness from a first-person perspective, one is understanding it in relationship to one’s own personal experience, taking subjectivity as the foreground and objective reality as the background. One is considering consciousness through one’s own experience, and grounding assumptions on what is real and important on the basis of that personal subjective vantage. In contrast, a third-person perspective takes the objective world as the frame-of-reference. Personal experiences that cannot be independently verified are therefore suspect and inferences must be drawn, as they are in all of science, on the basis of people’s measurable behaviors and physiological responses. In my view, it is no accident that these two approaches to thinking about consciousness have historically been described in terms of differences in *perspective* as they self-evidently entail thinking about consciousness from distinctly different frames-of-reference.

In short, I maintain that the notion of distinct conflicting perspectives akin to those associated with perceptual reversible images aptly applies to many conceptual distinctions, but especially apply when it comes to characterizing the objective/subjective divide. The corollary of this claim is the possibility that, like the alternative perspectives of reversible images, the objective/subjective divide may be usefully informed by recognizing that both perspectives represent equally meaningful interpretations that cannot be reduced to one another, but may be better understood from a meta-perspective that acknowledges the larger context in which they are both embedded.

In my view, the importance of the distinct perspectives that emerge from alternative frames-of-reference simply cannot be overstated. In addition to its self-evident effects in the context of perception, frames-of-reference are a powerful determinant of the actions that people take in important real-life situations. For example, doctors’ prescriptions of how to treat an epidemic is profoundly influenced by whether the treatment is framed in terms of lives saved or lives lost even when it corresponds to precisely the same scenario (Tversky & Kahneman 1981). In physics, fundamental breakthroughs

have repeatedly taken place as a function of changes in scientists' frame-of-reference. For example, Newton's laws of gravity emerged when he realized that the same frame-of-reference that applies to forces on the ground equally applies to the motion of the heavens (Westfall 1980). Einstein's special theory of relativity was fostered by his replacement of the notion of an absolute frame-of-reference with a frame-of-reference defined relative to the observer (2001). Given the significance of perspective and frame-of-reference in other contexts it stands to reason that something so salient as whether one is thinking about consciousness from their own perspective or from the objective perspective of science should profoundly impact the questions that they ask and the answers that they reach.

In the case of reversible images, the best way to understand how they can correspond to two so entirely distinct yet self-consistent representations is to practice alternating between vantages. Although at first it is very difficult to see how the spinning dancer alternatively rotates in two different directions, with practice one comes to appreciate the two vantages that the image affords, and thus to understand why her direction changes. The primary goal of my paper is to explore the hypothesis that a deeper understanding of the subjective/objective divide can emerge in a similar fashion. By thoroughly considering each vantage from the perspective of the other, it is hoped that a meta-perspective will emerge that recognizes the logical consistency of each, while not attempting to reduce either one to the other.

Gottschling suggests that my emphasis on "meta-perspective" is an unnecessary strategic move that ultimately detracts from the primary value of my paper. Part of her difficulty with the meta-perspective emphasis may arise from my inadequately situating the second section of my paper in the context of this construct, and the seeming equation of meta-perspective with non-reductionism in the third section. However, the value of considering alternative perspectives in overcoming the limitations that can emerge when one solely considers a single vantage has merit regardless of whether one ascribes to any of the ontological speculations I suggest in the

third section of my paper. Independent of the conclusions that one derives, there seems to be great value in systematically considering subjective experience from the vantage of a third-person perspective, and objective reality from the vantage of a first-person perspective, which are the goals of section 2 and section 3 respectively.

3 Reflections on section 3: Gaining a third-person perspective on people's first-person experience

In the second section of my paper I review research that attempts to inform our understanding of the first-person experience using the third-person perspective of science. This approach takes at its starting point a theoretical distinction between experiential consciousness (corresponding to the contents of on-going experiences) and meta-consciousness (or meta-awareness—the terms are used interchangeably) corresponding to the explicit re-representation of the contents of experiential consciousness. These levels are illustrated by the case of mind-wandering while reading. In this context, experiential consciousness corresponds to the content of the mind-wandering episode and meta-awareness is initially absent but suddenly emerges with the realization that one was mind-wandering rather than attending to the text.

An important implication of the distinction between experiential consciousness and meta-consciousness is that people can have experiences (e.g., mind-wandering) that they either fail to notice explicitly (temporal dissociations) or notice but manage to mischaracterize (translation dissociations). I review a program of research that has fleshed out this distinction in various contexts, with a particular focus on mind-wandering. Using assorted methodologies including the combination of experience sampling measures, self-catching, and behavioral measures, we find evidence that people routinely fail to notice episodes of mind-wandering but are nevertheless accurate at reporting it when they are directly queried.²

² A very recent paper (Seli et al. in press) suggests some variability in the accuracy of mind-wandering reports as assessed by the corres-

Gottschling devotes the bulk of her remarks to discussing efforts to develop a third-person science of first-person experience. In general, she is sympathetic to the approach. However, she raises a variety of concerns and makes a number of useful suggestions. As noted, I will not endeavor to respond to all of her concerns; however, there are several that stand out, and so I will consider them in turn.

Gottschling's primary reservation about the distinction between experiential consciousness and meta-awareness is that she is not persuaded by my characterization of experiential consciousness. Essentially she does not see how it is possible to "distinguish conscious processes which are not accessed from unconscious activity" (Gottschling [this collection](#), p. 11). Although it is true that there are some situations where it may be difficult to distinguish experienced but not meta-aware from unconscious processes (as in the case of potentially unconscious emotions, see [Schooler et al. 2015](#)), often this distinction is quite straightforward. For example, when people are surprised to suddenly realize that they are mind-wandering instead of paying attention to what they reading. In this case, it is evident that they were experiencing the contents of the mind-wandering as they are typically able to report them. It is simply that they had not engaged in the reflective process of noting that they were mind-wandering instead of reading. In short, Gottschling is unpersuaded by a mental state—"conscious processes which are not accessed"—that I never actually postulated. Essentially, she layered onto the construct the notion that experiential consciousness is not accessed, and then criticized it for this reason.

In fact, although I am not committed to the notion that non-conscious higher order thoughts underpin all conscious thoughts ([Rosenthal 1986](#)), I have no problem with Gottschling's attempted revision to my notion of experiential consciousness, namely that it represents a third-order level of consciousness. Indeed I have speculated about this possibility in the

pendence of such reports to behavioral indices of lapses. Nevertheless, people appear to have some access to when their reports are likely to be more vs less accurate as evidenced by a significant correlation between confidence in self-reports and correspondence to the behavioral indices of mind-wandering.

past (see [Schooler et al. 2015](#)). I am therefore entirely comfortable with Gottschling's suggestion that "meta-awareness would include a third-order state, in his terminology a re-re-representation whereas the experience of mind-wandering would involve only a second-order state, a re-representation" ([this collection](#), p. 16). Just so long as the second-order cognition is not *experienced* as a reflection about experience, I have no problems with whatever non-conscious higher-order cognitions may be required to produce it.

Although Gottschling's concerns with the notion of experiential consciousness seem to be largely a product of her reading into my distinction more than was intended, her suggestion that it may be helpful to consider more fine-grained levels of meta-awareness is a worthwhile idea that merits development. As Gottschling observes, there is a need for "an improved taxonomy of different kinds of reflection and 'taking stock' ... awareness itself might come in degrees and at differently levels of representation" ([this collection](#), p 20). Indeed, one feature that has been notably absent from my discussion of meta-consciousness (here and elsewhere) is consideration of the possibility of monitoring processes that may take place at the experiential level, without explicit re-representation at the meta-level. For example, sometimes when people are on-task they may experience a palpable sense of sustained attention without having explicitly to note to themselves that they are on-task. Similarly, when mind-wandering, people sometimes report that they knew they were mind-wandering. This awareness, however, may not necessarily be associated with an explicit acknowledgment of that fact. Rather they maintain a continuous unstated awareness that they are off-task. In short, a further distinction may be needed between a non-propositional "feeling of awareness" that one is doing something ("experiential monitoring") and the verbal/ propositional state of meta-awareness that may occur when people intermittently take stock of their mental state, as when one suddenly thinks to themselves, "Darn! I was mind-wandering again!"

The notion that sometimes people explicitly re-represent their state to themselves (meta-awareness) whereas other times they simply "just

know” they are in that state (experiential monitoring) would also be consistent with alternative mindfulness practices (Thompson 2014). For instance, open-monitoring involves monitoring the content of experience from moment-to-moment without deliberately attending to any particular object (Lutz et al. 2008). Open-monitoring cultivates an aspect of mindfulness described as “observing”, measured with items such as “When I walk, I deliberately notice the sensation of my body moving” (Baer et al. 2006). This seems akin to what I am referring to as experiential monitoring. A somewhat different practice involves labeling one’s experiences as they occur with short tags like “thinking,” “feeling,” or “sensation.” This cultivates an aspect of mindfulness called “describing”, measured with items such as: “My natural tendency is to put my experiences into words.” This process of re-representing experience in words seems akin to meta-awareness.

The distinction between experiential monitoring and meta-awareness might also speak to another of Gottschling’s concerns, namely the question of whether meta-awareness is necessarily all-or-none (as I intimated) or more continuous (as she proposes). Although research would be required to tease out this conjecture, it seems quite plausible to me that experiential monitoring might take place at a continuous level with individuals ranging from either dimly to explicitly aware of what they are doing. In contrast, a more discrete process may occur when individuals suddenly realize that they are engaging in a mental state (e.g., mind-wandering) that they had not previously noticed.

Several other paper concerns that Gottschling raises about my paper, including the possibility of unconscious emotions and how the distinction between experiential consciousness and meta-awareness relates to other distinctions of consciousness (including those of Dehaene et al. 2006; Block 1995 and Rosenthal 1986) are discussed in other locations (e.g., Schooler et al. 2015). While she points out a number of other modest blemishes that I will not address, ultimately the approach for gaining a third-person perspective of first-person experience that I articulated in section 2 of my paper appears logically intact.

4 Reflections on section 4: Toward a meta-perspective for considering the meta-physics of first- versus third-person perspective

Gottschling seems less optimistic about the contribution of the third section of my paper. She dismisses speculations I derive from considering third-person science from the vantage of first-person experience, as a “largely unnecessary strategic move” (Gottschling this collection, p. 1) that “does not seem to fit with the rest of the project” (p. 22). I concur with Gottschling that first person experience can be assessed from the third person perspective of science without also considering objective science from a first-person perspective. In the past I have routinely considered what science has to say about first-person experience without considering the other side of the coin (e.g., Schooler 2002; Schooler et al. 2011; Schooler et al. 2015). Clearly the two sides of the discussion are not logically co-dependent on one another.

I acknowledge that the final section of the paper was not necessary for shoring up any of my arguments in the second section. Nevertheless I maintain that it adds an important balance to the discussion by illustrating the potential value of considering both first- and third-person approaches from the vantage of the alternative perspective. In this concluding section of my paper, I change my frame-of-reference from a third- to a first-person perspective, and consider the current assumptions of science from this vantage. I identify three aspects of existence that I argue are axiomatic from a first-person perspective, including: the existence of experience, the flow of time, and the fact that the present is qualitatively different from the past or the future. I argue that all three of these essential elements are either unexplained by science (i.e., experience) or outright discounted as an illusion of consciousness (i.e., the flow of time, the privileged present). I contend that while many aspects of experience could be illusory, it is hard (indeed impossible for me) to conceive of how experience, the flow of time, or the privileged nature of the present could be among them. On these grounds, I suggest that there may be something missing from the current

account of objective science and speculate that an additional subjective dimension of time might fit the bill. I argue that a subjective dimension of time would provide: 1) a realm of reality for experience to reside, 2) the additional degree of freedom necessary to enable the flow of time in physics' current "block universe", and 3) a way to conceptualize the present. I readily acknowledge that such an account is highly speculative, but I offer it as an example of the type of meta-perspective that I think could emerge by attempting to reconcile the axioms required for both objective and subjective frames-of-reference.

Gottschling's assessment of my arguments in this section are largely a rehash of standard critiques of the "explanatory gap" (Levine 1983) and the hard problem of consciousness (Chalmers 1996). The standard refrain is that the inability of science to account for subjectivity corresponds to an epistemological gap not an ontological one. The fact that we cannot explain something, and perhaps never will be able to, does not require us to assume a different ontological foundation for reality. I concede that this kind of mysterian (McGinn 1989) account of the explanatory gap, although profoundly unsatisfying, is difficult to dispute. However, she largely ignores the more novel aspects of my arguments. Namely, she disregards my claim that not only is the current physicalist account unable to explain consciousness, it outright rejects two additional subjectively self-evident aspects of reality. It rejects the flow of time and the privileged present. While she acknowledges in a footnote that she finds this aspect of the paper "inspiring," it does not impact her overall dismissal of the need for a meta-perspective. As she puts it, "what the proposed meta-perspective might be and how it is helpful despite acknowledging our common sense intuition eludes my understanding not at an epistemological level but at an ontological level" (Gottschling this collection, p. 23).

Gottschling's reaction to the third section of my paper was not unexpected. As I noted in the close of my paper, "my arguments on this point will likely remain wholly unpersuasive to those who cannot conceive of subjective experience as offering an epistemological authority that rivals science." I recognize that it will be an uphill

battle to persuade philosophers and scientists steeped in the supremacy of the third-person perspective to consider that conclusions drawn from our own experience could possibly carry ramifications comparable to conventional objective science. But at the end of the day all of the science that we believe we know is necessarily delivered to us through our subjective experience. While what we know about objective reality is necessarily dependent on experience, the same is not the case for experience. Objective reality could conceivably be an illusion. This could all be a dream or we could be the proverbial brain in a vat. But the *experience* of objective reality is unquestionable, as even an illusory experience is still an experience. Given that the existence of objective reality is ultimately on less certain ground than the existence of experience, it is far from obvious why the third-person frame-of-reference holds its current unchallenged dominion.

5 Conclusion

I suspect that my big-picture approach to replying to Gottschling's very detailed analysis may be unsatisfying to some (Gottschling included) who might have expected point-by-point replies to each of her concerns. However, I hope that my stepping-back tactic enabled me to address the major concerns that were raised. At the outset I noted the close parallels between the factors that contribute to conceptual and perceptual processes. In addition to the value of perspective shifting, it might also be noted that stepping-back is another strategy that is useful in both conceptual and perceptual domains. For example, it is easier to decipher a highly pixelated photo from a distance than up close. Similarly, when people confront conceptual insight problems from a more distant perspective (e.g., imagining themselves a year from now) they are often better able reach a solution (Förster et al. 2004). Conceptual stepping back can enable one to distinguish the metaphorical "forest from the trees." It remains unclear whether there could be a genuine meta-perspective that enables us to accommodate the assumptions of both the first- and third- person perspectives. But if such a perspective does ex-

ist, it seems likely that finding it will require stepping back...way back.

The Cybernetic Bayesian Brain

From Interoceptive Inference to Sensorimotor Contingencies

Anil K. Seth

Is there a single principle by which neural operations can account for perception, cognition, action, and even consciousness? A strong candidate is now taking shape in the form of “predictive processing”. On this theory, brains engage in predictive inference on the causes of sensory inputs by continuous minimization of prediction errors or informational “free energy”. Predictive processing can account, supposedly, not only for perception, but also for action and for the essential contribution of the body and environment in structuring sensorimotor interactions. In this paper I draw together some recent developments within predictive processing that involve predictive modelling of internal physiological states (*interoceptive inference*), and integration with “enactive” and “embodied” approaches to cognitive science (*predictive perception of sensorimotor contingencies*). The upshot is a development of predictive processing that originates, not in Helmholtzian perception-as-inference, but rather in 20th-century cybernetic principles that emphasized homeostasis and predictive control. This way of thinking leads to (i) a new view of emotion as active interoceptive inference; (ii) a common predictive framework linking experiences of body ownership, emotion, and exteroceptive perception; (iii) distinct interpretations of active inference as involving disruptive and disambiguatory—not just confirmatory—actions to test perceptual hypotheses; (iv) a neurocognitive operationalization of the “mastery of sensorimotor contingencies” (where sensorimotor contingencies reflect the rules governing sensory changes produced by various actions); and (v) an account of the sense of subjective reality of perceptual contents (“perceptual presence”) in terms of the extent to which predictive models encode potential sensorimotor relations (this being “counterfactual richness”). This is rich and varied territory, and surveying its landmarks emphasizes the need for experimental tests of its key contributions.

1 Introduction

An increasingly popular theory in cognitive science claims that brains are essentially prediction machines (Hohwy 2013). The theory is variously known as the Bayesian brain (Knill & Pouget 2004; Pouget et al. 2013), predictive processing (Clark 2013; Clark this collection), and the predictive mind (Hohwy 2013; Hohwy this collection), among others; here we use the term PP (predictive processing). (See Table 1 for a glossary of technical terms.) At its most fundamental, PP says that perception is the res-

ult of the brain inferring the most likely causes of its sensory inputs by minimizing the difference between actual sensory signals and the signals expected on the basis of continuously updated predictive models. Arguably, PP provides the most complete framework to date for explaining perception, cognition, and action in terms of fundamental theoretical principles and neurocognitive architectures. In this paper I describe a version of PP that is distinguished by (i) an emphasis on predictive modelling of in-

Table 1: A glossary of technical terms.

Allostasis	The process of achieving homeostasis.
Active inference	Classically conceived as the minimization of prediction error by performing actions that confirm sensory predictions. However, as argued in this paper, it may also involve the performance of actions to disconfirm current predictions or to disambiguate among competing perceptual hypotheses.
Counterfactually-equipped predictive model	A predictive or generative model that encodes not only the likely causes of current sensory inputs but also (and explicitly) the likely causes of fictive sensory inputs conditioned on possible but unexecuted actions.
Counterfactual richness	A predictive model is counterfactually rich if it encodes a rich repertoire of potential sensorimotor relations, i.e., relations between potential actions and their expected sensory consequences.
Exteroception/exteroceptive	The classic senses conveying signals originating in the external environment.
Free energy	An information-theoretic quantity that bounds or limits the surprise associated with encountering an input, given a generative/predictive model mapping causes to sensory inputs. Under fairly general assumptions, free energy is the long-run sum of prediction error.
Free energy principle (FEP)	The FEP says that organisms obey a fundamental imperative towards the avoidance of (information-theoretically) surprising events, according to which they must minimize the long-run average surprise of sensory states, since surprising sensory states are (in the long run) likely to reflect conditions incompatible with continued existence.
Homeostasis	Any regulative processes that enable a system to keep certain variables within specific bounds.
Interoception/interoceptive	The sense of the internal physiological condition of the body.
Interoceptive inference	The predictive modelling of internal physiological states.
Interoceptive sensitivity	A characterological trait that reflects individual sensitivity to interoceptive signals, usually operationalized via heartbeat detection tasks.
Perceptual presence	The sense of the subjective reality of the contents of perception.
PPSMC	Predictive Perception of SensoriMotor Contingencies. A new theory that integrates predictive processing with sensorimotor theory. It says that mastery of a sensorimotor contingency is equivalent to the induction and deployment of a counterfactually-equipped predictive model linking potential actions to their expected sensory consequences.
Predictive processing (PP)/predictive coding	A scheme, dating back at least to Hermann von Helmholtz, which conceives of perception as probabilistic inference on the causes of sensory signals. Predictive coding is one specific implementation of predictive processing that rests on algorithms developed in the setting of data compression.
Sensorimotor contingency (SMC)	SMCs describe ways in which sensory signals change given actions in specific contexts; they are “rules” describing sensorimotor dependencies.
Sensorimotor theory	A cognitive theory which says that visual experiences arises from an implicit knowledge or mastery of SMCs. On this theory, perception is an activity.

ternal physiological states and (ii) engagement with alternative frameworks under the banner of “enactive” and “embodied” cognitive science (Varela et al. 1993).

I first identify an unusual starting point for PP, not in Helmholtzian perception-as-inference, but in the mid 20th-century cybernetic theories associated with W. Ross Ashby (1952, 1956; Conant & Ashby 1970). Linking these origins to their modern expression in Karl Friston’s “free energy principle” (2010), perception emerges as a *consequence* of a more fundamental imperative towards homeostasis and control, and not as a process designed to furnish a detailed inner “world model” suitable for cognition and action planning. The ensuing view of PP, while still fluently accounting for (exteroceptive) perception, turns out to be more naturally applicable to the predictive perception of internal bodily states, instantiating a process of *interoceptive inference* (Seth 2013; Seth et al. 2011). This concept provides a natural way of thinking of the neural substrates of emotional and mood experiences, and also describes a common mechanism by which interoceptive and exteroceptive signals can be integrated to provide a unified experience of body ownership and conscious selfhood (Blanke & Metzinger 2009; Limanowski & Blankenburg 2013).

The focus on embodiment leads to distinct interpretations of *active inference*, which in general refers to the selective sampling of sensory signals so as to improve perceptual predictions. The simplest interpretation of active inference is the changing of sensory data (via selective sampling) to conform to current predictions (Friston et al. 2010). However, by analogy with hypothesis testing in science, active inference can also involve seeking evidence that goes *against* current predictions, or that *disambiguates* multiple competing hypotheses. A nice example of the latter comes from self-modelling in evolutionary robotics, where multiple competing self-models are used to specify actions that are most likely to provide disambiguatory sensory evidence (Bongard et al. 2006). I will spend more time on this example later. Crucially, these different senses of active inference rest on the capacity of predictive models to encode

counterfactual relations linking potential (but not necessarily executed) actions to their expected sensory consequences (Friston et al. 2012; Seth 2014b). It also implies the involvement of model comparison and selection—not just the optimization of parameters assuming a single model. These points represent significant developments in the basic infrastructure of PP.

The notion of counterfactual predictions connects PP with what at first glance seems to be its natural opponent: “enactive” theories of perception and cognition that explicitly reject internal models or representations (Clark this collection; Hutto & Myin 2013; Thompson & Varela 2001). Central to the enactive approach are notions of “sensorimotor contingencies” and their “mastery” (O’Regan & Noë 2001), where a sensorimotor contingency refers to a rule governing how sensory signals change in response to action. On this approach, the perceptual experience of (for example) redness is given by an implicit knowledge (mastery) of the way red things behave given certain patterns of sensorimotor activity. This mastery of sensorimotor contingencies is also said to underpin *perceptual presence*: the sense of subjective reality of the contents of perception (Noë 2006). From the perspective of PP, mastery of a sensorimotor contingency corresponds to the learning of a counterfactually-equipped predictive model connecting potential actions to expected sensory consequences. The resulting theory of PPSMC (Predictive Perception of SensoriMotor Contingencies), Seth 2014b) provides a much needed reconciliation of enactive and predictive theories of perception and action. It also provides a solution to the challenge of perceptual presence within the setting of PP: perceptual presence obtains when the underlying predictive models are *counterfactually rich*, in the sense of encoding a rich repertoire of potential (but not necessarily executed) sensorimotor relations. This approach also helps explain instances where perceptual presence seems to be lacking, such as in synaesthesia.

This is both a conceptual and theoretical paper. Space limitations preclude any significant treatment of the relevant experimental lit-

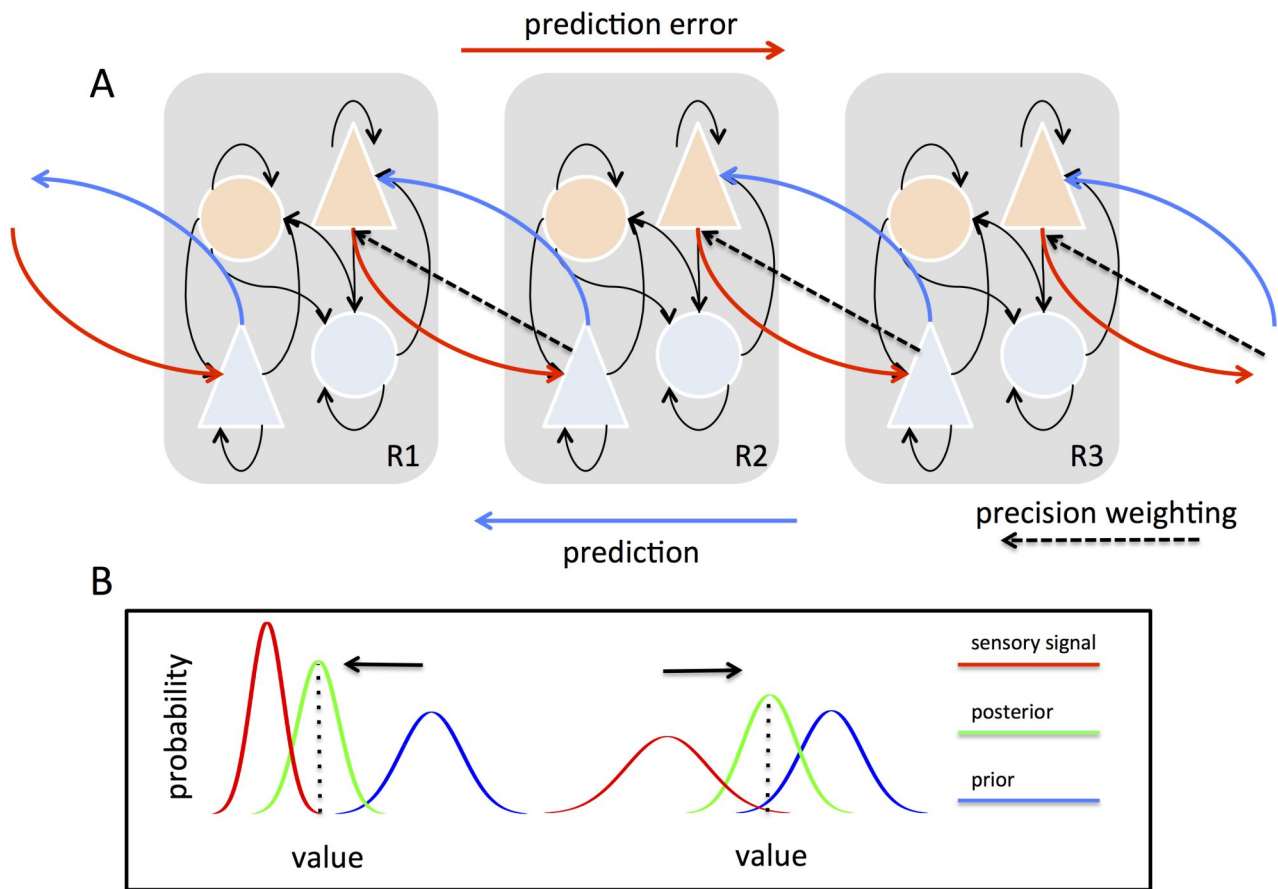

Figure 1: **A.** Schemas of hierarchical predictive coding across three cortical regions; the lowest on the left (R1) and the highest on the right (R3). Bottom-up projections (red) originate from “error units” (orange) in superficial cortical layers and terminate on “state units” (light blue) in the deep (infragranular) layers of their targets; while top-down projections (dark blue) convey predictions originating in deep layers and project to the superficial layers of their targets. Prediction errors are associated with precisions, which determine the relative influence of bottom-up and top-down signal flow via precision weighting (dashed lines). **B.** The influence of precisions on Bayesian inference and predictive coding. The curves show probability distributions over the value of a sensory signal (x -axis). On the left, high precision-weighting of sensory signals (red) enhances their influence on the posterior (green) and expectation (dotted line) as compared to the prior (blue). On the right, low sensory precision weighting has the opposite effect. Figure adapted from Seth (2013).

erature. However, even an exhaustive treatment would reveal that this literature so far provides only circumstantial support for the basics of PP, let alone for the extensions described here. Yet an advantage of PP theories is that they are grounded in concrete computational processes and neurocognitive architectures, giving us confidence that informative experimental tests can be devised. Implementing such an experimental agenda stands as a critical challenge for the future.

2 The predictive brain and its cybernetic origins

2.1 Predictive processing: The basics

PP starts with the assumption that in order to support adaptive responses, the brain must discover information about the external “hidden” causes of sensory signals. It lacks any direct access to these causes, and can only use information found in the flux of sensory signals them-

selves. According to PP, brains meet this challenge by attempting to predict sensory inputs on the basis of their own emerging models of the causes of these inputs, with prediction errors being used to update these models so as to minimize discrepancies. The idea is that a brain operating this way will come to encode (in the form of predictive or generative models) a rich body of information about the sources of signals by which it is regularly perturbed (Clark 2013).

Applied to cortical hierarchies, PP overturns classical notions of perception that describe a largely “bottom-up” process of evidence accumulation or feature detection. Instead, PP proposes that perceptual content is determined by top-down predictive signals emerging from multi-layered and hierarchically-organized generative models of the causes of sensory signals (Lee & Mumford 2003). These models are continually refined by mismatches (prediction errors) between predicted signals and actual signals across hierarchical levels, which iteratively update predictive models via approximations to Bayesian inference (see Figure 1). This means that the brain can induce accurate generative models of environmental hidden causes by operating only on signals to which it has direct access: *predictions* and *prediction errors*. It also means that even low-level perceptual content is determined via cascades of predictions flowing from very general abstract expectations, which constrain successively more fine-grained predictions.

Two further aspects of PP need to be emphasized from the outset. First, sensory prediction errors can be minimized either “passively”, by changing predictive models to fit incoming data (perceptual inference), or “actively”, by performing actions to confirm or test sensory predictions (active inference). In most cases these processes are assumed to unfold continuously and simultaneously, underlining a deep continuity between perception and action (Friston et al. 2010; Verschure et al. 2003). This process of active inference will play a key role in much of what follows. Second, predictions and prediction errors in a Bayesian framework have associated *precisions* (inverse variances, Figure 1). The precision of a prediction error is an in-

dicator of its reliability, and hence can be used to determine its influence in updating top-down predictive models. Precisions, like mean values, are not given but must be inferred on the basis of top-down models and incoming data; so PP requires that agents have *expectations about precisions* that are themselves updated as new data arrive (and new precisions can be estimated). Precision expectations can therefore balance the influence of different prediction-error sources on the updating of predictive models. And if prediction errors have low (expected) precision, predictive models may overwhelm error signals (hallucination) or elicit actions that confirm sensory predictions (active inference).

A picture emerges in which cortical networks engage in recurrent interactions whereby bottom-up prediction errors are continuously reconciled with top-down predictions at multiple hierarchical levels—a process modulated at all times by precision weighting. The result is a brain that not only encodes information about the sources of signals that impinge upon its sensory surfaces, but that also encodes information about how its own actions interact with these sources in specifying sensory signals. *Perception* involves updating the parameters of the model to fit the data; *action* involves changing sensory data to fit (or test) the model; and *attention* corresponds to optimizing model updating by giving preference to sensory data that are expected to carry more information, which is called precision weighting (Hohwy 2013). This view of the brain is shamelessly model-based and representational (though with a finessed notion of representation), yet it also deeply embeds the close coupling of perception and action and, as we will see, the importance of the body in the mediation of this interaction.

2.2 Predictive processing and the free energy principle

PP can be considered a special case of the *free energy principle*, according to which perceptual inference and action emerge as a consequence of a more fundamental imperative towards the avoidance of “surprising” events (Friston 2005, 2009, 2010). On the free energy principle, or-

ganisms – by dint of their continued survival—must minimize the long-run average surprise of sensory states, since surprising sensory states are likely to reflect conditions incompatible with continued existence (think of a fish out of water). “Surprise” is not used here in the psychological sense, but in an information-theoretic sense—as the negative log probability of an event’s occurrence (roughly, the unlikeliness of the occurrence of an event).

The connection with PP arises because agents cannot directly evaluate the (information-theoretic) surprise associated with an event, since this would require—impossibly—the agent to average over all possible occurrences of the event in all possible situations. Instead, the agent can only maintain a lower limit on surprise by minimizing the difference between actual sensory signals and those signals predicted according to a generative or predictive model. This difference is *free energy*, which, under fairly general assumptions, is the long-run sum of prediction error.

An attractive feature of the free energy principle is that it brings to the table a rich mathematical framework that shows how PP can work in practice. Formally, PP depends on established principles of Bayesian inference and model specification, whereby the most likely causes of observed data (*posterior*) are estimated based on optimally combining *prior expectations* of these causes with observed data, by using a (generative, predictive) model of the data that would be observed given a particular set of causes (*likelihood*). (See Figure 1 for an example of priors and posteriors.) In practice, because optimal Bayesian inference is usually intractable, a variety of approximate methods can be applied (Hinton & Dayan 1996; Neal & Hinton 1998). Friston’s framework appeals to previously worked-out “variational” methods, which take advantage of certain approximations (e.g., Gaussianity, independence of temporal scales)—thus allowing a potentially neat mapping onto neurobiological quantities (Friston et al. 2006).¹

1 Some challenging questions surface here as to whether prediction errors are used to update priors, which corresponds to standard Bayesian inference, or whether they are used to update the underlying generative/predictive model, which corresponds to learning.

The free energy principle also emphasizes *action* as a means of prediction error minimization, this being *active inference*. In general, active inference involves the selective sampling of sensory signals so as to minimize uncertainty in perceptual hypotheses (minimizing the entropy of the posterior). In one sense this means that actions are selected to provide evidence compatible with current perceptual predictions. This is the most standard interpretation of the concept, since it corresponds most directly to minimization of prediction error (Friston 2009). However, as we will see, actions can also be selected on the basis of an attempt to find evidence going against current hypotheses, and/or to efficiently disambiguate between competing hypotheses. These finessed senses of active inference represent developments of the free energy framework. Importantly, action itself can be thought of as being brought about by the minimization of *proprioceptive* prediction errors via the engagement of classical reflex arcs (Adams et al. 2013; Friston et al. 2010). This requires transiently low precision-weighting of these errors (or else predictions would simply be updated instead), which is compatible with evidence showing sensory attenuation during self-generated movements (Brown et al. 2013).

A more controversial aspect of the free energy principle is its claimed generality (Hohwy this collection). At least as described by Friston, it claims to account for adaptation at almost any granularity of time and space, from macroscopic trends in evolution, through development and maturation, to signalling in neuronal hierarchies (Friston 2010). However, in some of these interpretations reliance on predictive modelling is only implicit; for example the body of a fish can be considered to be an implicit model of the fluid dynamics and other affordances of its watery environment (see section 2.3). I am not concerned here with these broader interpretations, but will focus on those cases in which biological (neural) mechanisms plausibly implement explicit predictive inference via approximations to Bayesian computations—namely, the Bayesian brain (Knill & Pouget 2004; Pouget et al. 2013). Here, the free energy principle has potentially the greatest explanat-

ory power, especially given the convergence of empirical evidence (see [Clark 2013](#) and [Hohwy 2013](#) for reviews) and computational modelling showing how cortical microcircuits might implement approximate Bayesian inference ([Bastos et al. 2012](#)).

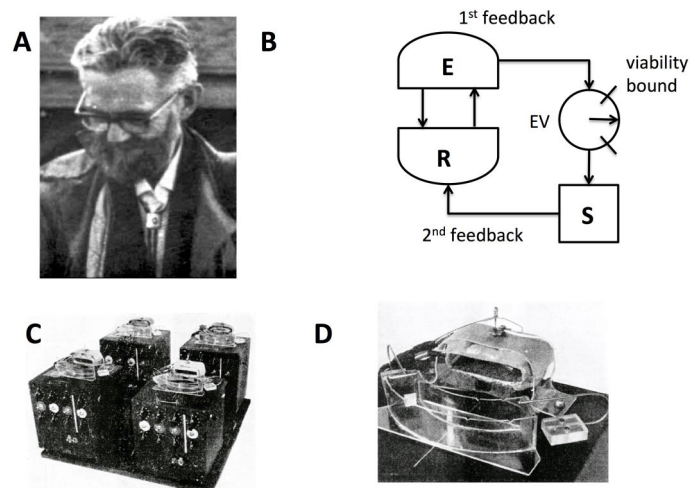

Figure 2: **A.** W. Ross Ashby, British psychiatrist and pioneer of cybernetics (1903–1972). **B.** A schematic of ultrastability, based on Ashby’s notebooks. The system R homeostatically maintains its essential variables (EVs) within viability limits via first-order feedback with the environment E . When first-order feedback fails, so that EVs run out-of-bounds, second order “ultrastable” feedback is triggered so that S (an internal controller, potentially model-based) changes the parameters of R governing the first-order feedback. S continually changes R until homeostatic relations are regained, leaving the EVs again within bounds. **C.** Ashby’s “homeostat”, consisting of four interconnected ultrastable systems, forming a so-called “multistable” system. **D.** One ultrastable unit from the homeostat. Each unit had a trough of water with an electric field gradient and a metal needle. Instability was represented by the non-central needle positions, which on occurring would alter the resistances connecting the units via discharge through capacitors. For more details see [Ashby \(1952\)](#) and [Pickering \(2010\)](#).

2.3 Predictive processing, free energy, and cybernetics

Typically, the origins of PP are traced to the work of the 19th Century physiologist Hermann von Helmholtz, who first formalized the idea of perception as inference. However, the Helmholt-

zian view is rather passive, inasmuch as there is little discussion of active inference or behaviour. The close coupling of perception and action emphasized in the free energy principle points instead to a deep connection between PP and mid-twentieth-century cybernetics. This is most obvious in the works of [W. Ross Ashby \(Ashby 1952; 1956; Conant & Ashby 1970\)](#) but is also evident more generally ([Dupuy 2009; Pickering 2010](#)). Importantly, cybernetics adopted as its central focus the *prediction and control of behaviour* in so-called teleological or purposeful machines.² More precisely, cybernetic theorists were (are) interested in systems that appear to have goals (i.e., teleological) and that participate in circular causal chains (i.e., involving feedback) coupling goal-directed sensation and action.

Two key insights from the first wave of cybernetics usefully anticipate the core developments of PP within cognitive science. These are both associated with Ashby, a key figure in the movement and often considered its leader, at least outside the USA ([Figure 2](#)).

The first insight consists in an emphasis on the homeostasis of internal *essential variables*, which, in physiological settings, correspond to quantities like blood pressure, heart rate, blood sugar levels, and the like. In Ashby’s framework, when essential variables move beyond specific viability limits, adaptive processes are triggered that re-parameterize the system until it reaches a new equilibrium in which homeostasis is restored ([Ashby 1952](#)). Such systems are, in Ashby’s terminology, *ultrastable*, since they embody (at least) two levels of feedback: a first-order feedback that homeostatically regulates essential variables (like a thermostat) and a second-order feedback that allostatically³ re-organises a system’s input–output relations when first-order feedback fails, until a new homeostatic regime is attained. In the most basic case, as implemented in Ashby’s famous “homeostat” ([Figure 2](#)), this second-order feedback simply involves random changes to system

² This underlines the close links between cybernetics and behaviourism. Perhaps this explains why cybernetics was so reluctant to bring phenomenology into its remit, an exclusion which, looking back, seems like a missed opportunity.

³ Allostasis: the process of achieving homeostasis.

parameters until a new stable regime is reached. The importance of this insight for PP is that it locates the function of biological and cognitive processes in generalizing homeostasis to ensure that internal essential variables remain within expected ranges.

Another way to summarize the fundamental cybernetic principle is to say that adaptive systems ensure their continued existence by successfully responding to environmental perturbations so as to maintain their internal organization. This leads to the second insight, evident in Ashby's *law of requisite variety*. This states that a successful control system must be capable of entering at least as many states as the system being controlled: "only variety can force down variety" (Ashby 1956). This induces a functional boundary between controller and environment and implies a minimum level of complexity for a successful controller, which is determined by the causal complexity of the environmental states that constitute potential perturbations to a system's essential variables. This view was refined some years later, in a 1970 paper written with Roger Conant entitled "Every good regulator of a system must be a model of that system" (Conant & Ashby 1970). This paper builds on the law of requisite variety by arguing (and attempting to formally show) that the nature of a controller capable of suppressing perturbations imposed by an external system (e.g., the world) must instantiate a model of that system. This provides a clear connection with the free energy principle, which proposes that adaptive systems minimize a limit on free energy (long-run average surprise) by inducing and refining a generative model of the causes of sensory signals. It also moves beyond Ashby's homeostat by implying that model-based controllers can engage in more successful multi-level feedback than is possible by random variation of higher-order parameters.

Putting these insights together provides a distinctive way of seeing the relevance of PP to cognition and biological adaptation. It can be summarized as follows. The purpose of cognition (including perception and action) is to maintain the homeostasis of essential variables and of internal organization (ultrastability).

This implies the existence of a control mechanism with sufficient complexity to respond to (i.e., suppress) the variety of perturbations it encounters (law of requisite variety). Further, this structure must instantiate a model of the system to be controlled (good regulator theorem), where the system includes both the body and the environment (and their interactions). As Ashby himself tells us "[t]he whole function of the brain can be summed up in: error correction" (quoted in Clark 2013, p. 1). Put this way, perception emerges as a *consequence* of a more fundamental imperative towards organizational homeostasis, and not as a stage in some process of internal world-model construction. This view, while highlighting different origins, closely parallels the assumptions of the free energy principle in proposing a primary imperative towards the continued survival of the organism (Friston 2010).

It may be surprising to consider the legacy of cybernetics in this light. This is because many previous discussions of this legacy focus on examples which show that complex, apparently goal-directed behaviour can emerge from simple mechanisms interacting with structured bodies and environments (Beer 2003; Braitenberg 1984). On this more standard development, cybernetics challenges rather than asserts the need for internal models and representations: it is often taken to justify slogans of the sort "the world is its own best model" (Brooks 1991). In fact, cybernetics is agnostic with respect to the need for deployment of explicit internally-specified predictive models. If environmental circumstances are reasonably stable, and mappings between perturbations and (homeostatic) responses reasonably straightforward, then the good regulator theorem can be satisfied by controllers that only implicitly model their environments. This is the case, for instance, in the Watt governor: a device that is able exquisitely to control the output of (for instance) a steam engine, in virtue of its mechanism, and not through the deployment of explicit predictive models or representations (see Figure 3 and Van Gelder 1995; note that the governor can

be described as an implicit model since it has variables – e.g., eccentricity of the metal balls from the central column – which map onto environmental variables that affect the homeostatic target – engine output). However, where there exist many-to-many mappings between sensory states and their probable causes, as may be the case more often than not, it will pay to engage explicit inferential processes in order to extract the most probable causes of sensory states, insofar as these causes threaten the homeostasis of essential variables.

Figure 3: The Watt governor. This system, a central contributor to the industrial revolution, enabled precise control over the output of (for example) steam engines. As the speed of the engine increases, power is supplied to the governor (A) by a belt or chain, causing it to rotate more rapidly so that the metal balls have more kinetic energy. This causes the balls to rise (B), which closes the throttle valve (C), thereby reducing the steam flow, which in turn reduces engine speed (D). The opposite happens when the engine speed decreases, so that the governor maintains engine speed at a precise equilibrium.

In summary, rather than seeing PP as originating solely in the Helmholtzian notion of “perception as inference”, it is fruitful to see it also as part of a process of model-based *predictive control* entailed by a fundamental imperative towards internal homeostasis. This shift in perspective reveals a distinctive agenda for PP in cognitive science, to which I shall now turn.

3 Interoceptive inference, emotion, and predictive selfhood

3.1 Interoceptive inference and emotion

Considering the cybernetic roots of PP, together with the free energy principle, leads to a potentially counterintuitive idea. This is that PP may apply more naturally to *interoception* (the sense of the internal physiological condition of the body) than to *exteroception* (the classic senses, which carry signals that originate in the external environment). This is because for an organism it is more important to avoid encountering unexpected interoceptive states than to avoid encountering unexpected exteroceptive states. A level of blood oxygenation or blood sugar that is unexpected is likely to be bad news for an organism, whereas unexpected exteroceptive sensations (like novel visual inputs) are less likely to be harmful and may in some cases be desirable, as organisms navigate a delicate balance between exploration and exploitation (Seth 2014a), testing current perceptual hypotheses through active inference (see section 5, below), all ultimately in the service of maintaining organismic homeostasis.

Perhaps because of its roots in Helmholtz, PP has largely been developed in the setting of visual neuroscience (Rao & Ballard 1999), with a related but somewhat independent line in motor control (Wolpert & Ghahramani 2000). Recently, an explicit application of PP to interoception has been developed (Seth 2013; Seth & Critchley 2013; Seth et al. 2011; see also Gu et al. 2013). On this theory of *interoceptive inference* (or equivalently *interoceptive predictive coding*), emotional states (i.e., subjective feeling states) arise from top-down predictive inference of the causes of interoceptive sensory signals (see Figure 4). In direct analogy to exteroceptive PP, emotional content is constitutively specified by the content of top-down interoceptive predictions *at a given time*, marking a distinction with the well-studied impact of expectations on *subsequent* emotional states (see e.g., Ploghaus et al. 1999; Ueda et al. 2003). Furthermore, interoceptive prediction errors can

be minimized by (i) updating predictive models (perception, corresponding to new emotional contents); (ii) changing interoceptive signals through engaging autonomic reflexes (autonomic control or active inference); or (iii) performing behaviour so as to alter external conditions that impact on internal homeostasis (allostasis; Gu & Fitzgerald 2014; Seth et al. 2011).

Figure 4: Inference and perception. Green arrows represent exteroceptive predictions and predictions errors underpinning perceptual content, such as the visual experience of a tomato. Orange arrows represent proprioceptive predictions (and prediction errors) underlying action and the experience of body ownership. Blue arrows represent interoceptive predictions (and prediction errors) underlying emotion, mood, and autonomic regulation. Hierarchically higher levels will deploy multimodal and even amodal predictive models spanning these domains, which are capable of generating multimodal predictions of afferent signals.

Consider an example in which blood sugar levels (an essential variable) fall towards or beyond viability thresholds, reaching unexpected and undesirable values (Gu & Fitzgerald 2014; Seth et al. 2011). Under interoceptive inference, the following responses ensue. First, interoceptive prediction error signals update top-down expectations, leading to sub-

jective experiences of hunger or thirst (for sugary things). Because these feeling states are themselves surprising (and non-viable) in the long run, they signal prediction errors at hierarchically-higher levels, where predictive models integrate multimodal interoceptive and exteroceptive signals. These models instantiate predictions of temporal sequences of matched exteroceptive and interoceptive inputs, which flow down through the hierarchy. The resulting cascade of prediction errors can then be resolved either through autonomic control, in order to metabolize bodily fat stores (active inference), or through allostatic actions involving the external environment (i.e., finding and eating sugary things).

The sequencing and balance of these events is governed by relative precisions and their expectations. Initially, interoceptive prediction errors have high precision (weighting) given a higher-level expectation of stable homeostasis. Whether the resulting high-level prediction error engages autonomic control or allostatic behaviour (or both) depends on the precision weighting of the corresponding prediction errors. If food is readily available, consummatory actions lead to food intake (as described earlier, these actions are generated by the resolution of proprioceptive prediction errors). If not, autonomic reflexes initiate the metabolization of bodily fat stores, perhaps alongside appetitive behaviours that are predicted to lead to the availability of food, conditioned on performing these behaviours.⁴

3.2 Implications of interoceptive inference

Several interesting implications arise when considering emotion as resulting from interoceptive inference (Seth 2013). First, the theory generalizes previous “two factor” theories of emotion that see emotional content as resulting from an interaction between the perception of physiolo-

⁴ It is interesting to consider possible dysfunctions in this process. For example, if high-level predictions about the persistence of low blood sugar become abnormally strong (i.e., low blood sugar becomes chronically expected), allostatic food-seeking behaviours may not occur. This process, akin to the transition from hallucination to delusion in perceptual inference (Fletcher & Frith 2009), may help understand eating disorders in terms of dysfunctional signalling of satiety.

gical changes (James 1894) and “higher-level” cognitive appraisal of the context within which these changes occur (Schachter & Singer 1962). Instead of distinguishing “physiological” and “cognitive” levels of description, interoceptive inference sees emotional content as resulting from the multi-layered prediction of interoceptive input spanning many levels of abstraction. Thus, interoceptive inference integrates cognition and emotion within the powerful setting of PP.

The theory also connects with influential frameworks that link interoception with decision making, notably the “somatic marker hypothesis” proposed by Antonio Damasio (1994). According to the somatic marker hypothesis, intuitive decisions are shaped by interoceptive responses (somatic markers) to potential outcomes. This idea, when placed in the context of interoceptive inference, corresponds to the guidance of behavioural (allostatic) responses towards the resolution of interoceptive prediction error (Gu & Fitzgerald 2014; Seth 2014a). It follows that intuitive decisions should be affected by the degree to which an individual maintains accurate predictive models of his or her own interoceptive states; see Dunn et al. 2010, Sokol-Hessner et al. 2014 for evidence along these lines.

There are also important implications for disorders of emotion, selfhood, and decision-making. For example, anxiety may result from the chronic persistence of interoceptive prediction errors that resist top-down suppression (Paulus & Stein 2006). Dissociative disorders like alexithymia (the inability to describe one’s own emotions), and depersonalization and derealisation (the loss of sense of reality of the self and world) may also result from dysfunctional interoceptive inference, perhaps manifest in abnormally low interoceptive precision expectations (Seth 2013; Seth et al. 2011). In terms of decision-making, it may be productive to think of addiction as resulting from dysfunctional active inference, whereby strong interoceptive priors are confirmed through action, overriding higher-order or hyper-priors relating to homeostasis and organismic integrity. It has even been suggested that

autism spectrum disorders may originate in aberrant encoding of the salience or precision of interoceptive prediction errors (Quattrocki & Friston 2014). The reasoning here is that aberrant salience during development could disrupt the assimilation of interoceptive and exteroceptive cues within generative models of the “self”, which would impair a child’s ability to properly assign salience to socially relevant signals.

3.3 The predictive embodied self

The maintenance of physiological homeostasis solely through direct autonomic regulation is obviously limited: behavioural (allostatic) interactions with the world are necessary if the organism is to avoid surprising physiological states in the long run. The ability to deploy adaptive behavioural responses mandates the original Helmholtzian view of perception-as-inference, which has been the primary setting for the development of PP so far. A critical but arguably overlooked middle ground, which mediates between physiological state variables and the external environment, is the *body*. On one hand, the body is the material vehicle through which behaviour is expressed, permitting allostatic interactions to take place. On the other, the body is itself an essential part of the organismic system, the homeostatic integrity of which must be maintained. In addition, the experience of owning and identifying with a particular body is a key component of being a conscious self (Apps & Tsakiris 2014; Blanke & Metzinger 2009; Craig 2009; Limanowski & Blankenburg 2013; Seth 2013).

It is tempting to ask whether common predictive mechanisms could underlie not only classical exteroceptive perception (like vision) and interoception (see above), but also their integration in supporting conscious and unconscious representations of the body and self (Seth 2013). The significance of this question is underlined by realising that just as the brain has no direct access to causal structures in the external environment, it also lacks direct access to its own body. That is, given that the brain is in the business of inferring the causal sources of

Figure 5: The interaction of interoceptive and exteroceptive signals in shaping the experience of body ownership. **A.** Set-up for applying cardio-visual feedback in the rubber hand illusion. A Microsoft Kinect obtains a real-time 3D model of a subject's left hand. This is re-projected into the subject's visual field using a head-mounted display and augmented reality (AR) software. **B.** The colour of the virtual hand is modulated by the subject's heart-beat. **C.** A similar set-up for the full-body illusion whereby a visual image of a subject's body is surrounded by a halo pulsing either in time or out of time with the heartbeat. Panels A and B are adapted from [Suzuki et al. \(2013\)](#); panel C is adapted from [Aspell et al. \(2013\)](#).

sensory signals, a key challenge emerges when distinguishing those signals that pertain to the body from those that originate from the external environment. A clue to how this challenge is met is that the physical body, unlike the external environment, constantly generates and receives internal input via its interoceptive and proprioceptive systems ([Limanowski & Blankenburg 2013](#); [Metzinger 2003](#)). This suggests that the experienced body (and self) depends on the brain's best guess of the causes of those sensory signals most likely to be “me” ([Apps & Tsakiris 2014](#)), across interoceptive, proprioceptive, and exteroceptive domains ([Figure 4](#)).

There is now considerable evidence that the *experience of body ownership* is highly plastic and depends on the multisensory integration of body-related signals ([Apps &](#)

[Tsakiris 2014](#); [Blanke & Metzinger 2009](#)). One classic example is the *rubber hand illusion*, where the stroking of an artificial hand synchronously with a participant's real hand, while visual attention is focused on the artificial hand, leads to the experience that the artificial hand is somehow part of the body ([Botvinick & Cohen 1998](#)). According to current multisensory integration models, this change in the experience of body ownership is due to correlation between vision and touch overriding conflicting proprioceptive inputs ([Makin et al. 2008](#)). Through the lens of PP, this implies that prediction errors induced by multisensory conflicts will over time update self-related priors ([Apps & Tsakiris 2014](#)), with different signal sources (vision, touch, proprioception) each precision-weighted according to their expected reliability, and all in

the setting of strong prior expectations for correlated input.⁵

While the potential for exteroceptive multisensory integration to modulate the experience of body ownership has been extensively explored both for the ownership of body parts and for the experience of ownership of the body as a whole (for reviews, see Apps & Tsakiris 2014; Blanke & Metzinger 2009), only recently has attention been paid to interactions between interoceptive and exteroceptive signals. Initial evidence in this line of investigation was indirect, for example showing correlation between susceptibility to the rubber hand illusion and individual differences in the ability to perceive interoceptive signals (“interoceptive sensitivity”, typically indexed by heartbeat detection tasks; Tsakiris et al. 2011). Other relevant studies have shown that body ownership illusions lead to temperature reductions in the corresponding body parts, perhaps reflecting altered active autonomic inference (Moseley et al. 2008; Salomon et al. 2013).

Emerging evidence now points more directly towards the predictive multisensory integration of interoceptive and exteroceptive signals in shaping the experience of body ownership. Two recent studies have taken advantage of so-called “cardio-visual synchrony” where virtual-reality representations of body parts (Suzuki et al. 2013) or the whole body (Aspell et al. 2013) are modulated by simultaneously recorded heartbeat signals, with the modulation either in-time or out-of-time with the actual heartbeat (Figure 5). These data suggest that statistical correlations between interoceptive (e.g., cardiac) and exteroceptive (e.g., visual) signals can lead to the updating of predictive models of self-related signals through (hierarchical) minimization of prediction error, just as happens for purely exteroceptive multisensory conflicts in the classic rubber hand illusion.

While these studies underline the plausibility of common predictive mechanisms underlying emotion, selfhood, and perception, many open questions nevertheless remain. A key challenge is to detail the underlying neural opera-

tions. Though a detailed analysis is beyond the scope of the present paper, it is worth noting that attention is increasingly focused on the insular cortex (especially its anterior parts) as a potential source of interoceptive predictions, and also as a comparator registering interoceptive prediction errors. The anterior insula has long been considered a major cortical locus for the integration of interoceptive and exteroceptive signals (Craig 2003; Singer et al. 2009); it is strongly implicated in interoceptive sensitivity (Critchley et al. 2004); it is sensitive to interoceptive prediction errors—at least in some contexts (Paulus & Stein 2006); and it has a high density of so-called “von Economo” neurons,⁶ which have been frequently though circumstantially associated with consciousness and selfhood (Critchley & Seth 2012; Evrard et al. 2012).

3.4 Active inference, self-modeling, and evolutionary robotics

What role might *active* inference play in predictive self-modelling? Autonomic changes during illusions of body ownership (see above) are consistent with active inference; however they do not speak directly to its function. In the classic rubber hand illusion, hand or finger movements can be considered active inferential tests of self-related hypotheses. If these movements are not reflected in the “rubber hand”, the illusion is destroyed—presumably because predicted visual signals are not confirmed (Apps & Tsakiris 2014). However, if hand movements are mapped to a virtual “rubber hand”—through clever use of virtual and augmented reality—the illusion is in fact strengthened, presumably because the multisensory correlation of peri-hand visual and proprioceptive signals constitutes a more stringent test of the perceptual hypothesis of ownership of the virtual hand (Suzuki et al. 2013). This introduces the idea that active inference is not simply about confirming sensory predictions but also involves seeking “disruptive” actions that are most informative with respect to testing current predictions,

⁵ Interestingly the expectation of perceptual correlations seems to be sufficient for inducing the rubber hand illusion (Ferri et al. 2013).

⁶ These are long-range projection neurons found selectively in hominid primates and certain other species.

and/or at disambiguating competing predictions (Gregory 1980). A nice example of how this happens in practice comes from *evolutionary robotics*⁷—which is obviously a very different literature, though one that inherits directly from the cybernetic tradition.

In a seminal 2006 study, Josh Bongard and colleagues described a four-legged “starfish” robot that engaged in a process much like active inference in order to model its own morphology so as to be able to control its movement and attain simple behavioural goals (Bongard et al. 2006). While there are important differences between evolutionary robotics and (active) Bayesian inference, there are also broad similarities; importantly, both can be cast in terms of model selection and optimization.

The basic cycle of events is shown in Figure 6. The robot itself is shown in the centre (A). The goal is to develop a controller capable of generating forward movement. The challenge is that the robot’s morphology is unknown to the robot itself. The system starts with a range of (generic prior) potential self-models (B), here specified by various configurations of three-dimensional physics engines. The robot performs a series of initially random actions and evaluates its candidate self-models on their ability to predict the resulting proprioceptive afferent signals. Even though all initial models will be wrong, some may be better than others. The key step comes next. The robot evaluates new candidate actions *on the extent to which the current best self-models make different predictions as to their (proprioceptive) consequences*. These disambiguating actions are then performed, leading to a new ranking of self-models based on their success at proprioceptive prediction. This ranking, via the evolutionary robotics methods of mutation and replication, gives rise to a new population of candidate self-models. The upshot is that the system swiftly develops accurate self-models that can be used to generate controllers enabling movement (D). An interesting feature of this process is that it is

highly resilient to unexpected perturbations. For instance, if a leg is removed then proprioceptive prediction errors will immediately ensue. As a result, the system will engage in another round of self-model evolution (including the co-specification of competing self-models and disambiguating actions) until a new, accurate, self-model is regained. This revised self-model can then be used to develop a new gait, allowing movement, even given the disrupted body (E, F).⁸

This study emphasizes that the operational criterion for a successful self-model is not so much its fidelity to the physical robot, but rather its ability to predict sensory inputs under a repertoire of actions. This underlines that predictive models are recruited for the control of behaviour (as cybernetics assumes) and not to furnish general-purpose representations of the world or the body.

The study also provides a concrete example of how actions can be performed, not to achieve some externally specified goal, but to permit inference about the system’s own physical instantiation. Bayesian or not, this implies active inference. Indeed, perhaps its most important contribution is that it highlights how active inference can prescribe *disruptive* or *disambiguating* actions that generate sensory prediction errors under competing hypotheses, and not just actions that seek to confirm sensory predictions. This recalls models of attention based on maximisation of Bayesian surprise (Itti & Baldi 2009), and is equivalent to hypothesis testing in science, where the best experiments are those concocted on the basis of being most likely to falsify a given hypothesis (disruptive) or distinguish between competing hypotheses (disambiguating). It also implies that agents encode predictions about the likely sensory consequences of a range of potential actions, allowing the selection of those actions likely to be the most disruptive or disambiguating. This concept of a *counterfactually-equipped predictive model* bring us nicely to our next topic: so-called *en-active* cognitive science and its relation to PP.

⁷ Evolutionary robotics involves the use of population-based search procedures (genetic algorithms) to automatically specify control architectures (and/or morphologies) of mobile robots. For an excellent introduction see (Bongard 2013).

⁸ Videos showing the evolution of both gait and self-model are available from http://creativemachines.cornell.edu/emergent_self_models

4 Predictive processing and enactive cognitive science

4.1 Enactive theories, weak and strong

The idea that the brain relies on internal representations or models of extra-cranial states of affairs has been treated with suspicion ever since the limitations of “good old fashioned arti-

ficial intelligence” became apparent ([Brooks 1991](#)). Many researchers of artificial intelligence have indeed returned to cybernetics as an alternative framework in which closely coupled feedback loops, leveraging invariants in brain-body-world interactions, obviate the need for detailed internal representations of external properties ([Pfeifer & Scheier 1999](#)). The evolutionary robotics methodology just described is

often coupled with simple dynamical neural networks in order to realize controllers that are tightly embodied and embedded in just this way (Beer 2003). Within cognitive science, such anti-representationalism is most vociferously defended by the movement variously known as “enactive” (Noë 2004), “embodied” (Gallese & Sinigaglia 2011), or “extended” (Clark & Chalmers 1998) cognitive science. Among these approaches, it is enactivism that is most explicitly anti-representationalist. While enactive theorists might agree that adaptive behaviour requires organisms and control structures that are systematically sensitive to statistical structures in their environment, most will deny that this sensitivity implies the existence and deployment of any “inner description” or model of these probabilistic patterns (Chemero 2009; Hutto & Myin 2013).

This tradition has weak and strong expressions. At the weak extreme is the truism that perception, cognition, and behaviour—and their underlying mechanisms—cannot be understood without a rich appreciation of the roles of the body, the environment, and the structured interactions that they support (Clark 1997; Varela et al. 1993). Weak enactivism is eminently compatible with PP, as seen especially with emerging versions of PP that stress embodiment through self-modelling and interoception, and which emphasize the importance of agent-environment coupling (embeddedness) through active inference. At the other extreme lie claims that explanations based on internal representations or models of any sort are fundamentally misguided, and that a new explicitly non-representational vocabulary is needed in order to make sense of the relations between brains, bodies, and the world (O’Regan et al. 2005). Strong enactivism is by definition incompatible with PP since it rejects the core concept of the internal model.

4.2 Sensorimotor contingency theory

A landmark in the strongly enactive approach is SMC (sensorimotor contingency) theory, which says that perception depends on the “practical mastery” of sensorimotor dependencies relevant

to behaviour (O’Regan & Noë 2001). In brief, SMC theory claims that experience and perception are not things that are “generated” by the brain (or by anything else for that matter) but are, rather, “skills” consisting of fluid patterns of on-going interaction with the environment (O’Regan & Noë 2001). For instance, on SMC theory the conscious visual experience of redness is given by *the exercise of practical mastery of the laws governing how interactions with red things unfold* (these laws being the “SMC”s). The theory is not, however, limited to vision: the experiential quality of the softness of a sponge would be given by (practical mastery of) the laws governing its squishiness upon being pressed.

Two aspects of SMC theory deserve emphasis here. The first is that the concept of an SMC rightly underlines the close coupling of perception and action and the critical importance of ongoing agent-environment interaction in structuring perception, action, and behaviour. This is inherited from Gibsonian notions of perceptual affordance (Gibson 1979) and has certainly advanced our understanding of why different kinds of perceptual experience (vision, smell, touch, etc.) have different qualitative characters.

The second is that *mastery* of an SMC requires an essentially *counterfactual* knowledge of relations between particular actions and the resulting sensations. In vision, for instance, mastery entails an implicit knowledge of the ways in which moving our eyes and bodies would reveal additional sensory information about perceptual objects (O’Regan & Noë 2001). Here SMC theory has made an important contribution to our understanding of *perceptual presence*. Perceptual presence refers to the property whereby (in normal circumstances) perceptual contents appear as subjectively real, that is, as *existing*. For example, when viewing a tomato, we see it as real inasmuch as we seem to be perceptually aware of some of its parts (e.g., its back) that are not currently causally impacting our sensory surfaces. Looking at a picture of a tomato does not give rise to the same subjective impression of realness. But how can we be aware of parts of the tomato that, strictly speaking, we do not

see? SMC theory says the answer lies in our (implicit) mastery of SMCs, which relate potential actions to their likely sensory effects; and it is in this sense that we can be perceptually aware of parts of the tomato that we cannot actually see (Noë 2006).

SMC theory has often been set against naïve representationalist theories in cognitive science that propose such things as “pictures in the head” or that (like good-old-fashioned-AI) treat accurate representations of external properties as general-purpose goal states for cognition. This is all to the good. Yet by dispensing with implementation-level concepts such as predictive inference, it struggles with the important question of what exactly is going on in our heads during the exercise of mastery of a sensorimotor contingency.⁹

4.3 Predictive perception of sensorimotor contingencies

A powerful response is given by integrating SMC theory with PP, in the guise of PPSMC (Predictive Perception of SensoriMotor Contingencies; Seth 2014b). An extensive development of PPSMC is given elsewhere (see Seth 2014b plus commentaries and response). Here I summarize the main points. First, recall that under PP prediction errors can be minimized either by updating perceptual predictions or by performing actions, where actions are generated through the resolution of proprioceptive prediction errors. Also recall that PP is inherently hierarchical, so that at some hierarchical level predictive models will encode multimodal and even amodal expectations linking exteroceptive (sensory) and proprioceptive (motor) sensations. These models generate predictions about linked sequences of sensory and proprioceptive (and possibly interoceptive) inputs corresponding to specific actions, with predictions becoming increasingly modality-specific at lower hierarchical levels. These multi-level predictive models can

therefore be understood as instantiating the implicit sub-personal knowledge of sensorimotor constructs underlying SMCs and their acquisition. Put simply, hierarchical active inference implies the existence of predictive models encoding information very much like that required by SMC theory.

The next step is to incorporate the notion of *mastery* of SMCs, which, as mentioned, implies an essentially counterfactual kind of implicit knowledge. The simple solution is to augment the predictive models that animate PP with counterfactual probability densities.¹⁰ As introduced earlier (section 4.1), counterfactually-equipped predictive models encode not only the likely causes of current sensory input, but also the likely causes of fictive sensory inputs conditioned on possible but not executed actions. That is, they encode how sensory inputs (and their expected precisions) would change on the basis of a repertoire of possible actions (expressed as proprioceptive predictions), even if those actions are not performed. The counterfactual encoding of expected precision is important here, since it is on this basis that actions can be selected for their likelihood of minimizing the conditional uncertainty associated with a perceptual prediction. There is a mathematical basis for manipulating counterfactual beliefs of this kind, as shown in a recent model where counterfactual PP drives oculomotor control during visual search (Friston 2014; Friston et al. 2012).¹¹ Here the main point is that counterfactually-rich predictive models supply just what is needed by SMC theory: an answer to the question of what is going on inside our heads during the exercise of mastery of SMCs.

Counterfactual PP makes sense from several perspectives (Seth 2014b). As mentioned above, it provides a neurocognitive operationalisation of the notion of mastery of SMCs that is central to enactive cognitive science. In doing so it dissolves apparent tensions between enactive

⁹ At a recent symposium of the AISB society that focused on SMC theory, it was stated that “the main question is how to get the brain into view from an enactive/sensorimotor perspective. [...] Addressing this question is urgently needed, for there seem to be no accepted alternatives to representational interpretations of the inner processes” (O’Regan & Dagenaar 2014).

¹⁰ See Beaton (2013) for a distinct approach to incorporating counterfactual ideas in SMC theory. Beaton’s approach remains squarely within the strongly enactivist tradition.

¹¹ There are also some challenges lying in wait here. For instance, it is not immediately clear how important assumptions like the Laplace approximation can generalize to the multimodal probability distributions entailed by counterfactual PP (Otworowska et al. 2014).

cognitive science and approaches grounded in the Bayesian brain, but only at the price of rejecting the strong enactivist's insistence that internal models or representations—of any sort—are unacceptable.¹² PPSMC also provides a solution to the challenge of accounting for perceptual presence within PP. The idea here is that perceptual presence corresponds to the *counterfactual richness* of predictive models. That is, perceptual contents enjoy presence to the extent that the corresponding predictive models encode a rich repertoire of counterfactual relations linking potential actions to their likely sensory consequences.¹³ In other words, we experience normal perception as world-revealing precisely because the predictive models underlying perceptual content specify a rich repertoire of counterfactually explicit probability densities encoding the mastery of SMCs.

A good test of PPSMC is whether it can account for cases where normal perceptual presence is lacking. An important example is synaesthesia, where it is widely reported that synaesthetic “concurrents” (e.g., the inexistent colours sometimes perceived along with achromatic grapheme inducers) are not experienced as being part of the world (i.e., synaesthetes generally retain intact reality testing with respect to their concurrent experiences). PPSMC explains this by noticing that predictive models related to synaesthetic concurrents are counterfactually *poor*. The hidden (environmental) causes giving rise to concurrent-related sensory signals do not embed a rich and deep statistical structure for the brain to learn. In particular, there is very little sense in which synaesthetic concurrents depend on active sampling of their hidden causes. According to PPSMC, it is this comparative *counterfactual poverty* that explains why synaesthetic concurrents lack perceptual presence. SMC theory itself struggles to account for this phenomenon—not least because it struggles to account for synaesthesia in the first place (Gray 2003).

¹² There is a more dramatic conflict with “radical” versions of enactivism, in which mental processes, and in some cases even their material substrates, are allowed to extend beyond the confines of the skull (Hutto & Myin 2013).

¹³ Presence may also depend on the hierarchical depth of predictive models inasmuch as this reflects object-related invariances in perception. For further discussion see commentaries and response to (Seth 2014b).

There are some challenges to thinking that perceptual presence uniquely depends on counterfactual richness. One might think that the more familiar one is with an object, the richer the repertoire of counterfactual relations that will be encoded. If so, the more familiar one is with an object, the more it should appear to be real. But *prima facie* it is not clear that familiarity and perceptual presence go hand-in-hand like this.¹⁴ Also, some perceptual experiences (like the experience of a blue sky) can seem highly perceptually present despite engaging an apparently poor repertoire of counterfactual relations linking sensory signals to possible actions. An initial response is to consider that presence might depend not on counterfactual richness *per se*, but on a “normalized” richness based on higher-order expectations of counterfactual richness (which would be low for the blue sky, for instance). These considerations also point to potentially important distinctions between perceived *objecthood* and perceived *presence*, a proper treatment of which moves beyond the scope of the present paper.

5 Active inference

5.1 Counterfactual PP and active inference

Active inference has appeared repeatedly as an important concept throughout this paper. Yet it is more difficult to grasp than the basics of PP, which involve passive predictive inference. This is partly because several senses of active inference can be distinguished, which have not previously been fully elaborated.

In general, active inference can be harnessed to drive action, or to improve perceptual predictions. In the former case, actions emerge from the minimization of proprioceptive prediction errors through engaging classical reflex arcs (Friston et al. 2010). This implies the existence of generative models that predict time-varying flows of proprioceptive inputs (rather than just end-points), and also the transient reduction of expected precision of proprioceptive prediction

¹⁴ Thanks to my reviewers for raising this provocative point.

errors, corresponding to sensory attenuation (Brown et al. 2013).

In the latter case, actions are engaged in order to generate new sensory samples, with the aim of minimizing uncertainty in perceptual predictions. This can be achieved in several different ways, as is apparent by analogy with experimental design in scientific hypothesis testing. Actions can be selected that (i) are expected to *confirm* current perceptual hypotheses (Friston et al. 2012); (ii) are expected to *disconfirm* such hypotheses; or (iii) are expected to *disambiguate* between competing hypotheses (Bongard et al. 2006). A scientist may perform different experiments when attempting to find evidence against a current hypothesis than when trying to decide between different hypotheses. In just the same way, active inference may prescribe different sampling actions for these different objectives.

These distinctions underline that active inference *implies* counterfactual PP. In order for a brain to select those actions most likely to confirm, disconfirm, or decide between current predictive model(s), it is necessary to encode expected sensory inputs and precisions related to potential (but not executed) actions. This is evident in the example of oculomotor control described earlier (Friston et al. 2012). Here, saccades are guided on the basis of the expected precision of sensory prediction errors so as to minimize the uncertainty in current perceptual predictions. Note that this study retained the higher-order prior that only a single perceptual prediction exists at any one time, precluding active inference in its disambiguatory sense.

Several related ideas arise in connection with these new readings of active inference. Seeking disconfirmatory or disruptive evidence is closely related to maximizing Bayesian surprise (Itti & Baldi 2009). This also reminds us that the best statistical models are usually those that successfully account for the most variance with the fewest degrees of freedom (model parameters), not just those that result in low residual error *per se*. In addition, disambiguating competing hypotheses moves from Bayesian model selection and optimization to model comparison, where arbitration among

competing models is mediated by trade-offs between accuracy and model complexity (Rosa et al. 2012).

The information-seeking (or “infotropic”¹⁵) role of active inference puts a different gloss on the free energy principle, which had been interpreted simply as minimization of prediction error. Rather, now the idea is that systems best ensure their long-run survival by inducing the *most predictive* model of the causes of sensory signals, and this requires disruptive and/or disambiguating active inference, in order to always put the current-best model to the test. This view helps dissolve worries about the so-called “dark room problem” (Friston et al. 2012), in which prediction error is minimized by predicting something simple (e.g., the absence of visual input) and then trivially confirming this prediction (e.g., by closing one’s eyes).¹⁶ Previous responses to this challenge have appealed to the idea of higher-order priors that are incompatible with trivial minimization of lower-level prediction errors: closing one’s eyes (or staying put in a dark room) is not expected to lead to homeostatic integrity on average and over time (Friston et al. 2012; Hohwy 2013). It is perhaps more elegant to consider that disruptive and disambiguatory active inferences imply exploratory sampling actions, independent of any higher-order priors about the dynamics of sensory signals *per se*. Further work is needed to see how cost functions reflecting infotropic active inference can be explicitly incorporated into PP and the free energy principle.

5.2 Active interoceptive inference and counterfactual PP

What can be said about counterfactual PP and active inference when applied to *interoception*? Is there a sense in which predictive models underlying emotion and mood encode counterfactual associations linking fictive interoceptive signals (and their likely causes) to autonomic or allostatic controls? And if so, what phenomeno-

¹⁵ Chris Thornton came up with this term (personal communication).

¹⁶ The term “dark room problem” comes from the idea that a free-energy-minimizing (or surprise-avoiding) agent could minimize prediction error just by finding an environment that lacks sensory stimulation (a “dark room”) and staying there.

logical dimensions of affective experience depend on these associations? While these remain open questions, we can at least sketch the territory.

We have seen that active inference in exteroception *implies* counterfactual processing, so that actions can be chosen according to their predicted effects in terms of (dis)confirming or disambiguating sensory predictions. The same argument applies to interoception. For active interoceptive inference to effectively disambiguate predictive models, or (dis)confirm interoceptive predictions, predictive models must be equipped with counterfactual associations relating to the likely effects of autonomic or (at higher hierarchical levels) allostatic controls. At least in this sense, interoceptive inference then also involves counterfactual expectations.

That said, there are likely to be substantial differences in how counterfactual active inference plays out in interoceptive settings. For instance, it may not be adaptive (in the long run) for organisms to continually attempt to disconfirm current interoceptive predictions, assuming these are compatible with homeostatic integrity. To put it colloquially, we do not want to drive our essential variables continually close to viability limits, just to check whether they are always capable of returning. This recalls our earlier point (section 4.1) that predictive control is more naturally applicable to interoception than exteroception, given the imperative of maintaining the homeostasis of essential variables. In addition, the causal structure of counterfactual associations encoded by interoceptive predictive models is undoubtedly very different than in cases like vision. These differences may speak to the substantial phenomenological differences in the kind of perceptual presence associated with these distinct conscious contents (Seth et al. 2011).

6 Conclusion

This paper has surveyed predictive processing (PP) from the unusual viewpoint of cybernetic origins in active homeostatic control (Ashby 1952; Conant & Ashby 1970). This shifts the perspective from perceptual inference as fur-

nishing representations of the external world for the consumption of general-purpose cognitive mechanisms, towards model-based predictive control as a primary survival imperative from which perception, action, and cognition ensue. This view is aligned with the free energy principle (Friston 2010); however it attempts to account for specific cognitive and phenomenological properties, rather than for adaptive systems in general. Several implications follow from these considerations. Emotion becomes a process of active interoceptive inference (Seth 2013)—a process that also recruits autonomic regulation and influences intuitive decision-making through behavioural allostasis. A common predictive principle underlying interoception and exteroception also provides an integrative view of the neurocognitive mechanisms underlying embodied selfhood, in particular the experience of body ownership (Apps & Tsakiris 2014; Limanowski & Blankenburg 2013; Suzuki et al. 2013). In this view, the experience of embodied selfhood is specified by the brain’s “best guess” of those signals most likely to be “me” across exteroceptive and interoceptive domains. From the perspective of cybernetics the embodied self is both that which needs to be homeostatically maintained and also the medium through which allostatic interactions are expressed.

A second influential line deriving from cybernetics sets PP within the broader context of model-based versus enactivist perspectives on cognitive science. On one hand, cybernetics has been cited in support of non-representational cognitive science in virtue of its showing how simple mechanisms can give rise to complex and apparently goal-directed behaviour by capitalizing on agent-environment interactions, mediated by the body (Pfeifer & Scheier 1999). On the other, the cybernetic legacy shows how PP can put mechanistic flesh on the philosophical bones of enactivism, but only by embracing a finessed form of representationalism (Seth 2014b). A key concept within enactive cognitive science is that of mastery of sensorimotor contingencies (SMCs). This concept is useful for understanding the qualitative character of distinct perceptual modalities, yet as expressed within enactivism it lacks a firm implementation basis. “Pre-

dictive Perception of SensoriMotor Contingencies” (PPSMC) addresses this challenge by proposing that SMCs are implemented by predictive models of sensorimotor relations, underpinned by the continuity between perception and action entailed by active inference. *Mastery* of sensorimotor contingencies depends on predictive models of counterfactual probability densities that specify the likely causes of sensory signals that *would* occur *were* specific actions taken. By relating PP to key concepts in enactivism, this theory is able to account for phenomenological features well treated by the latter, such as the experience of perceptual presence (and its absence in cases like synaesthesia).

Considering these issues leads to distinct readings of active inference, which at its most general implies the selective sampling of sensory signals to minimize uncertainty about perceptual predictions. At a finer grain, active inference can involve performing actions to confirm current predictions, to disconfirm current predictions, or to disambiguate competing predictions. These different senses rest on the concept of counterfactually-equipped predictive models; and they generalize the free energy principle to include Bayesian-model comparison as well as optimization and inference.

In summary, the ideas outlined in this paper provide a distinctive integration of predictive processing, cybernetics, and enactivism. This rich blend dissolves apparent tensions between internalist and enactivist (model-based and model-free) views on the neural mechanisms underlying perception, cognition, and action; it elaborates common predictive mechanisms underlying perception and control of self and world; it provides a new view of emotion as active interoceptive inference, and it shows how “counterfactual” predictive processing can account for the phenomenology of conscious presence and its absence in specific situations. It also finesses the concept of active inference to engage distinct forms of hypothesis testing that prescribe different sampling actions (one bonus is that the “dark room problem” is elegantly solved). At the same time, new and difficult challenges arise in validating these ideas experi-

mentally and in distinguishing them from alternative explanations that do not rely on internally-realised inferential mechanisms.

Acknowledgements

I am grateful to the Dr. Mortimer and Theresa Sackler Foundation, which supports the work of the Sackler Centre for Consciousness Science. This work was also supported by ERC FP7 grant CEEDs (FP7-ICT-2009-5, 258749). Many thanks to Thomas Metzinger and Jennifer Windt for inviting me to make this contribution, and for the insightful and helpful reviewer comments they solicited. I’m also grateful to Kevin O’Regan and Jan Dagenaar for inviting me to speak at a symposium entitled “Consciousness without inner models?” (London, April 2014), which provided a feisty forum for debating some of the ideas presented here.

Perceptual Presence in the Kuhnian-Popperian Bayesian Brain

A Commentary on Anil K. Seth

Wanja Wiese

Anil Seth's target paper connects the framework of PP (predictive processing) and the FEP (free-energy principle) to cybernetic principles. Exploiting an analogy to theory of science, Seth draws a distinction between three types of active inference. The first type involves confirmatory hypothesis-testing. The other types involve seeking disconfirming and disambiguating evidence, respectively. Furthermore, Seth applies PP to various fascinating phenomena, including perceptual presence. In this commentary, I explore how far we can take the analogy between explanation in perception and explanation in science.

In the first part, I draw a slightly broader analogy between PP and concepts in theory of science, by asking whether the Bayesian brain is Kuhnian or Popperian. While many aspects of PP are in line with Karl Popper's falsificationism, other aspects of PP conform to how Thomas Kuhn described scientific revolutions. Thus, there is both a sense in which the Bayesian brain is Kuhnian, and a sense in which it is Popperian. The upshot of these considerations is that falsification in PP can take many different forms. In particular, active inference can be used to falsify a model in more ways than identified by Seth.

In the second part of this commentary, I focus on Seth's PPSMCT (predictive processing account of sensorimotor contingency theory) and its application to perceptual presence, which assigns a crucial role to counterfactual richness. In my discussion, I question the significance of counterfactual richness for perceptual presence. First, I highlight an ambiguity inherent in Seth's descriptions of the target phenomenon (perceptual presence vs. objecthood). Then I suggest that counterfactual richness may not be the crucial underlying feature (of either perceptual presence or objecthood). Giving a series of examples, I argue that the degree of *represented causal integration* is an equally good candidate for accounting for perceptual presence (or objecthood), although more work needs to be done.

Keywords

Active inference | Binocular rivalry | Counterfactual richness | Cybernetics | Demarcation problem | Falsification | Free-energy principle | Naïve falsificationism | Objecthood | Paradigm change | Perceptual presence | Predictive processing | Rubber hand illusion | Scientific progress | Sensorimotor contingencies | Sophisticated falsificationism

1 Introduction

One of the relevant aspects of Seth's discussion is the way in which it highlights interesting links to theoretical precursors of PP. In doing so, he broadens the historical context in which the framework is usually situated. However, these considerations are not just relevant for the

history of science, they also constitute a theoretical underpinning of several ways in which Seth has recently developed PP accounts of various phenomena. Due to limited space, I can only address some of these here. In particular, I will focus on his three interpretations of active

inference, and on his PP account of perceptual presence. In so doing, I will also try to take the analogy between explanation in perception and explanation in science a little further than it has previously been taken.

In section 2, I will briefly summarize Seth's view on the connection between cybernetics and the free-energy principle. One of the results of his considerations is that a distinction can be drawn between three types of active inference. The first type involves confirmatory hypothesis-testing. The other types involve seeking disconfirming and disambiguating evidence, respectively. Seth does not say much about what it takes to disconfirm or falsify a hypothesis or model. Furthermore, he seems to suggest that not all types of active inference he distinguishes are currently part of PP (at least in the version described by Karl Friston's FEP): "[t]hese points represent significant developments of the basic infrastructure of PP" (Seth 2014, p. 3).¹ In section 3, I will provide clarification of the notion of falsification by referring to the works of Karl Popper, Imre Lakatos, and Thomas Kuhn. I will also provide examples to show that different types of falsification are part and parcel of PP, not extensions of the basic infrastructure. In section 4, I point out an ambiguity in Seth's account of perceptual presence (perceptual presence vs. objecthood). After this, I suggest that counterfactual richness may not be the crucial underlying feature (of either perceptual presence or objecthood). Giving a series of examples, I argue that the degree of *represented causal integration* is an equally good candidate for accounting for perceptual presence (or objecthood), although more work needs to be done.

2 Cybernetics and the free-energy principle

In his very rich target paper, Anil Seth calls attention to one of the less well-considered precursors of PP: cybernetics. A central concept of cybernetics is the notion of homeostasis, which denotes an equilibrium of the system's paramet-

ers. This equilibrium is maintained by keeping the system's essential variables, like levels of blood oxygenation or blood sugar (cf. Seth this collection, p. 7), within a certain range (cf. *ibid.* pp. 7-8.). The process of achieving homeostasis is called allostasis (cf. *ibid.* p. 8). Cybernetic systems are teleological, i.e., goal-directed, because they are always trying to reach and preserve homeostasis. This suggests that control is more important than perception (cf. *ibid.* p. 9), and, as Seth emphasizes, it prioritizes interoceptive control over exteroceptive control: the main goal is to control the system's essential variables; interaction with the world is only necessary to the extent that it affects these variables (*ibid.* pp. 9-10.).

The principles of cybernetics fit astonishingly well to ideas motivating Karl Friston's FEP (which can, in some respects, be seen as a generalization of predictive processing).² The fundamental assumption behind this principle is that biological systems seek to "maintain their states and form in the face of a constantly changing environment" (Friston 2010, p. 127). This is obviously similar to the goal of achieving homeostasis.³ Another focus of FEP is active inference, because action can reduce the surprisal of the agent's states (which is necessary to "resist a tendency to disorder", Friston 2009, p. 293); perceptual inference can only reduce the free-energy bound on surprise (Friston 2009, p. 294). This is in stark contrast with the Helmholtzian roots of PP, according to which action is primarily in the service of perception:

[...] wir beobachten unter fortdauernder eigener Thätigkeit, und gelangen dadurch zur Kenntniss des Bestehens eines gesetzlichen Verhältnisses zwischen unseren Innervationen und dem Präsentwerden der verschiedenen Eindrücke aus dem Kreise

¹ Unless stated otherwise, all page numbers refer to the target paper by Anil Seth.

² It is more general, because predictive processing only plays a role in it if combined with the Laplace approximation (which entails, roughly, that probability distributions are approximated by Gaussian distributions). This approximation, however, also turns FEP into a more specific version, by assuming that the brain codes probability distribution as Gaussian distributions (which is not entailed by the general predictive processing framework discussed in Clark 2013, for instance).

³ In fact, the free-energy principle seems to be partly inspired by cybernetic ideas. Friston (2010, p. 127), for instance, cites Ashby (1947) when explaining the motivation for FEP.

der zeitweiligen Präsentabilien. Jede unserer willkürlichen Bewegungen, durch die wir die Erscheinungsweise der Objecte abändern, ist als ein Experiment zu betrachten, durch welches wir prüfen, ob wir das gesetzliche Verhalten der vorliegenden Erscheinung, d.h. ihr vorausgesetztes Bestehen in bestimmter Raumordnung, richtig aufgefasst haben.⁴ (Helmholtz 1959, p. 39)

According to this view, the main target of action is to find confirmatory evidence for internally-generated hypotheses. In short, the contrast between these two views can be described as “action as hypothesis-testing” versus “action as predictive control”. Whereas the first seems to fit best to the Helmholtzian roots of PP (and puts action in the service of perception), the second seems to fit better to its cybernetic origins. Most notably, the free-energy principle combines both aspects, but assigns a pivotal role to action (perceptual inference only makes the free-energy bound on surprise tight, active inference leads to a further reduction of free energy, reducing surprise implicitly).

Seth compares model selection and optimization in evolutionary robotics to how these processes are implemented in active inference (pp. 14-15.). He cites the famous starfish robot developed by Josh Bongard, Victor Zykov, & Hod Lipson (2006) as an example. In a first phase, the robot generates multiple competing models of its own morphology and performs actions for which these models predict different sensory feedback. By comparing these predictions to the actual feedback, the starfish can thus exclude some of the possible models. When the robot has eliminated all but one model, a second phase starts and it uses this model to control its body and generate walking behavior (action as predictive control). Crucially, when the robot’s morphology changes (when an ex-

perimenter removes one of its limbs), it can switch back to the first phase, re-creating competing models and using action to eliminate most of them (action as hypothesis-testing).

Seth points out that the second phase, in which the robot walks around, suggests that the main purpose of predictive models is to control behavior effectively, regardless of how accurately it represents the world or the body (p. 15). In the first phase, by contrast, exploratory actions are conducted in order to learn something about the body, not to reach a goal involving its environment (ibid.). As noted above, such instances of action conform more to Helmholtzian than to cybernetic roots (action as hypothesis-testing).

What this shows is that action can fulfill different purposes—not just theoretically, but also in real applications. The robot starfish uses action in at least two ways. Drawing on the often-noted analogy between PP and scientific practice (cf. Gregory 1980), Seth explores further purposes of action. This leads to a distinction between three types of active inference (pp. 18f.). The first involves active sampling to confirm predictions derived from currently active models; the second is employed to seek evidence that would disconfirm currently held hypotheses; the third involves sampling in order to disambiguate between alternative hypotheses (p. 19).

Crucially, Seth does not elaborate much on the notion of falsification or disconfirmation. He relates disconfirmation to Bayesian surprise (which formalizes the extent to which new evidence leads to a revision of prior representations, cf. Baldi & Itti 2010). Accordingly, he characterizes seeking falsifying evidence in terms of maximizing Bayesian surprise. However, the paper quoted in this context, Itti & Baldi (2009) only investigates the hypothesis that surprising information attracts attention, not that subjects act to maximize surprise. Friston et al. (2012, p. 6) clarify the relation between FEP and maximization of Bayesian surprise:

The term Bayesian surprise can be a bit confusing because minimizing surprise per se (or maximizing model evidence) in-

4 “[...] we observe under constant own activity, and thereby achieve knowledge of the existence of a lawful relation between our innervations and the presence of different impressions of temporary presentations [Präsentabilien]. All of our willful movements through which we change the appearance of things should be considered an experiment, through which we test whether we have grasped correctly the lawful behavior of the appearance at hand, i.e. its supposed existence in determinate spatial structures.” (My translation)

volves keeping Bayesian surprise (complexity) as small as possible. This paradox can be resolved here by noting that agents expect Bayesian surprise to be maximized and then acting to minimize their surprise, given what they expect.

In the following section, I will clarify the notion of falsification, and discuss the ways in which it is used in PP. More specifically, I will illustrate various types of active inference by drawing a slightly broader analogy with theory of science. In particular, I will consider views put forward by Karl Popper and Thomas Kuhn, respectively. This will serve to help us get a handle on the general merits of confirmation and disconfirmation. Furthermore, both Popper's falsificationism and Kuhn's paradigm change can be related to aspects of predictive processing, which will hopefully lead to a better understanding of hypothesis-testing in PP. As a consequence, I invite Seth to provide a refined treatment of the relation between falsification and active inference.

3 Is the Bayesian brain Kuhnian or Popperian?⁵

The free-energy principle subsumes the Bayesian brain hypothesis⁶ (cf. Friston 2009, p. 294). According to this view, processing in the brain can usefully be described as Bayesian inference. This means that the brain implements a probabilistic model that is updated in light of sensory signals using Bayes' theorem. More specifically, the brain combines prior knowledge about hidden causes in the world with a measurement of likelihood describing how probable the observed (sensory) evidence is, given various possible hidden causes. The result is a distribution (posterior) that describes how probable various possible causes are, given the obtained evidence. The process of determining the pos-

terior is often called *model inversion*. In FEP, this type of inference is approximated using variational Bayes, which establishes the connection to predictive processing (cf. footnote 2 above). FEP can thus either be seen as a particular instance of the Bayesian brain hypothesis, or as a generalization.

As mentioned above, it is often pointed out that perceptions in PP are analogous to scientific hypotheses. The Bayesian brain is thus a hypothesis-testing brain (this analogy is also referred to in titles of papers by Jakob Hohwy, see Hohwy 2010, 2012). Thanks to active inference, the Bayesian brain performs an active kind of hypothesis testing. The three types of active inference distinguished by Seth assign a role to both confirmation and disconfirmation (falsification). This dual role of active inference is also emphasized by (Friston et al. 2012, p. 19):

The resulting active or embodied inference means that not only can we regard perception as hypotheses, but we could regard action as performing experiments that confirm or disconfirm those hypotheses.

Further exploration of the analogy to theory of science reveals a puzzle: as we will see, doubts can be raised regarding the idea that a theory gains merit when it is confirmed (or even regarding the very notion of theory confirmation). Does this mean that the Bayesian brain generates hypotheses in an unscientific way?

3.1 The Popperian Bayesian brain

3.1.1 Conceptual clarification: From naïve to sophisticated falsificationism

According to Popper, science advances mainly by seeking falsifying evidence. In fact, falsifiability is Popper's proposed solution to the demarcation problem, i.e., the problem of specifying the difference between science and pseudo-science. Scientific theories posit universal propositions (scientific laws) that can never be proven in a strict sense, because only finite observations can be made. The next observation could, in principle, always disconfirm a universal em-

⁵ It should be noted that Popper rejected interpretations of confirmation (or corroboration) in terms of probabilities (cf. Popper 2005[1934], ch. X), as well as Bayesian interpretations of probability theory (cf. Popper 2005[1934], ch. *XVII). Here, I only suggest that a useful analogy between Popper's theory of science and the Bayesian brain can be drawn.

⁶ Seth identifies PP and the Bayesian brain (cf. p. 1). I follow suit in this commentary.

pirical hypothesis. Hence, being verifiable cannot be a criterion for being scientific, because theories cannot be empirically verified (cf. Popper 2005[1934], pp. 16-17.). Conversely, it is possible to *falsify* a universal statement using a single empirical proposition:

Diese Überlegungen legen den Gedanken nahe, als Abgrenzungskriterium nicht die Verifizierbarkeit, sondern die *Falsifizierbarkeit* des Systems vorzuschlagen; [...] *Ein empirisch-wissenschaftliches System muß an der Erfahrung scheitern können.* (Popper 2005[1934], p. 17)⁷

Scientific theories thus cannot, according to Popper, be verified, but only falsified. However, when attempts to falsify a hypothesis have failed, we can say that the theory has been *corroborated*—which still means that the theory could be falsified in the future (cf. Popper 2005[1934], ch. X).

How can we apply these ideas to predictive processing? First, we have to find an analogy to scientific theories. I suggest that models can be treated analogously to theories, because in PP, predictions or hypotheses are derived from models and then compared to bottom-up signals. This also fits the way in which Seth describes the starfish example (namely in terms of model selection). What does it mean that a model is falsified in PP?

The question is not a trivial one, as there seems to be a crucial disanalogy between hypothesis-testing in Popper's sense and hypothesis-testing in the Bayesian brain. The reason why scientific theories are falsifiable is that they allow deriving hypotheses deductively. This means if a hypothesis is falsified, the theory is falsified as well. By contrast, hypotheses in the Bayesian brain are not deductively entailed by the models from which they are derived: the relation between model and hypothesis is *probabilistic* (the hypothesis is more or less probable, given the model). Hence, when a hypothesis or prediction elicits a large prediction error, this

does not falsify the model; rather, it calls for an update to the effect that the model becomes less likely. Furthermore, according to Popper, it does not make sense to say that such hypotheses are corroborated to a greater or lesser extent. For being corroborated means that attempts at falsification have failed. But if it is in principle impossible to falsify a hypothesis, then saying that it has been corroborated becomes empty—worse, such hypotheses are not even scientific hypotheses (cf. Popper 2005[1934], pp. 248-249.). This, then, constitutes the puzzle mentioned above: if hypotheses in PP are not falsifiable, does this mean the Bayesian brain is unscientific?

This conclusion—that no useful analogy to Popper's theory of science can be drawn—rests on a naïve understanding of falsification (as emphasized by Imre Lakatos, cf. Lakatos 1970).⁸ A closer look at the notion of falsification reveals that the analogy can be upheld. Furthermore, it helps us gain a better grasp of the notion of falsification in the context of PP.

First of all, we can note that in actual scientific practice, it is not the case that scientists attempt to falsify an isolated, single hypothesis—and then try to come up with a new theory when the hypothesis has been falsified. Rather, scientists often operate with different versions of a theory at the same time, or seek to find the best parameters for a model. The outcomes of an empirical study are then used to eliminate some of the different theories or parameter ranges. This has already been acknowledged by Popper (cf. 2005[1934], p. 63., fn. 10). As Thomas Nickles puts it:

According to Popper, at any time there may be several competing theories being proposed and subsequently refuted by failed empirical tests—rather like balloons being launched and then shot down, one by one. (2014)

The result of this falsification procedure is that some of the competing theories are eliminated. This can already be seen as a slight departure

⁷ “These considerations suggest proposing not verifiability, but falsifiability as a demarcation criterion; [...] An empirical-scientific system must be able to break down in the light of empirical evidence.” (My translation)

⁸ I am grateful to Thomas Metzinger for pointing me to Lakatos' work on falsificationism.

from what Imre Lakatos calls naïve falsificationism: for the elimination may be based on a comparison, not on an isolated falsification procedure. If some of the theories are in some sense better than the others (for instance, by making more empirical predictions, or by being less complex), then they can be preferred without having *independent* reasons to reject the eliminated theories. However, Popper's falsificationism is even more sophisticated.

Popper noted that there were no theory-neutral empirical propositions. Descriptions of empirical facts are not immediately given, they are based on observations and involve interpretations (cf. Popper 2005[1934], p. 84, fn. 32). This means it is always possible to add auxiliary hypotheses to a theory, and thereby make the theory compatible with seemingly falsifying evidence. As a consequence, when it comes to determining whether a theory is scientific or not, we cannot consider an isolated theory, but must assume a diachronic stance, in which we consider how a theory is modified in the light of new evidence. Such modifications (e.g., auxiliary hypotheses) increase the empirical content of the theory (cf. Lakatos 1970, p. 183). As Popper puts it:

Bezüglich der Hilfhypothesen setzen wir fest, nur solche als befriedigend zuzulassen, durch deren Einführung der 'Falsifizierungsgrad' des Systems [...] nicht herabgesetzt, sondern gesteigert wird; in diesem Fall bedeutet die Einführung der Hypothese eine Verbesserung: Das System verbietet mehr als vorher.⁹ (Popper 2005[1934], p. 58)

When confronted with evidence that contradicts predictions, we are thus never forced to reject the theory from which the prediction has been derived. We may always modify the theory. But this modification must not be *ad hoc*. Auxiliary hypotheses that only make the theory compatible with the evidence, without having any addi-

tional value (without allowing new predictions), are not scientific.

Lakatos (1970) emphasizes that this entails a refined notion of falsificationism. He calls this sophisticated falsificationism (or sophisticated *methodological* falsificationism). A theory can only be falsified in this "sophisticated" manner when it has been replaced by a theory that:

1. has more empirical content (makes new predictions), and
2. makes at least one prediction that is empirically corroborated (cf. Lakatos 1970, pp. 183-184.).

3.1.2 Sophisticated falsification in the Bayesian brain

Popper's sophisticated falsificationism¹⁰ can more easily be applied to predictive processing, because it does not require that we reject a model whenever its predictions yield large prediction errors. Instead, the model can be updated to achieve a better fit with the data. Furthermore, we find a counterpart for the insight that there are no theory-neutral observations: bottom-up signals are never treated as raw data, but as being (more or less) noisy. Hence, prediction errors are weighted by expected precisions. When the expected precision is extremely low, prediction errors will be attenuated. A low expected precision can thus be seen as analogous to an auxiliary hypothesis that makes the model compatible with otherwise contradicting evidence. What is more, it is not an *ad hoc* move, because the precision estimate itself is also constantly being updated in light of the evidence. Similarly, when a model generates a significant amount of prediction error, but is strongly supported by a higher-level model with high prior probability, a relatively high amount of prediction error may not lead to a major revision of the model.

¹⁰ Lakatos (1970) points out that Popper himself never made a sharp distinction between naïve and sophisticated falsificationism, but that he accepted the assumptions underlying sophisticated falsificationism, at least in parts of his work—whereas the person Karl Popper may have been more of a naïve than a sophisticated falsificationist.

⁹ "Regarding such auxiliary hypotheses we stipulate that we allow only those hypotheses for which the 'degree of falsifiability' of the system is not decreased, but increased; in this case the introduction of auxiliary hypotheses means an improvement: The system prohibits more than before." (My translation)

Model competition in PP can also be seen as an instance of sophisticated falsificationism. Competition need not be resolved by eliminating those models that yield the largest prediction errors (as in the starfish robot). Instead, it may be that some models make more specific *counterfactual* predictions. Indeed, this seems to be the main rationale behind active inference in FEP.

According to the formalization provided in [Friston et al. \(2012, p. 4\)](#), active inference involves minimizing the entropy of a counterfactual density. This density links future internal states and hidden controls to hidden states, which cause sensory states; hidden controls are hidden states that can be changed by action ([Friston et al. 2012, p. 3](#)). A density has low entropy, roughly, if it assigns high values to a relatively small subset of states, and low values to most other sets of states. Predictions based on a probability density with very low entropy can thus be made with a high level of confidence, because most other possibilities are more or less ruled out (due to the low values assigned to them by the density). Formally, this is reflected in the proposition that the negative entropy of the counterfactual density is a monotonic function of the precision of counterfactual beliefs ([Friston et al. 2012, p. 4](#)).

The entropy of the counterfactual density is minimized with respect to hidden controls. In effect, this is a selection process, in which a model (here: a counterfactual density) is selected that has minimal entropy. The other models are eliminated, because they have higher entropies. We can say they are falsified in the sense of sophisticated falsificationism (but not in the sense of naïve falsificationism).

Another way in which model competition can be resolved without naïve falsification can be illustrated by the famous “wet lawn” example (cf. [Pearl 1988](#)). Suppose you enter your garden and find that the lawn is wet. There are at least two models that can explain this: either your sprinkler has been on during the night or it has rained. Let us assume that both models are initially equally likely (i.e., they have the same prior probability). When you now observe that your neighbor’s garden is also wet, the rain

model is corroborated, because it makes the strong prediction that the neighbor’s lawn is wet (i.e., the conditional probability that the neighbor’s lawn is wet, given that it has rained, is high). The other model is not incompatible with this evidence, but it is not supported by it as much (because the conditional probability that the neighbor’s lawn is wet, given that your sprinkler has been on, is not as high). In other words, it has been explained away. As [Jakob Hohwy](#) puts it:

The Rain model accounts for all the evidence leaving no evidence behind for the Sprinkler model to explain. Even though the Sprinkler model did increase its probability in the light of the first observation, it seems intuitive right to say that its probability is now returned to near its prior value. The model has been explained away. ([2010, p. 137](#))

Explaining away is another example of sophisticated falsification. Even when two or more models are compatible with the evidence (and with each other), there can be reason to prefer one of them and reject the others.

The clarification in this section should have shown that there is more to falsification than just “disconfirming” a hypothesis, and that competition between models can be resolved in different ways, not only in the way exemplified by the starfish robot. Furthermore, different types of sophisticated falsificationism are part and parcel of predictive processing.

Does this mean that the Bayesian brain is Popperian? This conclusion would be premature. The above can at best show that there are many situations in which the Bayesian brain is a sophisticated falsificationist. But there may be situations in which not even sophisticated falsification is possible or necessary. In the following section, I will argue that predictive processing also has Kuhnian aspects.

3.2 The Kuhnian Bayesian brain

According to Kuhn, scientific research develops in different recurring phases. Most of the time,

scientists work within an established paradigm, in which implications of theories are explored and puzzles are solved (cf. [Kuhn 1962](#), ch. IV). In this phase, falsification or confirmation do not play a role:

Normal science does and must continually strive to bring theory and fact into closer agreement, and that activity can easily be seen as testing or as a search for confirmation or falsification. Instead, its object is to solve a puzzle for whose very existence the validity of the paradigm must be assumed. Failure to achieve a solution discredits only the scientist and not the theory. (cf. [Kuhn 1962](#), p. 80)

At some stage, however, there will be anomalies, i.e., empirical observations that cannot be explained within the current paradigm. When these anomalies accumulate, scientists will try to explore new concepts and methods. If, using new concepts and methods, previously unexplainable anomalies can be accounted for, a scientific revolution can result, through which a new paradigm is established. Kuhn shares the sophisticated falsificationist's insight that theories are never rejected in isolation:

[...] the act of judgment that leads scientists to reject a previously accepted theory is always based upon more than a comparison of that theory with the world. The decision to reject one paradigm is always simultaneously the decision to accept another, and the judgment leading to that decision involves the comparison of both paradigms with nature *and* with each other. (cf. [Kuhn 1962](#), p. 77)

This shows that Kuhn's theory is in some respects in line with sophisticated falsificationism—but he goes beyond it, in that he doubts that a paradigm that has been adopted instead of another is always better or closer to the truth. The reason for this is that he claims competing paradigms to be incommensurable (cf. also [Feyerabend 1962](#)), which means that they typically use radically different concepts and methods (cf.

[Oberheim & Hoyningen-Huene 2013](#), §1). A new paradigm that becomes dominant is thus not marked by being closer to the truth, but mainly by constituting a departure from the old paradigm (cf. [Kuhn 1962](#), pp. 170-171). This seems to entail that scientific progress need not be a process in which theories approximate the truth to an ever higher degree.

Can we find an analogon for such a transition from one paradigm to the other in predictive processing? Above, we saw that the sophisticated falsificationist assumes that scientific progress happens only when a theory makes new predictions, and thereby leads to the discovery of new states of affairs. This need not always be the case in the Bayesian brain. When a model is changed to minimize free-energy, this does not mean that the empirical content or predictive power has been increased. A particularly clear example of this can be found in perceptual phenomena like binocular rivalry.

In binocular rivalry (cf. [Blake & Logothetis 2002](#)), subjects are presented with two different images, one to the left eye, the other to the right eye, e.g., a face and a house. According to a predictive coding account put forward by [Jakob Hohwy](#), [Andreas Roepstorff](#) & [Karl Friston](#) (2008), the brain generates two main competing models of what the stimuli depict, one corresponding to the face, the other corresponding to the house. However, only one of these models is consciously experienced at any given time (although there can be intermittent phases in which subjects report seeing a mixture of both stimuli, i.e., parts of the house and parts of the face at the same time, but usually non-overlapping). This means that the brain will tend to settle into one of two classes of states (one corresponding to perceiving the house, the other to perceiving the face). Since each of the models can only account for part of the visual input, both cause a significant amount of prediction error (cf. [Hohwy et al. 2008](#), p. 691). Over time, the prior probability of the currently assumed model (house or face, respectively) will decrease, leading to a revision of the hypothesis, until the brain settles into a state corresponding to the other percept, at least temporarily (cf. [Hohwy et al. 2008](#), pp.

692–694).¹¹ The crucial difference between this and cases like the wet lawn example or model selection in the starfish robot is that neither of the two competing models is in any sense better than the other (in terms of empirical content, simplicity, predictive power, etc.).

We can recast binocular rivalry in terms of Kuhnian paradigm changes. If we liken each of the two models (house/face) to a paradigm, we can say that perceiving a single object in binocular rivalry corresponds to the phase of normal science, in which many phenomena (inputs) can be explained. After some time, however, there are anomalies (increasing prediction error), which leads to a scientific crisis in which new directions are explored (intermittent phase in which no unified percept is generated), until a new form of scientific practice becomes dominant (scientific revolution), and a new phase of normal science (temporarily stable perception) is reached. The transition from one percept to the other does not go along with increased veridicality: neither of the two percepts is closer to the truth than the other.¹² This may also support the cybernetic idea that internal models are used in the pursuit of homeostasis, not to approximate the truth (as also noted by [Seth this collection](#), p. 15).

There is another analogy between the Bayesian brain and Kuhn's theory of science. According to Kuhn, it is indeterminate whether an anomaly (an unexpected experimental result, for instance) is something that should be regarded as just another puzzle or as a reason to reject the whole paradigm:

¹¹ Two possible reasons why the probability of the currently assumed model decreases are offered by the authors: either there is a hyper-prior to the effect that the world changes (which is why a static hypothesis becomes less likely over time), or there are random effects that lead to multistability, such that neural dynamics switch from one basin of attraction to another (cf. [Hohwy et al. 2008](#), p. 692).

¹² In fact, it seems that the notion of incommensurability has been inspired by Gestalt switches (as in the perception of a Necker cube), which are very similar to phenomena like binocular rivalry. However, [Kuhn](#) explicitly pointed out that there is a crucial difference between a Gestalt switch and a paradigm change: “[...] the scientist does not preserve the gestalt subject's freedom to switch back and forth between ways of seeing. Nevertheless, the switch of gestalt, particularly because it is today so familiar, is a useful elementary prototype for what occurs in full-scale paradigm shift” (1962, p. 85). I am grateful to Sascha Fink for drawing my attention to this statement.

Excepting those that are exclusively instrumental, every problem that normal science sees as a puzzle can be seen, from another viewpoint, as a counterinstance and thus as a source of crisis. ([Kuhn 1962](#), p. 79)

If it is treated as a puzzle, it yields questions like: how can we account for this phenomenon within our established framework? If it is treated as a counterinstance, a more fundamental solution is needed. This is analogous to the fact that whether two models in predictive processing are compatible or not depends on (hyper)priors (cf. [FitzGerald et al. 2014](#), p. 2). When a hyper-prior has it that two models are incompatible, this can either lead to a competition, in which one of the models is eliminated, or it can lead to a revision of the hyper-prior. (Which of the two possibilities corresponds more to puzzle solving, and which to something more fundamental will depend on whether the lower-level models or the high-level prior initially have a higher probability.) This is illustrated by the RHI (rubber hand illusion).

In the RHI ([Botvinick & Cohen 1998](#)), the brain harbors two contradictory sensory models. According to the visual model, tactile stimulation occurs on the surface of the rubber hand. According to the proprioceptive model, the felt strokes occur at a different location (i.e., where the real hand is located). While there is, in and of itself, no contradiction between these models, it is likely that the brain has a prior that favors common-cause explanations of sensory signals. Relative to this prior, there is a tension between the models: they seem to indicate that the seen stroking and the felt touch occur at distinct locations, which is odd, because they occur synchronously (and the prior has it that synchronous effects have a common cause, which speaks against two distinct locations). As [Jakob Hohwy](#) puts it:

[...] we have a strong expectation that there is a common cause when inputs co-occur in time. This makes the binding hypothesis of the rubber hand scenario a better explainer, and its higher likelihood

promotes it to determine perceptual inference and thereby resolve the ambiguity. (2013, p. 105)

Notice that the common-cause hypothesis (that the touch is felt where it is seen) only becomes the dominating hypothesis because the design of the study prevents subjects from confirming the distinct-causes hypothesis (e.g., by looking at their real hands). Because of the common-cause hypothesis, there is an ambiguity in the percepts. This ambiguity can be resolved in at least two ways: either by adjusting the lower-level (perceptual) models (to the effect that the felt touch occurs at the same location as the seen stroking); or by active inference (which in this case would lead to a rejection of the higher-level model corresponding to the common-cause hypothesis). The first way corresponds to puzzle solving, the second more closely to a paradigm change. Note that the analogy will be the stronger the more remote the hyper-prior is from the perceptual models.

I hope to have shown that the Bayesian brain has aspects that make it Popperian, as well as aspects that make it Kuhnian. At the very least, it should have become clear that falsification is a more complex concept than depicted in Seth's target paper (which seems to tend towards a more naïve form of falsificationism).

4 Perceptual presence

We have seen how fruitful analogies between PP and theory of science can be. As mentioned above, an early formulation of the analogy between perception and hypothesis-testing can be found in Richard Gregory's seminal paper "Perceptions as Hypotheses". There, we also find the suggestion that percepts *explain* sensory signals (cf. Gregory 1980, p. 13).¹³

How far can we take the analogy between explanation in perception and explanation in science? If we know what a good explanation is in science, does this give us a clue to the conditions under which percepts are experi-

enced as real? Interestingly, there are accounts of scientific explanation that assign an essential role to counterfactual knowledge (cf. Waskan 2008). If someone purports to know why a certain event happened or why a phenomenon was observed, we expect her to also be able to tell us what *would* have happened if some of the initial conditions had been different. Similarly, when the Bayesian brain explains sensory signals by inferring their hidden causes, we would expect the brain's generative model to also have the resources to infer in what ways sensory signals would be different, had there been a change to their hidden causes.

This highlights the relevance of counterfactual models. Seth points out that counterfactuals play a crucial role in active inference. The consideration above may be another way to show the relevance of counterfactual models. Furthermore, it also highlights the usefulness of counterfactual *richness*. The richer a counterfactual model of hidden causes, the better the brain's explanation of sensory signals (all other things being equal). In general, we may also be inclined to say that the richer the counterfactual model, the higher the confidence that it helps track the *real* explanation of sensory signals. But does this mean it goes along with experienced *realness* (or *perceptual presence*)?

This is, basically, what Seth proposes in his PP account of perceptual presence (cf. Seth 2014). But what is perceptual presence in the first place? On the one hand, Seth characterizes the notion by contrasting examples. For instance, objects like a tomato possess perceptual presence, whereas afterimages do not. On the other hand, Seth provides the following characterization:

In normal circumstances perceptual content is characterized by subjective veridicality; that is, the objects of perception are experienced as real, as belonging to the world. When we perceive the tomato we perceive it as an externally existing object with a back and sides, not simply as a specific view [...]. (2014, p. 98)

¹³ It should be noted that Gregory ascribes "far less explanatory power" (1980, p. 196) to perceptions than to scientific hypotheses.

The tomato is not perceived as a flat, red disc. Although you do not see the back and sides of the tomato in the same way that you see the front, there is still a sense in which both are *perceptually present* (cf. Noë 2006, p. 414). I shall now point to two ambiguities in Seth's description of the explanandum. This calls for a conceptual clarification, regarding which I shall make a tentative suggestion. After that, I shall argue that there may be possible counterexamples to Seth's hypothesis that perceptual presence correlates with the counterfactual richness of generative models.

4.1 Ambiguities in Seth's description of the explanandum

The tomato is not only experienced as perceptually present, it is also perceived as an *object* in the external world. In a commentary on Seth, Tom Froese (2014, p. 126) has therefore suggested that Seth conflates perceptual presence with experienced *objecthood*. This proposal has some plausibility, because the tomato is perceived as a real object, whereas afterimages are not experienced as objects (they are more like unstable colored shades). After all, even Seth admits, in his target paper, that it may be important to distinguish presence from objecthood (p. 18). This is one way in which Seth's definition of the explanatory target is ambiguous: is it about experienced *presence* or experienced *objecthood* (cf. also Seth 2014, pp. 105f.)? (This question becomes more pressing still when we consider the etymology of "realness" or "reality": the Latin origin of the word is *res* (thing), which makes it a little confusing that Seth seems to identify perceptual presence with the sense of subjective reality, cf. Seth this collection, p. 2.)

Another ambiguity is related to the notion of a counterfactual model. In his target paper Seth defines a counterfactual model as a model encoding "how sensory inputs (and their expected precisions) would change on the basis of a repertoire of possible actions" (Seth this collection p. 17). On the one hand, one may ask if counterfactual models in the brain necessarily encode SMCs (sensorimotor contingencies). For

the perception of a ripe tomato on a bush, it might be equally relevant to encode how sensory signals pertaining to the tomato would change if the wind were to blow the bush or if the tomato were to fall down. On the other hand, it is unclear how *explicit* a counterfactual representation has to be. Jakob Hohwy (2014) suggests that a rich causal structure could be modeled by extracting higher-order invariants (features that do not change if the tomato is dangling in the wind or has fallen down, for instance). Higher-order invariants are relatively perspective-independent.¹⁴ The degree of perceptual presence would then correspond to the "depth of the inverted model"¹⁵ (Hohwy 2014, p. 128). In his target paper, Seth notes that the depth of the model may indeed play a role (see footnote 13).

Two ambiguities are thus to be found in Seth's account. One concerns the characterization of the target phenomenon (experienced *realness* versus experienced *objecthood*). The other lies in the description of the represented causal structure: *counterfactual richness* versus *perspective-independence* of hidden causes. Counterfactual richness and causal "depth" are not completely independent. Below, I will give some examples that may be useful to explore the relationship between these two features. Furthermore, I will suggest that it could be helpful to consider another feature with respect to which the represented causal structure of objects may vary. This feature is the degree of

¹⁴ As I am using the term here, the depth of a model can be measured by its location in the predictive processing hierarchy (that is, whether it is high or low in the hierarchy). Estimates at higher levels track features that change more slowly (i.e., features that remain invariant when things change, for instance, when the subject changes her *perspective* on a perceptual object like a tomato by walking around the tomato or by turning it—hence the term "perspective-(in)dependence"). A model of a perceived object is deep when it represents features that change relatively slowly. Alternatively, one could stipulate that a model is deep when it represents features that change slowly *and* features that change more quickly. In fact, this may come closer to what Hohwy has in mind, but it blurs the distinction between perspective-dependence and causal integration. Hohwy writes: "[c]oncurrents are causes that do not interact on their own with other causes (presumably a fence won't occlude a concurrent)" (2014, p. 128). But encapsulated causes can be represented both at lower parts of the hierarchy (possible example: afterimages) and at higher parts of the hierarchy (possible example: certain conscious thoughts). This suggests that at least causal encapsulation can be dissociated from perspective-dependence and -independence.

¹⁵ The inverted model is the posterior distribution, the computation of which is based on the likelihood and the prior (see above).

causal encapsulation. For representations not only differ with respect to their counterfactual richness or their degree of perspective-dependence, but also with respect to the extent to which the represented causal structure is encapsulated or integrated. (In what follows, I will use the notion of a counterfactual model mainly in the sense in which Seth uses it: counterfactual models in this sense involve representations of possible bodily actions by the subject of experience.)

A phenomenal representation of a tomato on a plate is not only counterfactually rich and relatively perspective-dependent, the represented causal structure is also causally *integrated*.¹⁶ It is, for instance, represented as being causally related to the plate, because it is experienced as lying *on* the plate (that is, it is not hovering above it). Furthermore, it is in possible causal contact with virtually all other objects in its vicinity (e.g., the subject's hands).

Contrast this with the experience of what is happening in a classical video game—say, a racing game. The player influences how the images on the two-dimensional screen change, because she has control over the vehicle. Hence, we can assume that representations of gaming sequences are (usually) counterfactually rich. At the same time, they are also perspective dependent (although they mainly depend on the *virtual* perspective from which objects are represented in the game). However, virtual objects in the game are experienced as causally encapsulated: although objects can interact with each other in the virtual world, they do not interact with most other parts of the player's environment. For instance, they will never break out of the screen and fly around in the room in which the player is sitting. Furthermore, they can only be influenced vicariously through a controller or keyboard. Thus there is not causal encapsulation in *every* respect (the virtual world is not experienced as completely disambiguated from the rest of the experienced world), but in *some* respects the encapsulation is rather strong (the

virtual world is spatially bounded, e.g., with the screen as the limit). Note that many modern video games are less causally encapsulated, for instance when they are played on a touchscreen (or on devices with a three-dimensional screen, or in an immersive virtual reality).¹⁷

As mentioned above, causal integration and counterfactual richness are not completely independent. High counterfactual richness implies a certain degree of causal integration (at least in some respects), for it means that at least the subject can interact with the experienced object in some way—regardless of how separate the represented causal structure is from the rest of the subject's surroundings.

Similarly, highly perspective-invariant representations typically also involve the representation of an encapsulated causal structure. Abstract conscious thoughts, for instance, cannot be touched with the hand or other concrete objects. However, the implied encapsulation only holds in some respects. Sometimes thoughts can evoke strong emotions or a sequence of mental imagery. In certain obsessive-compulsive disorders, for instance, subjects will first have a thought (“My hands are dirty”), presumably followed by a feeling of disgust and the urge to wash the hands, which then leads to motor behavior (washing the hands); this, in turn, may be followed by the thought that the hands are still dirty. The content of the conscious thought is relatively perspective-invariant, and yet it involves, presumably, representations of causal structure that link it to concrete objects in the world.

As long as we interpret counterfactuals only as representations of sensorimotor contingencies, it may also seem that perspective-invariant¹⁸ representations are counterfactually poor. However, if we include representations of possible *mental* actions and their effects, we can also conceive of counterfactually-rich perspective-invariant representations. A possible example is a philosophical argument or a theory, which someone can contemplate in their mind, being aware that there are several possible ways

¹⁶ Another possible term for this would be *causally open*, in the sense that it is represented as being in potential causal exchange with other objects in its surrounding. By integration, I thus do not mean integration *within* (or internal integration), but integration *with* other objects.

¹⁷ Thanks to Jennifer Windt for suggesting immersive video games as a further example.

¹⁸ Perspective-invariant representations are maximally perspective-independent.

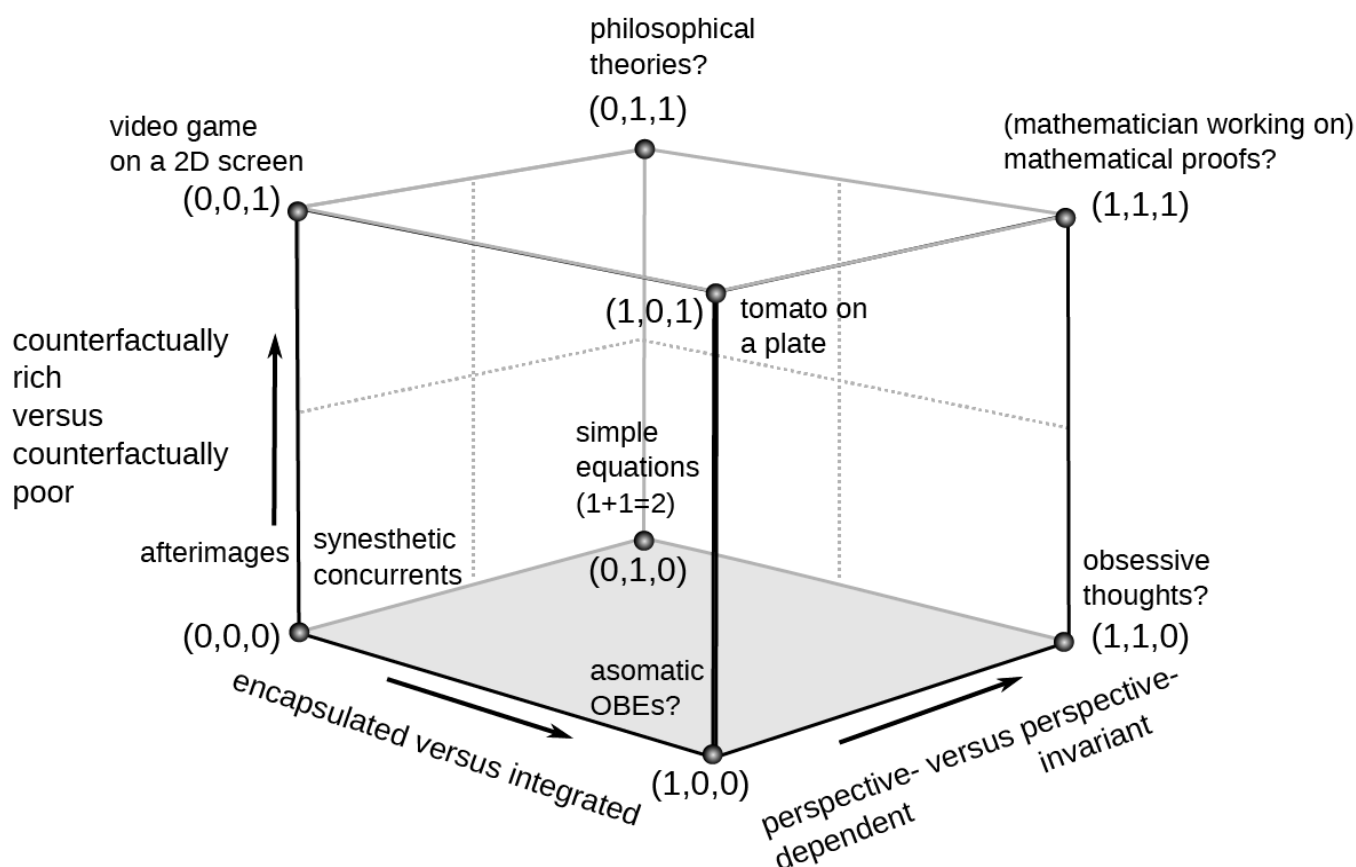

Figure 1: The figure illustrates how classes of experiences can be located in a cube, according to the extent to which they display counterfactual richness, perspective-independence, and causal integration (see main text for explanations). The cube (without the labels) is adapted from cube figures in [Godfrey-Smith \(2009\)](#); talks by Daniel Dennett brought this style of illustration to my attention.

in which the argument could be probed and attacked, or several important cases to which the theory could be applied.

Bearing in mind that the degree of causal encapsulation is not completely independent from the other two dimensions (counterfactual richness and perspective-invariance), we can depict different types of conscious experiences in a cube, where the three axes stand for the three dimensions described (see [Figure 1](#)). The most interesting locations in this cube are, of course, its eight corners, because they depict classes of experiences for which each of the three features is either completely absent or maximally pronounced. Finding examples of these “extremal experiences” is no easy task.¹⁹ Even neural representations of synesthetic concurrents, Seth’s prime example of coun-

terfactually poor models, may, at first sight, seem to be located somewhere in the middle of the perspective-dependence axis.

Grapheme-color concurrents, for instance, are not simply triggered by graphic representations of glyphs, but by representations of abstract objects, i.e., graphemes, associated with certain glyphs (cf. [Mroczko et al. 2009](#)). Hence, it may seem that the hidden cause of the concurrent is not simply an object in the world, but also involves an abstract object, i.e., a grapheme, the representation of which is perspective-invariant. This would suggest that synesthetic concurrents cannot conclusively be placed in one of the cube’s corners, because their represented hidden causes involve very high-level invariants.

On the other hand, one could object that the concurrent itself is represented in a rather perspective-dependent way. It may be part of a

¹⁹ In fact, it may be that the corners only constitute hypothetical endpoints. Thanks to Jennifer Windt for pointing this out.

causal network involving hidden causes that are represented in perspective-invariant ways, but the synesthetic percept itself is not a representation of an abstract hidden cause.²⁰ Hence, on second thought, it seems that concurrents, as in grapheme-color synesthesia, are in fact located close to the origin of our coordinate system: the representations involved are relatively perspective dependent, and they are counterfactually poor. At the same time, they are causally encapsulated, because they do not interact with physical objects (they cannot be touched, etc.).

4.2 Does counterfactual richness correlate with perceptual presence (or objecthood)?

What does this tell us about experienced “presence” or “objecthood”? Are all examples of counterfactually rich representations in the cube perceptually present, or are they associated with a high degree of objecthood? If so, this would support Seth’s hypothesis that counterfactual richness correlates with perceptual presence (or objecthood). I believe that counterfactual richness can be dissociated both from perceptual presence and from objecthood. Olfactory experiences are, as argued by Michael Madary (2014), both counterfactually poor and perceptually present. This suggests that counterfactual richness does not correlate with perceptual presence. Similarly, experiences of classical video game sequences are counterfactually rich, but involve a low degree of perceptual presence; objects in the game are only experienced as virtual objects, not as real objects. Counterfactual richness and perceptual presence may therefore be doubly dissociable.

Trying to evaluate whether counterfactual richness correlates with phenomenal objecthood would presuppose that we know what phenomenal objecthood means. As I only have an intuitive grasp of what it means, I can only give a preliminary statement. To me, it seems that virtual objects in two-dimensional video games do not possess a high degree of phenomenal objecthood. But then again, even if a virtual tomato

could be manipulated in various ways with a controller, the corresponding representation would probably not be as counterfactually rich as a representation corresponding to the experience of a real tomato. Hence, it is difficult to arrive at a definitive verdict.

A more promising path may involve the experience of objects in asomatic OBEs (out-of-body experiences) or asomatic dream experiences (Windt 2010; Metzinger 2013). Counterfactuals, as conceived of by Seth, always involve action on the part of a subject. Most, if not all, (non-mental) actions involve the body, so representing counterfactuals involves representing (parts of) the body. In asomatic OBEs and asomatic dream experiences, subjects do not identify with a body, but with an unextended point in space. I speculate that in such cases, representations of objects are less counterfactually rich.²¹ This, however, does not necessarily mean that they are experienced as less present or as possessing less objecthood. There are still a lot of causal regularities involving external objects that may be tracked by models in the brain, even in the absence of an ordinary body representation. External objects can interact with each other, and counterfactual representations of possible causal processes may contribute to the experience of objecthood or perceptual presence. In particular, this is to be expected if none of the external objects are represented as causally encapsulated. If this bears out, it provides another reason to believe that counterfactual richness of generative models does not correlate with experienced objecthood. Let us now consider possible examples of other extremal experiences (in the corners of the cube) to investigate whether it is plausible to hypothesize that represented causal depth or causal encapsulation correlates with perceptual presence or objecthood.

The more perspective-invariant a representation, the more abstract it is. This also means that perspective-invariant representations typically involve an encapsulated causal structure. Thinking about a simple equation like

²⁰ This may point to an aspect regarding which Hohwy’s characterization of causal depth is ambiguous.

²¹ In fact, asomatic OBEs may be a better example than asomatic dream experiences, since such dreams typically lack concrete objects (cf. LaBerge & DeGracia 2000). I am grateful to Jennifer Windt for pointing this out.

“ $1+1=2$ ” may be an example of this. There is no way in which the target of this representation can causally interact with the window behind my desk or the red bottle in front of the window. Furthermore, most (or all) bodily movements will not influence the way I experience the thought that one plus one equals two. Hence, it is arguably also a counterfactually poor representation.

When we move up, in the direction of counterfactually rich phenomenal representations, we arrive at representations that are counterfactually rich, perspective-invariant, and still causally encapsulated. Above, I mentioned conscious thoughts about philosophical arguments or theories as possible examples. Such thoughts may involve mental imagery and inner speech, and perhaps even complex phenomenal simulations involving counterfactual situations. It is not obvious whether it makes sense to say that such thoughts involve counterfactual representations linking possible mental actions to their effects. This is even harder without presupposing a developed theory of mental action (for recent proposals, cf. Proust 2013; Wu 2013).

Mental actions are goal-directed. Performing a mental action may therefore, at least in some cases, be followed by a representation of a situation in which the goal is realized (one possible example might be: remembering a name; represented situation: telling someone the name). In the case of a theory, a mental action could be considering whether a certain claim is true or not (or whether it is plausible). This may trigger thoughts like: “Assuming this is the case, what implications would this have? Are these implications plausible, or likely to be true? Are there possible counterexamples?” It might also involve trying to formulate something more clearly.

Furthermore, thinking about a theory or problem may involve conscious counterfactual thoughts of the form “If I gave up this assumption, there would not be a contradiction among the remaining hypotheses anymore”, or “If the theory could account for this special case, it would be strengthened”. One difference to conscious perception of concrete objects is, presum-

ably, that such counterfactuals are *phenomenally* represented, whereas representations of SMCs are usually unconscious (and may impact on consciousness only indirectly).

Similar things apply to conscious thoughts about non-trivial mathematical expressions. For instance, if a mathematician sees the expression $(1 + x/n)^n$ she will probably think “If n tends to infinity, this expression will converge to e^x ”. Now, suppose the mathematician is investigating the asymptotic behavior of some complicated expression (e.g., she wants to find out what happens to a certain expression when n tends to infinity). While manipulating the terms on paper, she suddenly realizes that one factor contained in the expression is $(1 + x/n)^n$. As she is using pen and paper while thinking this, her brain will not only activate an abstract (but conscious) counterfactual thought, but probably also a representation of SMCs. These SMCs will involve taking the limit of the expression with which she started (i.e., $\lim_{n \rightarrow \infty}$), and this is now not only a mental action, but also a possible bodily action. She could write this down, and know that (if the limit exists) part of it would be e^x . Her mathematical investigation therefore involves:

- phenomenal representations regarding counterfactual mental actions;
- representations of SMCs (*embodied* versions of the above mentioned counterfactuals);
- a close coupling between writing, perceiving, and thinking.

The third point is especially important, because it suggests that for a mathematician working with pen and paper (or chalk and blackboard) the objects of her conscious thoughts are not causally encapsulated anymore. The causal structure represented while thinking about abstract concepts is intertwined with the causal structure represented while looking at written mathematical expressions. These causal relations are still relatively limited, but if the mathematician is completely absorbed in her work, the paper (or blackboard) may be all she is attending to in her environment at the moment, perhaps to the extent that she does not experi-

ence abstract relations represented by her notes as causally encapsulated anymore. It is conceivable that this aspect can be enhanced in virtual environments in which mathematical objects are not represented by writing on paper or blackboard, but by three-dimensional virtual objects that can be manipulated by touch or manual movements, for instance.²² Contrary to what one might at first think, there may thus be cases in which high-degrees of perspective-invariance go along with both counterfactual richness and high degrees of causal integration.

Another class of abstract thoughts that may be experienced as causally integrated could be obsessive thoughts, like the thought that one's hands are contaminated with germs. Such thoughts may be triggered by specific events (like touching a door knob) and may go along with a fear of getting sick (because of the contamination). Subjects may also try to avoid touching objects that they fear might be contaminated. The reason for this is that the hidden cause represented by the obsessive thought, i.e., potential germ contamination, is not causally encapsulated. It is causally connected to concrete objects in the subjects' environment: things that are perceived as contaminated can cause a contamination of the hands; on the other hand, contaminated hands can infect other objects with germs. Furthermore, the inferred hidden cause (germ contamination) is relatively perspective-invariant. Subjects arguably do not imagine bacteria crawling on their hands, although the obsessive thought may go along with an altered perception of the hands. Finally, the model involved is probably counterfactually poor, as most actions do not change the alleged contamination (with the possible exception of washing the hands or touching allegedly contaminated objects; but here, the counterfactual effect is probably just an increase or decrease in the acuteness of the felt contamination). Therefore, I list obsessive thoughts as candidate examples of counterfactually poor, perspective-invariant representations the contents of which are represented as causally integrated.

4.3 Do perspective-invariance or represented causal integration correlate with perceptual presence (or objecthood)?

The examples given are certainly not uncontroversial and perhaps not all of them can be sustained in the light of further research. But hopefully the cube can still fulfill heuristic purposes, and can illustrate the need to clarify the relations between counterfactual richness, perspective-dependence, and causal integration. But assuming that the examples given are located in roughly the right places within the cube, what does this tell us about perceptual presence or experienced objecthood? Above, I dismissed Seth's hypothesis that counterfactual richness correlates with either presence or objecthood. Let us now briefly consider perspective-invariance and causal integration. If conscious thoughts involve causally-deep models (that represent perspective-invariant features), then it seems that the depth of the represented causal structure does not correlate with presence or objecthood. The thought that one plus one equals two does not possess a high degree of objecthood or perceptual presence. Hence, it seems that Hohwy's hypothesis that the depth of the generative model (the degree of perspective-independence) correlates with objecthood or presence should be dismissed as well. But the remaining candidate, causal integration, does not unequivocally correlate with either presence of objecthood (*if* the examples I gave make sense). The represented causal structure in obsessive thoughts need not be encapsulated, and still they are probably not accompanied by experienced objecthood or perceptual presence. Perhaps this shows that one ought first to clarify whether it even makes sense to talk about the phenomenology of objecthood or presence with respect to conscious thoughts.

4.4 How does perception change when new sensorimotor contingencies are learnt?

Another relevant question is whether increasing the degree of counterfactual richness, causal integ-

²² This could be a case in which there is a particularly strong demand for the general ability of PP to combine "fast and frugal solutions" with "more structured, knowledge-intensive strategies" (Clark [this collection](#)).

ration, or causal depth of a model just modifies (or enriches) the inferred hidden causes, or whether it leads to the perception of a new, possibly more abstract object. This relates to the question raised in the target paper, namely whether a person who is highly familiar with an object perceives it as more real (because she has mastery of more SMCs) than other persons (Seth this collection, p. 18). Interestingly, research on learning new SMCs tentatively suggests that it leads to the perception of new (more abstract) objects.

Under the lead of Peter König, cognitive scientists from Osnabrück have, in recent years, developed a compass belt that indicates to the person wearing it (while moving) changes in directions (cf. Kaspar et al. 2014). The aim of this project (called *feelspace*) is to study how perception in new sensory modalities can be enabled by sensory augmentation.²³ The belt (see Figure 2) contains several vibrators, which always signal the direction of magnetic north. Subjects who wear the belt for a couple of weeks learn new SMCs, e.g., related to how the vibrating signals change when they turn around. A straightforward application of Seth's PPSMCT suggests that the increased counterfactual richness simply goes along with an increased perceptual presence (for the belt, or the vibrations, or the hip / waist, etc). But the authors of the study cited report that perception changes in different ways:

Initially the signal was predominantly perceived as tactile evolving to being perceived as location and direction information. Over time, the perception of tactile stimulation receded more and more into the background. Instead the subjects' reports focused more on changes in spatial perception. Furthermore, two months after the end of belt wearing the effects subjects reported – at least in the FRS questionnaire – diminished. (Kaspar et al. 2014, p. 59)

What changes is not just that SMCs for tactile stimulation on the skin where the belt is worn are learnt, but that these are connected to

more abstract information (regarding location and direction). This also makes sense in comparison with other sensory modalities. Knowledge of auditory SMCs, for instance, does not increase the perception of the inner ear. When the brain learns the relevant SMCs, it thereby learns about the hidden causes of signals in the inner ear. In fact, this may be another reason to believe that counterfactual richness goes along with phenomenal objecthood.

Figure 2: The figure shows two versions of the feelspace belt. (a) The original version used in Nagel et al. (2005). (b) The current version used in Karcher et al. (2012) and Kaspar et al. (2014). Images used with kind permission of Peter König.

This also suggests that when someone is more familiar with an object, the object itself need not become more real, but its connections to other objects might. The causal network in which it is embedded becomes more real. Perhaps the subject also experiences more abstract objects (corresponding to higher-level invariants).

All in all, I hope the examples given illustrate the need to provide a conceptually clearer account of counterfactual richness, causal depth, and causal integration. For at the moment it seems that they are too entangled to allow us to assess their potential relevance for experienced objecthood or presence in a rigorous way. Furthermore, it will be crucial to investigate how phenomenal properties are affected when there are *changes* in these three features (e.g., when counterfactual richness or causal integration is increased or decreased in a controlled way in a study).

5 Conclusion

I have tried to show that useful analogies between PP accounts and classical ideas in the-

²³ For more information on the project, see: <http://feelspace.cogsci.uni-osnabrueck.de/>

ory of science run deeper than portrayed in Seth's target paper. Based on such analogies, I have argued that a proper treatment of active inference needs to be more sophisticated than Seth's threefold distinction. In particular, Seth blurs a whole range of ways in which models can be falsified.

Furthermore, I have suggested that Seth's predictive processing account of perceptual presence may profit from taking not just the counterfactual richness of generative models, but also their degree of perspective-dependence and their causal encapsulation into account (as mentioned above, this suggestion is inspired by Jakob Hohwy's work). I have proposed a way in which examples of possible combinations of these features can be explored, which may serve as a useful tool for future research.

Thomas Kuhn (1962, p. 88) writes that "normal science usually holds creative philosophy at arm's length, and probably for good reasons". I thus hope that research on predictive processing and consciousness has not yet reached the phase of normal science, so that this commentary can still make a humble contribution.

Acknowledgments

I am grateful to two anonymous reviewers, and to Jennifer Windt and Thomas Metzinger especially for providing a vast number of comments and remarks, which helped tremendously in revising the first draft of this paper. This comment was written with support by a scholarship from the Barbara Wengeler foundation.

Inference to the Best Prediction

A Reply to Wanja Wiese

Anil K. Seth

Responding to Wanja Wiese's incisive commentary, I first develop the analogy between predictive processing and scientific discovery. Active inference in the Bayesian brain turns out to be well characterized by abduction (inference to the best explanation), rather than by deduction or induction. Furthermore, the emphasis on control highlighted by cybernetics suggests that active inference can be a process of "inference to the best prediction", leading to a distinction between "epistemic" and "instrumental" active inference. Secondly, on the relationship between perceptual presence and objecthood, I recognize a distinction between the "world revealing" presence of phenomenological objecthood, and the experience of "absence of presence" or "phenomenal unreality". Here I propose that world-revealing presence (objecthood) depends on counterfactually rich predictive models that are necessarily hierarchically deep, whereas phenomenal unreality arises when active inference fails to unmix causes "in the world" from those that depend on the perceiver. Finally, I return to control-oriented active inference in the setting of interoception, where cybernetics and predictive processing are most closely connected.

Keywords

Abduction | Control-oriented active inference | Falsification | Objecthood | Presence

1 Introduction

It is a pleasure to respond to [Wanja Wiese's](#) stimulating commentary ([this collection](#)), from which I learned a great deal. Much of what he says stands easily by itself, so here I select just a few key points which warrant further development in light of his analysis.

2 Active inference and hypothesis testing

A central claim in my target paper is that active inference, typically considered as the resolution of sensory prediction errors through action, should also (perhaps primarily) be considered as furnishing disruptive and/or disam-

biguatory evidence for perceptual hypotheses. This claim transparently calls on analogies with hypothesis testing in science (as well as on counterfactually-equipped generative models), and so invites comparisons with theoretical frameworks for scientific discovery, as Wiese nicely develops. In particular, [Wiese](#) notes that I do not "say much about what it takes to disconfirm or falsify a given hypothesis or model", inviting me to "provide a refined treatment of the relation between falsification and active inference" ([this collection](#), p. 2). This is what I shall attempt in this first section.

2.1 The abductive brain

Wiese rightly says that a strict Popperian analogy for active inference is inappropriate since Popperian falsification relies on hypotheses that are derived deductively. Deductive inferences are *necessary inferences*, meaning that their falsification in turn falsifies the premises (theories) from which they derive. Active inference in the Bayesian brain is not deductive for two important reasons. First, as Wiese notes, Bayesian inference is inherently probabilistic so that competing hypotheses become more or less likely, rather than corroborated or falsified. Probabilistic weighting of hypotheses suggests a process of *induction* rather than deduction. Inductive inferences are *non-necessary* (i.e., they are not inevitable consequences of their premises) and are assessed by observation of outcome statistics, by analogy with classical statistical inference. Second, Bayesian reasoning pays attention not just to outcome frequencies but to properties of the explanation (hypothesis) itself, as captured by the slogan that (Bayesian) perception is the brain's "best guess" of the causes of its sensory inputs. This indicates that the Bayesian brain is neither deductive nor inductive but *abductive* (Hohwy 2014), where abduction is typically understood as "inference to the best explanation". In Bayesian inference, what makes a "best" explanation rests not only on outcome frequencies, but also on quantification of model complexity (models with fewer parameters are preferred), and by priors, likelihoods, as well as hyper-priors which may make some prior-likelihood combinations more preferable than others. Importantly, abductive (and inductive) processes are *ampliative*, meaning that they are capable of going beyond that which is logically entailed by their premises. This is important for the Bayesian brain, because the fecundity and complexity of the world (and body) requires a flexible and open-ended means of adaptive response.

So, the Bayesian brain is an abductive brain. But I would like to go further, recalling that active inference enables predictive *control* in addition to perception. This emphasis is particularly clear in the parallels with cybernetics

and applications to interoception developed in the target article, where allostatic¹ control of 'essential variables' is paramount, and where predictive models are recruited towards this goal (Conant & Ashby 1970; Seth 2013). In this light, active inference in the cybernetic Bayesian brain becomes a process of "inference to the best *prediction*", where the "best" predictions are those which enable control and homeostasis under a broad repertoire of perturbations.² It will be interesting to fully develop criteria for "best-making" in this control-oriented form of abductive inference.

2.2 Sophisticated falsificationism, active inference, and model disambiguation

Where does this leave us with respect to theories of scientific discovery? Strict Popperian falsification was already discounted as an analogy for active inference. At the other extreme, parallels with Kuhnian paradigm shifts also seem inappropriate since these are not based on inference whether deductive, inductive, or abductive. Also, such shifts are typically unidirectional: having dispensed with the Copernican worldview once, we are unlikely to return to it in the future. These two points challenge Wiese's analogy between paradigm shifts and perceptual transitions in bistable perception (see Wiese's footnote 12, [this collection](#), p. 9). What best survives in this analogy is an appeal to hierarchical inference, where changes in "paradigm" correspond to alternations between hierarchically deep predictions, each of which recruit more fine-grained predictions which themselves each explain only part of the ongoing sensorimotor flux, under the hyper-prior that perceptual scenes must be self-consistent (Hohwy et al. 2008).

Wiese himself seems to favour Lakatos' interpretation of Popper, a "sophisticated falsificationism" where theories (perceptual hypotheses) can be modified rather than rejected outright, when predictions are not confirmed,

¹ Allostatic: the process of achieving homeostasis.

² There is an interesting analogy here to the overlooked "perceptual control theory" of William T. Powers, which says that living things control their perceived environment by means of their behavior, so that perceptual variables are the targets of control (1973).

and where hypotheses are not tested in isolation (more on this later). As Wiese shows, sophisticated falsification fits well with some aspects of Bayesian inference, like model updating. According to Lakatos, core theoretical commitments can be protected from immediate falsification by introducing “auxiliary hypotheses” which account for otherwise incompatible data (1970). The key criterion - in the philosophy of science sense - is that these auxiliary hypotheses are *progressive* in virtue of making additional testable predictions, as opposed to *degenerate*, which is when the core commitments become less testable.³ This maps neatly to counterfactually-equipped active inference, where hierarchically deep predictive models spawn testable counterfactual sensorimotor predictions which are selected on the basis of precision expectations, and which lead to effective updating (rather than “falsification”) of perceptual hypotheses. As Wiese notes, a good example of this is given by Friston and colleagues’ model of saccadic eye movements (Friston et al. 2012). When it comes to model comparison, sophisticated falsification may even approximate some aspects of abductive inference: “Explaining away is another example of sophisticated falsification. Even when two or more models are compatible with the evidence ... there can be reason to prefer one of them and reject the other” (Wiese this collection, p. 7). This strongly recalls Bayesian model comparison and “inference to the best explanation”, if not its control-oriented “inference to the best prediction” form.

One important clarification is needed about Wiese’s interpretation of model comparison, highlighting the critical roles of action and counterfactual processing. Wiese rightly emphasizes the important insight of Popper and Lakatos that hypotheses are never tested in

isolation, mandating a process of comparison among competing models or hypotheses. However, he implies a sequential testing of each hypothesis: “balloons being launched and then shot down, one by one” (see Wiese this collection, p. 6). This is quite different from the interpretation of model comparison pursued in my target article, where multiple models are considered in parallel, and where counterfactual predictions are leveraged to select the action (or experiment) most likely to *disambiguate* competing models. In Bayesian terms this is reflected in a shift towards model comparison and averaging (FitzGerald et al. 2014; Rosa et al. 2012), as compared to inference and learning on a single model. Bongard and colleagues’ evolutionary robotics example was selected precisely because it illustrates this point so well (Bongard et al. 2006). Here, repeated cycles of model selection and refinement lead to the prescription of novel actions that best disambiguate the current best models (note the plural). Indeed, it is the repeated refinement of disambiguatory actions that gives Bongard’s starfish robot its compelling “motor babbling” appearance. To reiterate: different actions may be specified when the objective is to disambiguate multiple models in parallel, as compared to testing models one-at-a-time. In the setting of the cybernetic Bayesian brain this example is important for two reasons: it underlines the importance of counterfactual processing (to drive the selection of disambiguatory actions) and it emphasizes that predictive modelling can be seen as a means of control in addition to discovery, explanation, or representation. In this sense it doesn’t matter how accurate the starfish self model is – what matters is whether it works.

2.3 Science as control or science as discovery?

The distinction between explanation and control returns us to the philosophy of science. Put simply, the views of Popper, Lakatos, and (less so) Kuhn, are concerned with how science reveals truths about the world, and how falsification of testable predictions participates in this process. Picking up the threads of abduction,

³ An important application of this idea is to the Bayesian brain itself as a scientific hypothesis. A concern about the Bayesian brain hypothesis is that it can be insulated from falsification by postulating convenient (typically unobservable) priors, much like adaptationist explanations in evolutionary biology can be critiqued as “just so” stories. The key question, not answered here, is whether neural mechanisms implement (approximations to) Bayesian inference, or whether Bayesian concepts merely provide a useful interpretative framework. In the former case one would require the Bayesian brain hypothesis to be progressive not degenerate.

control-oriented active inference, and “inference to the best prediction”, we encounter the possibility that theories of scientific discovery might themselves appear differently when considered from the perspective of control. Historically, it is easy to see the narrative of science as a struggle to gain increasing control over the environment (and over people), rather than a process guided by the lights of increasing knowledge and understanding.⁴ A proper exploration of this territory moves well beyond the present scope (see e.g., Glazebrook 2013). In any case, whether or not this perspective helps elucidate scientific practice, it certainly suggests important limits in how far analogies can be taken between philosophies of scientific discovery and the cybernetic Bayesian brain.

3 Perceptual presence and counterfactual richness

The second part of Wiese’s commentary picks up on the issue of *perceptual presence*, which in my target article was associated with the “richness” of counterfactual sensorimotor predictions (see also Seth 2014, 2015b). Wiese makes a number of connected points. First, he rightly notes an ambiguity between objecthood and presence in perceptual phenomenology, as presented in my target article (Seth this collection) and in Seth (2014). Second, he introduces the notion of *causal encapsulation* as a third phenomenological dimension, complementing counterfactual richness and perspective dependence. He spends some time developing examples based on cognitive phenomenology and mental action to illustrate how these dimensions might relate. Here, I will focus on the relationship between presence and objecthood from the perspective of counterfactual predictive processing – or more specifically the theory of “Predictive Processing of SensoriMotor Contingencies” (PPSMC; Seth 2014, 2015b).⁵

⁴ The continually increasing pressure to justify research in terms of “impact” – especially when seeking funding – highlights one way in which an emphasis on control (rather than discovery) is realized in scientific practice.

⁵ See also my response (Seth 2015b) to commentaries on (Seth 2014), which focuses on this issue.

3.1 Presence and objecthood together

As Wiese notes, when visually perceiving a real tomato (figure 1A) there is both a sense of *presence* (the subjective sense of reality of the tomato) and of *objecthood* (the perception that a (real) object is the cause of sensations). Importantly, while distinct, these properties are not independent. There is a “world-revealing” dimension to perceptual presence which is closely aligned with the experience of an externally-existing object: “How can it be true ... that we are perceptually aware, when we look at a tomato, of the parts of the tomato which, strictly speaking, we do not perceive. This is the puzzle of perceptual presence” (Noë 2006, p. 414).

Figure 1: A. An image of a tomato. B. An image of a clear blue sky.

How does this object-related world-revealing presence come about? In predictive processing (and by extension PPSMC), objecthood depends on predictive models encoding hierarchically deep invariances that accommodate complex nonlinear mappings from (object-related, world-revealing) hidden causes to sensory signals (Clark 2013; Hohwy 2013). There is a reciprocal dependency here between hierarchical depth and counterfactual richness, because (i) hierarchically deep invariances in generative models enable precise predictions about rich repertoires of counterfactual sensorimotor mappings, and (ii) counterfactual richness can scaffold the acquisition of hierarchically deep invariant predictions. One might even say that hierarchically deep invariances are partly *constituted* by (possibly latent) predictions of counterfactually rich sensorimotor mappings (Seth 2015b). These dependencies indicate that ob-

jecthood and world-revealing presence depend on *expectations about counterfactual richness*, rather than counterfactual richness *per se*. Altogether, counterfactually-informed active inference enables the extraction and encoding of hierarchically deep hidden causes of sensory signals. In virtue of hierarchical depth, these inferred causes will also be *perspective invariant*, in the sense that they will have been separated from those causes that depend on on actions (or other properties) of the perceiver (see [Wiese this collection](#), p. 11). In short, to the extent that objecthood and perceptual presence go together, so do hierarchical depth (encoding world-revealing invariances) and (expected) counterfactual richness.

3.2 Presence and objecthood apart

So far so good, but it is evident that presence and objecthood do not *always* go together ([Di Paolo 2014](#); [Froese 2014](#); [Madary 2014](#)), a phenomenological fact which requires further analysis ([Seth 2015b](#)). Presence without objecthood is exemplified in vision by the experience of a uniform deep blue sky (Figure 1B), and is also characteristic of non-visual modalities like olfaction ([Madary 2014](#)). The visual impression of a blue sky, or the tang of briny sea air, both seem perceptually present but without eliciting any specific phenomenology of objecthood. At the same time, the corresponding predictive models are likely to be hierarchically shallow and counterfactually poor: there is not much I can do (besides closing my eyes or looking away) to alter the sensory input evoking a blue-sky experience, and the inferred hidden causes are unlikely to lie behind multiple inferential layers. Hierarchical shallowness may explain the lack of phenomenal objecthood, but why isn't there also a lack of perceptual presence?

Blue-sky-experiences (and olfactory scenes) actually *do* lack the world-revealing presence associated with objecthood. But they do not appear *phenomenally unreal* in the sense that perceptual afterimages and synaesthetic concurrents are experienced as unreal. In PPSMC, phenomenal unreality can arise from an inferential failure to separate hidden causes

in the world, from those that depend on actions (or other properties) of the perceiver ([Seth 2015b](#)). This in turn emerges from violations of counterfactual predictions. For example, consider how saccadic eye movements engage counterfactual predictions. Perceptual afterimages track eye movements, violating counterfactual predictions associated with world-revealing hidden causes that rest on active inference. In contrast, counterfactual predictions associated with blue skies are less amenable to disconfirmation by eye movements, so (non-object-related) perceptual presence remains.⁶

Summarizing, perceptual presence, as an explanatory target, can be refined into (i) a *world-revealing presence* associated with objecthood and hierarchical depth, and (ii) a *phenomenal unreality* arising from a failure to inferentially separate hidden causes in the world from those associated with the perceiver. Both rely on counterfactual processing, and so both call on active inference. Perspective invariance is also implicated in objecthood (through hierarchical depth) and phenomenal unreality (through isolating worldly causes), suggesting that this dimension may not be as separable from counterfactual richness as proposed by [Wiese \(this collection, p. 13\)](#). But is that all there is to presence?

3.3 Causal encapsulation and embodiment

Wiese distinguishes three dimensions to perceptual presence: counterfactual richness (vs. poverty), perspective invariance (vs. dependence), and causal encapsulation (vs. integration). The third of these, causal encapsulation, is perhaps the hardest to pin down. The idea as I understand it, is that a representation (predictive model) is causally encapsulated if it is inferentially isolated from other hidden causes; by contrast it is causally *open* or *integrated* if it expresses a rich set of relations to other inferred

⁶ Phenomenal unreality on this story corresponds to a loss of “transparency” as described by ([Metzinger 2003](#)). For Metzinger, transparency is lost – and phenomenal unrealness results – when the “construction process” underlying perception becomes available for attentional processing. This maps neatly on a failure to inferentially unmix world-related from perceiver-related hidden causes – see [Seth \(2015b\)](#) for more on this.

causes. So, a predictive model underlying the experience of a tomato may be causally integrated with that underlying the experience of the table on which it lies, and the hand (maybe my hand), which is poised to reach out and pick it up. Here, there may be a relation between causal encapsulation/integration and the inferential unmixing of perceiver-related and world-related hidden causes: a failure to separate these causes would presumably prevent rich causal integration with other hidden causes in the world.

The concept of causal encapsulation highlights another interesting aspect of Wiese's commentary: the idea that counterfactual predictions may not always encode sensorimotor contingencies: "it might be equally relevant to encode how sensory signals pertaining to the tomato would change if the wind were to blow ... or if the tomato were to fall down" (Wiese [this collection](#), p. 11). While such extra-personal causal contingencies may be salient in many cases, I see them as secondary to sensorimotor body-related counterfactual predictions. By definition they do not involve active inference: I have to wait for the wind to change direction (though perhaps I might move to get a better view). This means that many central features of active inference discussed here – its relation to predictive control, homeostasis, and counterfactually-informed model disambiguation – do not apply.

The body re-emerges here as central, this time as a ground for the generation of counterfactual predictions. Specifically, bodily constraints shape counterfactual predictions since they place limits on how actions can be deployed in intervening upon the (inferred) causes of sensory input. This suggests that changing action repertoires would alter experiences of presence. Wiese raises out-of-body-experiences and dream experiences as a relevant context ([this collection](#), p. 15), where subjects sometimes identify their first-person-perspective, not with a body, but with an unextended point in space. I agree with him that examining world-revealing presence in these situations would be fascinating, if extremely difficult in practice.

The body is of course not only a source of counterfactual predictions, but also the target of counterfactually-informed active inference, both for representation (exemplified by the rubber-hand-illusion, as mentioned by Wiese) and for control.⁷ As emphasized in the target article, control-oriented active inference is particularly significant for *interoception*, where predictive modelling is geared towards allostasis and homeostasis rather than accurate representation (see also [Seth 2013](#)). Returning the focus to interoceptive inference raises a host of intriguing questions, which can only be gestured at here. One may straightaway wonder how counterfactual aspects of interoceptive inference shape the "presence" of emotional and body-related experiences. Is it possible to have an emotional experience lacking in "affective presence" – and what is the phenomenological correlate of "objecthood" for interoceptive experience? Other interesting questions are how precision weighting sets the balance between representation versus control in active interoceptive inference, and what it means to isolate "wordly" causes when both the means and the targets of active inference are realized in the body. These are not just theoretical questions: advances in virtual reality ([Suzuki et al. 2013](#)) and in methods for measuring interoceptive signals ([Hallin & Wu 1998](#)) promise real empirical progress on these issues.

4 Conclusions

This response has been shaped by Wiese's perspicuous focus on the philosophy of science and on the phenomenology of perceptual presence. My response to the first topic was to frame the Bayesian brain in terms of *control-oriented ab-*

⁷ Wiese, when discussing König's FeelSpace project ([Kaspar 2014](#)), interprets PPSMC as saying that increased practice with the FeelSpace compass belt – and hence increased counterfactual richness – would lead to "increased perceptual presence (for the belt, or the vibrations, or the hip/waist, etc.)" (Wiese [this collection](#), p. 17). I see things differently. The counterfactual predictions, while mediated by the belt, relate to hidden causes in the world (e.g., magnetic north). In fact, PPSMC says that FeelSpace practice would lead to hierarchically deep and counterfactually rich models of how "magnetic north" impacts on belt vibrations and the like, leading to increased world-revealing presence for these worldly causes but diminished perceptual presence of the tactile stimulation itself. Still, the FeelSpace project certainly provides a fertile empirical testbed for the ideas raised here.

duction, where falsification is replaced by “inference to the best prediction” as a criterion for progress. I also reinforced the dependency between active inference and counterfactual processing, which underpins the important case of disambiguatory active inference in Bayesian model comparison. With respect to perceptual presence I proposed a distinction between world-revealing presence and phenomenal unreality (Seth 2015b). World-revealing presence corresponds to objecthood and is associated with hierarchical depth, expected counterfactual richness, and perspective invariance of perceptual hypotheses. Phenomenal unreality transpires when perceptual inference fails to unmix world-related from perceiver-related causes; this corresponds to a loss of “phenomenal transparency” (Metzinger 2003) and depends on violation of counterfactual sensorimotor predictions. Space constraints prevented me considering Wiese’s discussion of the “presence” of cognitive phenomenology, like abstract mathematical and philosophical thinking, in these terms. There is of course a rich literature in linking such phenomena to the body (Lakoff & Nunez 2001), and hence perhaps to active inference where the concept of a “mental action” becomes critical (O’Brien & Soteriou 2009). Space constraints also prevented Wiese from elaborating on interoception, which I consider the most interesting setting for control-oriented active inference, in virtue of the cybernetics-inspired emphasis on homeostasis and allostasis. Interesting questions emerge here about how counterfactual processing plays into the phenomenology of interoceptive experience.

Cognitive scientists have long argued for a continuity between perception and action (Dewey 1896). To close, I suggest thinking instead of a continuum between *epistemic* and *instrumental* active inference. This is simply the idea that active inference – a continuous process involving both perception and action – can be deployed with an emphasis on predictive control (instrumental), or on revealing the causes of sensory signals (epistemic). This process intertwines interoception, proprioception, and exteroception, and autonomic and motoric action, with the balance always delicately orchestrated

by precision optimisation and counterfactual processing. Putting things this way provides a new way to link “life” and “mind” (Godfrey-Smith 1996) and may help reveal the biological imperatives underlying perception, emotion, and selfhood.

Acknowledgements

I am grateful to the Dr. Mortimer and Theresa Sackler Foundation, which support the work of the Sackler Centre for Consciousness Science. Many thanks to Thomas Metzinger, Jennifer Windt and the MIND group for inviting me to participate in this project, to Jakob Hohwy and Karl Friston for correspondence about abductive inference, and to Wanja Wiese for his excellent commentary.

The Ongoing Search for the Neuronal Correlate of Consciousness

Wolf Singer

A few decades ago the search for the neuronal correlates of consciousness was considered both technically intractable and philosophically questionable. Searching for a material substrate of phenomena accessible only from the first-person perspective appeared to be epistemically problematic. But the development of non-invasive imaging technologies and the availability of intracranial recordings from patients alleviated the imminent technical problems. Progress in the analysis of the connectome of the brain, and the introduction of multisite recordings from the cerebral cortex of animals led to a revision of concepts in the field of cognitive neuroscience, emphasizing principles of distributed processing in recurrent networks with non-linear dynamics, self-organization, and coding in high-dimensional-state space. These advances, together with the growing evidence for epigenetic shaping of brain functions by socio-cultural influences, pave the way for novel theories that attempt to bridge the gap between neuronal processes and subjective states.

Keywords

1 Introduction

Progress in brain research, especially in the domain of cognitive neuroscience, renders phenomena that have traditionally been subjects of the humanities amenable to scientific investigation. It has now become possible to investigate the neuronal underpinnings of mental phenomena such as perception, decision making, control of attention, language perception and production, action planning, storage and recall of memories, emotions and moods, desires and aversions, and last but not least consciousness. This research agenda is confronted with a number of fascinating challenges. One is the immense complexity

of the brain processes that underlie these highly-differentiated cognitive functions. Another results from the fact that many of the phenomena whose neuronal correlates are to be investigated are subjective phenomena, accessible and describable only from a first-person perspective. Hence there is an epistemically problematic gap between what is observable from the third-person perspective of scientific inquiry and the explananda that need to be defined in terms of first-person experience. Yet another challenge is that a relatively young scientific discipline is set to enter territories that

for millennia have been ploughed by great minds who have coined terms, formulated concepts, and constructed belief systems based on evidence extracted from introspection, intuition, and observations that relied exclusively on the natural senses. This raises numerous and on occasions frustrating problems for communication, because bridges have yet to be built between the more recent naturalistic description systems and the highly-differentiated terminology nurtured in the humanities. Some of these problems surface in passionate discussions on the existence of free will, the nature of perception, the constitution of the Self, and intentionality and mental causation—and above all on the question of whether it is even possible to identify neuronal correlates of mental, subjective phenomena.

In this chapter some of these challenges will be discussed from a neurobiological perspective. We shall first review the state of the art in the field of cognitive neuroscience, emphasizing recent changes in our views on the brain. These have been forced upon us by the novel data produced by new and powerful technologies. These insights show the brain to be a highly distributed, self-active system with non-linear dynamics; rather than a hierarchically-organized stimulus-response machine, as has been proposed by behaviourist theories. Subsequently, an excursion will be made into epistemology, to establish the extent to which brain research can contribute to philosophical discussions concerning the nature of perception. The process of perceiving will be interpreted as a constructive act in which sparse sensory signals are matched with a huge amount of stored knowledge; and the various sources of this knowledge will be discussed. This section will set the stage for the following discussion of the putative neuronal correlates of consciousness (NCC), as it will highlight the cognitive constraints and idiosyncrasies of cognitive systems that owe their abilities to evolutionary processes. Before reviewing various theories on the NCC, an attempt will be made to define the explanandum—in full awareness of the futility of this attempt. The review of experimental work in search of the NCC will be followed by a brief

account of our own experimental contributions, and then an attempt will be made to demystify the so-called “hard problem” of consciousness—the problem of finding a naturalistic explanation for the qualia, namely these immaterial connotations of our experiences. My proposal will be that the problem can be alleviated if we consider not only individual brains and biological evolution but also cultural evolution and the social realities that have emerged from socio-cultural interaction between human beings.

As this contribution addresses an interdisciplinary audience I considered it appropriate to not only refer to published work when alluding to experimental findings and concepts but to sometimes provide explicit and detailed background information. To this end I have adapted passages from a few of my own publications, in which I had addressed some of the issues that needed to be recapitulated for the sake of clarity in the present contribution. These passages include descriptions of experimental findings from my lab and descriptions of the state of the art in the neurosciences.

2 The state of the art in cognitive neuroscience: A paradigm shift

2.1 Classical views

As detailed in several previous reviews the neurosciences are about to undergo a paradigm shift towards concepts that consider the brain as a self-organizing complex system with non-linear dynamics that exploits a huge body of stored knowledge to interpret sensory signals, formulate hypotheses and to generate predictive models of the world in order to optimize adapted behavioral responses (Singer 2009, 2013). For many decades, the search for the neuronal underpinnings of cognitive and executive functions has been guided by the behaviourist view that the brain is essentially a highly complex and versatile stimulus-response machine, in which serial processing strategies prevail. This view received further support from early anatomical data that emphasized that feed-forward connections exhibit high topographic precision and possess strong driving synapses, while feedback

connections are diffuse and only modulatory. The rather impressive performance of artificial pattern-recognition systems based on such processing architectures suggested that neuroscientists were on the correct path. Accordingly, they set out to study the responses of neurons to sensory stimulations across the various stages of the processing hierarchy and analyzed activation patterns associated with motor output, hoping that these strategies would eventually lead to reductionist explanations of the neuronal mechanisms that support cognition, memory, decision making, planning, and motor behaviour. The strategy to follow the transformation of activity from the sensory surfaces over the numerous levels of hierarchically-organized processing structures to the respective effector organs proved to be extremely fruitful. Comparison of brains from different species provided compelling evidence that the basic principles according to which neurons function and exchange signals have been preserved throughout evolution with only minor modifications. For the comparatively simple nervous systems of certain invertebrates, this behaviourist approach allowed for near-complete descriptions of the neuronal mechanisms underlying particular behavioural manifestations. This nurtured the expectation that pursuing this research strategy would sooner or later allow us to explain in the same way the more complex behaviour of mammals—and ultimately also the highly-differentiated cognitive functions of primates and human subjects. However, in recent decades the pursuit of this approach has led to an accumulation of evidence that demands a revision of the classical hypothesis, which emphasizes serial feed-forward processing of sensory information within hierarchically-organized architectures.

2.2 Observations forcing an extension of classical views

Advances in the analysis of the cortical connectome, the introduction of multisite recording techniques, and the development of imaging methods assessing whole-brain activity have generated data that necessitate an extension of

classical views, raise novel questions, and likely provide new solutions to old problems.

Anatomical evidence: i) Within processing streams from sensory surfaces to executive organs, feedback projections are in general more numerous than feed-forward projections, emphasizing the importance of top-down control (Felleman & van Essen 1991). ii) Connections linking neurons within distinct cortical areas cross the boundaries between areas (Schwarz & Bolz 1991). Thus, the cerebral cortex appears to be a continuously coupled sheet, the different cortical areas being distinguished mainly by their input and output connections. iii) From primary sensory areas onwards, processing streams diverge into numerous parallel pathways whose nodes are linked by massive reciprocal connections, both within and across modalities (Markov & Kennedy 2013; Markov et al. 2013). iv) The rule that feed-forward connections originate in supra- and feedback projections in infragranular layers does not hold for nearby cortical areas (Markov & Kennedy 2013; Markov et al. 2013). Together with electrophysiological evidence (De Pasquale & Sherman 2011), this threatens the strict distinction between feed-forward driving and feedback modulatory connections. v) Finally, statistical analysis of interareal connectivity suggests an organisation resembling small-world, rich-club networks (see Van den Heuvel & Sporns 2013) that minimize path length between nodes (areas; Van den Heuvel & Sporns 2011; Sporns 2013). However, analysis of projections with cellular resolution suggests as one reason for short path length the surprisingly high degree of connectedness among cortical areas. Statistical analysis suggests that more than 60% of possible links between network nodes are actually realized (Markov & Kennedy 2013).

Functional evidence: i) Even in early sensory areas neurons lose their simple feature-specific responses when challenged with complex stimuli (David et al. 2004; Vinje & Gallant 2000). Moreover, responses are influenced by stimuli in other modalities, by attention, reward expectation, and contents in working memory, thus suggesting contextual modulation not only by intrinsic connections but also by top-down

projections (Engel et al. 2001; Calvert et al. 1997; Iurilli et al. 2012; Muckli & Petro 2013; Stokes et al. 2013). ii) The notion of strictly serial processing from input layer four, via layers three and two, to the output layers five and six of the cerebral cortex needs to be revised in light of evidence that vigorous responses can also be elicited by sensory input when parts of this canonical circuit are disrupted (Constantinople & Bruno 2013). The possibility that supra and infragranular compartments can operate in parallel is further supported by evidence that the two subdivisions engage in oscillatory activity in different frequency bands (gamma in supra- and alpha or beta in infragranular layers; Buffalo et al. 2011; Roopun et al. 2008). iii) Multisite recordings indicate that “spontaneous” fluctuations in the responsiveness of individual neurons are often the reflection of coordinated, highly structured spatio-temporal activity patterns rather than the result of noise (Kenet et al. 2003; Fries et al. 2001a). iv) Widely distributed cortical areas exhibit coherent fluctuations of their spontaneous activity, forming functionally-coupled networks that change in their composition in a state-dependent way (Fox et al. 2005; Hipp et al. 2012; Raichle 2011; Raichle et al. 2001). Thus, the cortex—and in a wider sense the brain—appears to be a highly active, pattern-generating system, rather than just a stimulus-driven device. v) Analysis of whole brain activity with functional magnetic resonance imaging (fMRI) and electroencephalographic (EEG) and magnetoencephalographic (MEG) measurements indicates that virtually all cognitive and executive functions are associated with the activation of networks of often widely-distributed cortical areas (Engen & Singer 2013; Friederici & Gierhan 2013; Hipp et al. 2011; Hodzic et al. 2009; Power & Petersen 2013). This suggests that distributed networks are a substrate of functions rather than individual specialized structures. vi) Finally, analysis of the brain’s dynamic signatures indicates that neuronal populations can engage in oscillatory activity in characteristic frequency bands and synchronize their discharges, such that the respective frequency bands and the composition of coherently active

cell groups depend on central states, attention, cognitive tasks, and goals of action (Buzsáki 2006; Singer 2010).

These novel anatomical and functional data suggest as a prevailing organizational principle distributed processing in densely coupled, recurrent networks with non-linear dynamics, which are capable of supporting high dimensional states. This organization requires a high degree of coordination of distributed processes, suggesting that special mechanisms are implemented to dynamically bind local processes into coherent global states, and to configure functional networks “on the fly” in a context- and goal-dependent way. It has also become clear that the brain is by no means a stimulus-driven system. Rather, it is self-active, permanently generating highly structured, high-dimensional spatio-temporal activity patterns. These patterns are far from being random, and instead seem to reflect the specificities of the functional architecture that is determined by genes, modified by experience throughout post-natal development, and further shaped by learning. These self-generated activity patterns in turn seem to serve as priors with which incoming sensory signals are compared. Perception is now understood as an active, reconstructive process, in which self-generated expectancies are compared with incoming sensory signals. The development of methods that allow simultaneous registration of the activity of large numbers of spatially-distributed neurons revealed a mind-boggling complexity of interaction dynamics—which in turn eludes the capacity of conventional analytical tools and, because of its non-linearity, challenges hypotheses derived from intuition.

In the last decade theoreticians have begun to explore and appreciate the immense computational power of such self-organizing recurrent networks that gave rise to concepts such as “reservoir computing”, “echo-state computing” or “liquid computing” (Buonomano & Maass 2009; Lukoševičius & Jaeger 2009). The evidence that resting-state activity is highly structured, that information is contained in the spatio-temporal relations between the responses of widely distributed neurons, and that stimulus-response functions depend crucially on state

variables generated within the brain are in principle compatible with such advanced concepts of information processing in highly non-linear, high-dimensional dynamic systems; but neurobiological approaches taking such considerations into account are still very rare.

2.3 Persisting explanatory gaps

Our rather detailed knowledge of the response properties of individual neurons in different brain structures, and of the microcircuits that shape these responses, stands in stark contrast to our ignorance of the complex and highly dynamic processes through which the myriads of spatially-distributed neurons interact in order to produce specific behaviours. Evidence from invasive and non-invasive multi-site recordings indicates that most higher brain functions result from the coordinated interaction of large numbers of neurons, which become associated in a context- and goal-dependent way into ad-hoc formed functional networks. These networks are dynamically configured on the backbone of the anatomical connections (for review see [von der Malsburg et al. 2010](#)). Evidence also indicates that these interactions give rise to extremely complex spatio-temporal patterns that are characterized by oscillations in a large number of different frequency bands, which can synchronize, exhibit phase shifts, and even cross frequency coupling ([Uhlhaas et al. 2009](#)). In the light of these novel data, the brain—and in particular the neocortex—appears to be a self-active, self-organizing “complex system” which exhibits non-linear dynamics, is capable of utilizing multiple dimensions for coding (space, amplitude, oscillation frequency, and phase), operates in a tightly-controlled range of self-organized criticality ([Shew et al. 2009](#); edge of chaos), and constantly generates highly-structured, high-dimensional activity patterns that are likely to represent stored information. However, how exactly information is encoded in the trajectories of these high-dimensional and non-stationary time series is largely unknown, and is the subject of increasingly intense research. Moreover, with the exception of a few studies in which selective manipulation of the activity of

defined neuron groups were shown to affect behaviour in a particular way ([Salzman et al. 1992](#); [Houweling & Brecht 2008](#); [Han et al. 2011](#)) most of the available evidence on the relations between neuronal responses and behaviour is still correlative in nature. This makes it difficult to determine whether an observed variable is an epiphenomenon of a hidden underlying process or is causally involved in accomplishing a particular function. Thus, systems neuroscience now faces the tremendous challenge of analyzing the principles of distributed dynamic coding and of obtaining causal evidence for the functional role of specific activation patterns, in order to distinguish between functionally-relevant variables and epiphenomena.

In conclusion, we have to abandon classical notions of the neuronal representation of perceptual objects and, in the same vein, that of motor commands. The consequence is that it becomes once again unclear how the distributed processes that deal with the various properties of a perceptual object—its visual, haptic, acoustic, olfactory and gustatory features—are bound together in order to give rise to a coherent representation or percept. Given this, it may appear more than bold to attempt to identify the neuronal correlates of consciousness—probably the highest and most mysterious of our cognitive functions.

2.4 What neuroscientists believe

Despite the numerous gaps in our understanding of integrated brain functions, neurobiologists agree on a number of general conclusions on the relation between brain processes and behavioural phenomena. The majority of neurobiologists seem to consent that all cognitive and executive functions that we can observe in human beings, including the highest mental activities and consciousness, are the result, not the cause, of neural interactions. Consequently, it is held that mental phenomena follow or emerge from neural interactions and do not precede them. Furthermore, it is assumed that all neural processes obey the known laws of nature. The reason for this is that the behaviour of organisms of low complexity, such as, for example,

molluscs or worms, can be fully explained by registering the activity of their neurons and establishing causal relations between the spatio-temporal patterns of this activity and the respective behaviour. There is, at present, no need to postulate any additional unknown forces, laws, or modes of interaction in order to explain their behaviour. The reason for this is that evolution is a very conservative process. Once an invention has been made that increases fitness it tends to be conserved, unless there is a major change in conditions that makes this invention obsolete or maladapted. Therefore, our nerve cells function in exactly the same way as those of snails. Likewise, the development of structures also follows a very conservative path. Since the first appearance of the cerebral cortex, the six-layered sheet of nerve cells that covers the hemispheres of the brain, no new structures have emerged. There is just more of the same, and this increase in complexity marks the difference between the brain of a human being and that of our nearest neighbours, the great apes. Apparently, this processing substrate and the associated gain of complexity marks the difference between species that failed and those that succeeded in promoting cultural evolution—with all its far reaching consequences. In this context, however, one needs to consider that cultural evolution created a socio-cultural environment of ever-increasing complexity that in turn contributes to the epigenetic shaping of brain architectures. Thus, even if the genetically-determined layout of brain architectures has changed little since the beginning of human civilisation, those features that can be modified by epigenetic shaping are likely to have undergone major modifications. This fact has not always been taken into account in the past; but its implications will be discussed below. But this additional twist concerns the epigenetic modifiability of our brains, and not its basic functional principles.

3 Contributions of neuroscience to philosophy

Once the neurosciences began to investigate the neuronal underpinnings of higher cognitive func-

tions, especially those realized in human brains, an increasing number of questions, traditionally investigated by the humanities, were addressed through empirical studies within the rapidly developing field of cognitive neuroscience. One obvious domain for this investigation was epistemology. Cognitive neuroscience explores from a third-person perspective the mechanisms that mediate our perception and the acquisition of knowledge. Longstanding discussions about the objectivity of cognition, the question of how constructive our perceptual processes really are, and how reliable or idiosyncratic they might be, need to be reconsidered on the basis of neurobiological data. Another question, to which the neurosciences will have to find an answer, is related to the mind-body problem: how can mental phenomena, namely immaterial entities such as the qualia of perception and social realities such as belief and value systems, emerge from the material interactions between nerve cells in human brains? These immaterial phenomena came into this world once the cognitive abilities of *Homo sapiens* initiated the evolution of cultures. They affect our lives as much as the material constraints of the world in which we evolve, but they have a different ontological status to the neuronal processes that brought them into this world. Yet another question that solicits discussion between neuroscientists and philosophers of mind is the nature of consciousness. The question of the constitution of the intentional Self is closely related to this issue, as is the conundrum of the existence of Free Will. If the material processes in individual brains and the social realities resulting from the interactions of humans are the basis and cause of mental phenomena, and if brain processes follow the known laws of nature, then there ought to be unifying description systems that bridge the gap between phenomena assessed from third- and first-person perspectives. If such approaches turn out to be feasible philosophical positions, the postulation of an ontological dualism will have to be modified. This will have far-reaching consequences for our self-understanding and the delineation of the border between “physics” and “metaphysics”.

3.1 An epistemic caveat

It is obvious that our perceptions and imaginations, as well as our ability to reason, are constrained by the cognitive abilities of our brains—and brains, like all other organs, are the product of an evolutionary process. Hence our brains have become adapted to the conditions of the mesoscopic world in which life has evolved. This is the world within the scale of millimeters to meters, it is the world where the laws of classical physics prevail; it is not the world of quantum physics and it is not the world of astrophysics. As a consequence, our cognitive functions have become adjusted to assure survival in this mesoscopic world. Problem-solving in this dangerous and poorly-predictable world requires the application of pragmatic heuristics and hence cognitive abilities that are in all likelihood not optimized to comprehend the essence behind the perceivable phenomena or the “absolute truth” in the Kantian sense. Evolution did not prepare us to directly perceive and understand processes at subatomic or cosmic scales, because they were and are completely irrelevant for our daily struggle for survival. Even more worrying is the possibility that the way in which we reason may also be limited by adaptation to those processes in the narrow range of the world that are relevant for survival and that we can access with our highly selective, specialized senses. In conclusion, it is very likely that our cognition is constrained. And this may apply not only to primary perception, but also to our way of deriving inferences from observables. If this were true it would pose unsurmountable barriers to our attempts to understand, just as it would challenge the consistency of mathematical theories and logical deductions. However, for these very reasons we have no way of knowing whether this is the case.

3.2 The contribution of neuroscience to epistemology

Growing insights into the neuronal mechanisms underlying perception provide compelling support for constructivist positions and emphasize the *epistemic caveats* formulated above. In the

light of neurobiological evidence, perceiving is essentially a constructive process. The sensory categories, for example those according to which we assign qualities to our experiences, are nothing but the idiosyncratic consequence of the layout of our sensory organs. These sample in a highly selective way a narrow range of physico-chemical signals, and this leads to the arbitrary classification of electromagnetic radiation with wavelengths between 400 to 700 nanometers as light, because the photoreceptors in the eye are sensitive to this wavelength range. Radiations with slightly longer wavelengths stimulate our temperature receptors and we categorise the respective sensations as temperature. A similar arbitrariness of category boundaries is observable in other sensory domains. The definition of perceptual objects, for example, is guided by a set of Gestaltrules that our brains apply in order to segment the spatio-temporal continuum of sensory signals into distinct objects—and this holds true for all sensory modalities. Objects are identified as such if they are delineated by spatial or temporal borders and exhibit some intrinsic coherence. This definition is appropriate in the mesoscopic world, but it does not apply to objects at atomic or subatomic scales. If we had no *a priori* definition of the properties of objects, we would not be able to distinguish objects, we would, for example, be unable to extract object-specific features from the continuous two-dimensional brightness distribution that cluttered scenes generate on the retina.

It is now well established by experimental evidence that the sparse sensory signals provided by our highly selective senses are interpreted by the brain on the basis of a vast amount of *a priori* knowledge that is stored in its own functional architecture. Our self-active brains permanently formulate knowledge and context-dependent expectancies, interpret sensory signals as a function of these inferences, and present the result of this constructive process to the workspace of consciousness. Paradoxically, we perceive the world around us as coherent even though our senses extract only a minute fraction of the available signals. Much of what we experience as actually perceived is read out from memory and is the result of reconstruction

and completion. This raises the question of the origins of this knowledge.

3.3 The sources of *a priori* knowledge

It is commonly accepted that all the knowledge a brain can possibly have, and the rules according to which this knowledge is applied for the interpretation of sensory signals and the execution of movements, reside in the functional architecture of the brain. This contradicts the analogy frequently drawn between computers and brains. Computers have processors and separate memories for programmes and for data. In the brain, however, there exist only neurons and connections. Both the stored knowledge and the programs for processing this knowledge reside in the layout of these connections, their polarity—that is, whether they are excitatory or inhibitory—and their graded efficacy. The question of the origin of stored information is thus reduced to the question of which processes determine the functional architecture of the brain.

The most important determinant of the functional architecture of brain—and hence the most important source of knowledge—is, of course, evolution. What makes our brain architectures comparable is evolutionary-acquired information that resides in the genes and determines the layout of the brain's connectome. It is knowledge about the world that is expressed in the functional architecture of brains every time an organism develops. In this sense evolution can be considered a cognitive process. This evolutionary-acquired knowledge pertains essentially to the conditions of the precultural world; and it is implicit—we are not aware of having it because we were not around when it was acquired. Still, we use it to interpret the signals provided by our sense organs and to structure adapted responses.

This inborn knowledge is subsequently complemented by extensive epigenetic shaping of the neuronal architectures, which adapt the developing brain to the actual conditions in which the individual develops. The human brain develops the majority of its connections only after birth, and this process continues approximately until the age of twenty or twenty-five

years. During this developmental period numerous new connections are formed, while many existing connections are removed; and this making and breaking is guided by the neuronal activity itself. Since, after birth, neuronal activity is modulated by interactions with the environment, the development of brain architectures is thus determined by a host of epigenetic factors derived from the natural and social environment. Through this process, the brain acquires knowledge about the specific conditions in which the newborn organism actually evolves, and thereby complements its genetically-inherited knowledge.

Figure 1: The brain assumes that light comes from above. The circular contours on the left board appear as concavities because the shadows are located at the right upper corner. The right board is actually the same as on the left, just rotated by 180 degrees. Now the shadows are on the lower left border and the contours appear convex.

A considerable part of this developmentally-acquired knowledge also remains implicit because of the phenomenon of childhood amnesia. Children before the age of about four years have only a limited capacity to remember in which context they have experienced and learnt particular contents. The reason for this is that the brain centres required for these storage functions—we call them episodic or biographical or declarative memories—have not yet matured. Thus, while young children learn very efficiently and store contents in a very robust way through structural modifications of their brain architec-

ture, they often have no recollection of the source of this knowledge. Because of this apparent lack of causation, the knowledge acquired in this way is implicit, similarly to evolutionary-acquired knowledge, and therefore often assumes the status of convictions that cannot be questioned.

Like innate knowledge, this acquired knowledge is used to shape cognitive processes and to structure our perceptions. Yet we are not aware that what we perceive is actually the result of such knowledge-based interpretations.

Figure 2: The checker-board illusion by Adelson, illustrating that even brightness perception depends on assumptions derived from context. (For further descriptions see text.)

Finally, there is knowledge acquisition by learning, which accompanies us throughout our lives. This is based on graded changes of the coupling strength of the existing connections between neurons. In the adult brain few new connections are formed and under normal conditions no breaking of connections occurs. The knowledge acquired by these learning processes also biases perception, but this is explicit, and its origins are known. One is usually aware of when and how it has been acquired and can therefore question its validity and by the same token the validity of what is perceived.

3.4 Examples illustrating the influence of priors on perception

The two examples depicted in [figure 1](#) and [figure 2](#) illustrate impressively how *a priori* knowledge structures our primary perceptions. The object in [figure 1](#) is a mould used to produce candies. On the left side one sees the inside of the mould, with its concavities, and on the left we see the rear side with its corresponding con-

vex protrusions. In reality, the pictures are identical, but one is rotated by 180°. The reason for our very different perceptions of the images is that the brain makes the *a priori* assumption that light comes from above—a well adapted assumption in a precultural world with only natural light sources. In this case contours that have the shadow above are interpreted as concave, and those with the shadow below as convex. Thus, an assumption of which we are not aware determines what we perceive. Another striking example is shown in [figure 2](#). It is hard to believe, but surfaces A and B have exactly the same luminance. They appear different because the brain sees the shadow that is caused by the cylinder on the right. Even though the amount of light reflected from surfaces A and B and impinging on the retina is exactly the same, the brain interprets the brightness of the two surfaces as different because it infers the following. Given that there is a shadow, surface B must be brighter than surface A—which has no shadow on it—in order to reflect the same amount of light. Thus, the brain “computes” the inferred brightness of the surfaces, but we are not aware of these computations. We just perceive the result and take it to be real, i.e., we see B as being much brighter than A. These two examples indicate that the brain generates inferences of which we are not aware, that it is permanently reconstructing the world according to *a priori* knowledge, and that we, as perceiving subjects, have to take for granted what the system finally offers us as conscious experience. As expected, this is not only the case with specially designed psycho-physical experiments, but is an essential feature of all our perceptual processes.

The mechanism leading to this “false” perception, to this “illusion”, has of course an important function. Our brain uses this principle to generate perceptual constancy, e.g., to keep colours and contrasts constant despite different illumination conditions. The spectral composition and the intensity of the sunlight change dramatically throughout the day, and therefore the spectral mix of light reflected from a particular, edible berry differs in the morning from that at noon. An animal that relies on colour to

distinguish one edible berry from another, slightly more violet and poisonous berry, cannot rely on an analysis of the “true” or actual spectral composition of reflected light. It first has to assess the spectral composition of the light source—the sunlight—and then must reconstruct the perceived colour. Our brains accomplish this by assessing the actual lighting conditions, by comparing the colours of the sky, of stones, of leaves and barks etc. and then, by using this contextual information, compute the “real” colour of the berries to identify that which is edible. Our brains are capable of assuring colour constancy despite changing illumination conditions, but we are completely unaware of the complexity of the computations assuring constancy and thereby survival in a changing world. In essence, all these operations are based on the evaluation of relations. We rarely perceive absolute values such as those measured by physical devices, be it intensities of stimuli, wave-lengths of sound or light waves, or chemical concentrations. We mostly perceive these variables in relation to others, as differences, increments and contrasts, such that these comparisons are made both across space and time. This is a very economical and efficient strategy because it emphasizes differences, permits coverage of wide ranges of intensities and, as mentioned above, allows for constancy. Given the advantages of these well-adapted heuristics it is at least questionable whether one should confront the resulting perceptions as illusions.

3.5 Conclusion of the excursion into epistemology

Evolution- and experience-dependent development determine and shape the architecture of the brain. Through these processes, knowledge about the world and strategies to use this knowledge for survival and reproduction are implemented in brain architectures. These in turn determine what and how an organism perceives and how it behaves. Because of the selection criteria that guides evolution, the brain adapted to the narrow segment of the world in which life has evolved, and its functions have been optimized to extract and process those signals that

best serve survival and reproduction. Thus the cognitive functions of the brain have probably not been optimized for understanding the deeper structure of the world that assures coherence across scales and cannot be perceived directly. Similarly, the rules according to which we evaluate contingencies and establish associations among events are implemented by specific molecular mechanisms that translate temporal correlations of neuronal activity into lasting changes in the efficacy of neuronal connections. These rules have been preserved virtually unchanged since the evolution of primitive nervous systems, and are at the basis of assignments of causality and the formation of associations. Again, these rules are highly efficient for the generation of models of the mesoscopic world and the formulation of predictions, but they do not apply to processes in the quantum world or to the relativistic dynamics of the universe. Given these specific adaptations of our cognitive functions, one might consider that similar restrictions may also hold for the way we reason. If so, this would present a serious challenge for the generalisation of models and theories based on extrapolation.

4 The contribution of the neurosciences to theories of consciousness

Some of the propositions summarized in the following chapter have been derived from experiments on the neuronal substrate of consciousness that have been described in detail in [Meloni & Singer \(2011\)](#) and [Aru et al. \(2012a, 2012b\)](#). A few decades ago, attempts to identify the neuronal correlates of consciousness (NCC) were considered futile. Because of the rapid development of non-invasive technology for the registration of neuronal activity in the human brain, and because of advances in the analysis of the neuronal underpinnings of higher cognitive functions, the search for NCC has now become a very active field of research in cognitive neuroscience. As expected, this new field is confronted with great challenges that are difficult to overcome. The explanandum is ill-defined; the prerequisites and consequences of conscious processing cannot easily be distinguished by ex-

periment from conscious processing per se; the experience of mental causation and agency is difficult to reconcile with contemporary concepts of self-organization; and finally it is difficult to bridge the epistemic gap between phenomena that are experienced from a first-person perspective and mechanisms described from a third-person perspective. Some of these problems will be addressed in the following paragraphs.

4.1 An attempt to define the explanandum

Most languages have coined a term for consciousness. Thus, it must be a robust phenomenon on which human beings can agree. However, while it is easy to use the term, it is virtually impossible to give a formal definition of what exactly it means. Nevertheless, the implicit understanding of what it is to be conscious seems to be sufficiently clear and widely accepted enough to justify a search for its neuronal correlates and, ultimately, to identify the neuronal mechanisms that enable a subject to be conscious of something. In their seminal paper, [Crick & Koch \(1990\)](#) propose that consciousness is a specific cognitive function and that, as such, it must have neuronal correlates that can be analyzed with the tools of the natural sciences. With the development of non-invasive imaging technologies, the tools became available to actually pursue this project and the search for the neuronal correlates of consciousness (NCC) became a mainstream endeavour.

Before discussing some of the proposed theories for NCC, I shall attempt to give an operational definition of what I mean when referring to awareness and consciousness or, in other terms, what it means to be aware of something or to be conscious. Subjects will be considered aware of something if they are able to report the presence or absence of the content of a cognitive process—irrespective of whether this content is made available by recall from stored memories or drawn from actual sensory experience. Thus, one criterion for awareness is the reportability of the presence of a cognitive content. These reports can in principle consist of any motor response, but to be on the safe side,

it is often requested that the report be verbal. The reason for this is that behavioural responses can be obtained under forced choice conditions that clearly indicate that the brain has processed and recognized the respective sensory material and produced a correct response even though the subject may not have been aware of having perceived the stimulus. There is thus an inherent ambiguity in non-verbal responses. They can but need not necessarily signal awareness, and this constrains research on NCC in animal experiments. Since consciousness is so difficult to define, an attempt will be made to avoid this term. Instead we shall use the adverb “consciously” and the adjective “conscious” in order to further specify particular brain states or aspects of a perceptual process. In addition, research into the hard problem of consciousness ([Chalmers 2000](#)) confronts the problem of explaining the phase transition from neuronal processes to the qualia of subjective experience, but this will be discussed only briefly at the end of this paper—and there in an enlarged context that transcends neurobiological approaches by also taking social interactions into account.

The state of being aware of something has a number of distinct properties that constrain the underlying neuronal mechanisms. One important feature of this state is unity or relatedness: Contents of which one is aware are experienced as simultaneously present and related to each other. Because of the distributed organization of brain processes, mechanisms supporting phenomenal awareness must therefore be able to bind together computational results obtained in multiple specialized and widely distributed processing areas. Another feature of awareness is that the contents that one is aware of change continuously but are bound together in time, appearing as a seamless flow that is coherent in space and time. Finally, subjects are only aware of a small fraction of on-going cognitive operations. Still, even signals of which subjects are not aware are often readily processed and impact behaviour ([Dehaene et al. 1998](#); [van Gaal et al. 2008](#)). Thus there must be gating mechanism that determines which signals are processed consciously, which are processed and control be-

haviour but remain unconscious, and which are excluded from processing altogether. Therefore, the identification of NCC requires a clear delineation between subconscious and conscious processes and an analysis of the mechanisms that gate access to awareness.

4.2 Conscious versus subconscious processing

As mentioned above, an enormous amount of knowledge is stored in the specific architectures of the brain, but we are not aware of most of these “given” heuristics, assumptions, and concepts. These routines determine the outcome of cognitive processes, which often have access to conscious recollection while themselves remaining hidden in the unconscious. We cannot move these implicit hypotheses and rules to the workspace of consciousness by focusing our attention on them, as is possible with most sensory signals and contents stored, for example, in “declarative memory”—the memory in which is inscribed what has been consciously experienced. Excluded from conscious experience are also certain sensory signals—such as those elicited, for example, by pheromones, which are processed by special olfactory subsystems—or the many signals from within the body—such as messages about blood pressures, sugar levels, and so on. It cannot be emphasized enough, however, that signals that are permanently excluded from conscious processing, as well as the facultatively-excluded signals from non-attended sensory stimuli, still have a strong impact on behaviour. Moreover, by influencing attentional mechanisms they can determine which of the stored memories or sensory signals will be transferred to the level of conscious processing. A hungry predator will search for traces of prey rather than mating partners, and so on.

One reason for the gated access of cognitive material to the level of awareness appears to be the limited capacity of the workspace of consciousness. Whether these limitations are due to the inability to attend to large numbers of items simultaneously, or whether they result from the restricted capacity of working memory, or even both, is subject to intense scientific investiga-

tion. The capacity of working memory is limited to about four to seven different items. The phenomenon of “change blindness”, which is the inability to detect local changes in two images presented in quick succession, demonstrates impressively our inability to attend to and consciously process all features of an image simultaneously. Because of these capacity constraints, conscious processing is in essence serial. Items are scrutinized and compared serially and therefore conscious processing is slow. Complex visual scenes are scanned serially and much of what we believe that we perceive simultaneously is actually reconstructed from memory. Which of the many signals finally reach the level of conscious awareness and can then be recalled depends on whether they are attended to, and this in turn is controlled either by external cues, such as the saliency of a stimulus, or by internal motifs, many of which we may actually not be aware of. And then it may occur that even an attentive, conscious search for content stored in declarative memory fails to raise it to the level of awareness. We are all familiar with the temporary inability to remember an episode or a name and have witnessed how a persisting subconscious search process suddenly lifts the content into the workspace of consciousness. It appears that we are not capable of controlling, at all times, which contents enter consciousness.

The differences between conscious and subconscious processes are further emphasized by evidence that the rules governing conscious deliberations and decisions most likely differ from those of subconscious processes. The former are based mainly on rational, logical, and syntactic rules, and the search for solutions is essentially based on serial computations. Arguments and facts are scrutinized one by one, and possible outcomes investigated. This strategy is suitable if variables are well defined, if sufficient time is available, if problems have a structure amenable to analytical treatment, and if precise solutions are required.

Subconscious mechanisms, by contrast, seem to rely more heavily on parallel processing, whereby a large number of variables enter into competition with one another. Then, a “winner takes all” algorithm leads to the sta-

bilization of the activity pattern that is the most likely, given the initial conditions and the heuristics derived either from inborn routines or from past experience. The domains of subconscious processing are situations requiring very fast responses or conditions where large numbers of underdetermined variables have to be considered simultaneously, and weighed against variables that have no or only limited access to conscious processing—such as the wealth of implicit knowledge and heuristics, vague feelings, hidden motives, or drives. The outcome of such subconscious processes manifests itself either in immediate behavioural responses or in what is called “gut feelings”. And it is often not possible to indicate with rational argument why exactly one has responded in such a way and why one feels that something is wrong or right. In experimental settings one can even demonstrate that the rational arguments given for or against a particular response do not correspond to the “real” causes. For the solution of complex problems with numerous entangled variables it often turns out that the subconscious processes lead to better solutions than conscious deliberations—and this is thought to be because of the wealth of heuristics exploitable by subconscious processing. Given the large amount of information and implicit knowledge to which consciousness has no or only sporadic access, and given the crucial importance of subconscious heuristics for decision-making and guidance of behaviour, first identifying the structure of a problem and then deciding whether one should rely on conscious deliberations or listen to the voices of the subconscious appears to be a well adapted strategy.

However, because the two systems operate according to different principles, the solutions to a particular problem may not always agree. Most of the decisions that get us through daily life rely on subconscious processing and follow well-adapted heuristics. If these decision processes do not lead to immediate action, they may still influence subsequent behaviour by manifesting themselves as what we call “gut feelings”. One has no conscious recollection of the reasons that lead to these feelings, but one clearly experiences the reactions of one’s

autonomous nervous system when the results of subconscious processes are in conflict with the outcome of conscious deliberations. In such situations one tends to say: “I decided according to all the rational arguments that I was aware of and took the best decision I could think of, but it somehow feels wrong.” The opposite situation is also possible, “I did what *felt* right to me, but if I think about it, it is absolutely crazy and irrational”. It is only when the two decision systems converge on the same solution one feels good, satisfied, and to some extent “free”.

After this brief excursion into the phenomenology of conscious and subconscious processes, intended to convey some connotations of consciousness, some of the most popular hypotheses about the constitution of consciousness in the brain will be reviewed.

4.3 Some competing hypotheses about the NCC

One class of theories focuses on the philosophical implications of the hard problem of consciousness without attempting to provide detailed descriptions of putative neuronal mechanisms (Searle 1997; Metzinger 2000; Dennett 1992; Chalmers 2000). Solutions to the hard problem have also been sought through transcending current concepts of neuronal processes and incorporating theories borrowed from other scientific disciplines. The most prominent of these approaches assumes that phenomena unravelled by quantum physics also play a role in neuronal processes, and that they might be able to account for the emergence of consciousness from material interactions in the brain (Hameroff 2006; Penrose 1994). None of the predictions of these theories are at present amenable to experimental verification, because there is no evidence that quantum phenomena such as entanglement, superposition and collapse of wave functions, etc., play a role at the macroscopic level of neuronal network functions. Quantum effects do of course exist at the level of molecular and submolecular interactions, but it appears highly unlikely that they are relevant for the macroscopic functions of neurons responsible for information processing. Thus quantum

theories of consciousness attempt to explain one poorly understood phenomenon with still unexplored and unproven mechanisms, and will therefore not be discussed further here.

Another class of theories pursues more modest goals and attempts to examine neuronal mechanisms potentially capable of supporting awareness of cognitive contents. Their aim is to define the neuronal mechanisms supporting the unitary character of awareness, its coherence in space and time, and the control of states that distinguish between conscious and unconscious processing (for review of relevant experimental findings see [Melloni & Singer 2011](#); [Aru et al. 2012a](#)).

The most intuitively plausible solution for the unity of awareness is convergence of the results obtained in distributed processing areas to a singular structure at the top of the processing hierarchy. Theories derived from this intuition predict the activation of specific cortical areas when subjects are aware of stimuli. Consequently, these regions should remain inactive during unconscious processing of the same material. Likewise, lesions of these putative areas should abolish the ability to become aware of perceptual objects. So far, a region with such universal “observer functions” has not been identified, and this option is considered theoretically implausible by some ([Dennett 1992](#)). There is also little—if any—experimental evidence for such a scenario. If brain lesions abolish the functions of sensory areas or regions involved in the recall of memories, patients lose the ability to consciously experience the respective sensory contents or memories, but the ability to process other material consciously remains unaffected. Moreover, behavioural and brain imaging studies have shown that unconscious processing engages very much the same areas as conscious processing, including the frontal and prefrontal cortices ([Lau & Passingham 2007](#); [van Gaal et al. 2008](#)). Thus there is no compelling evidence for specific areas supporting conscious processing. There are prominent examples of the selective elimination from conscious perception of those aspects of the stimulus material that are processed in specific regions without affecting awareness of other con-

tents, such as syndromes of agnosia and blindsight ([Cowey & Stoerig 1991](#)), which result from selective lesions of sensory subsystems.

There are, however, systems and pathways in the brain whose destruction abolishes all conscious experience—but these cannot be considered to be the NCC. Rather, these systems adjust the narrow dynamic range within which the brain has to be kept in order to be operational and to perform the computations that ultimately give rise to awareness. These systems are addressed as modulatory systems; they originate mainly in deep structures of the brain and control global brain states via widely-diverging ascending projections.

Another class of theories favours the notion that the mechanisms supporting awareness of stimulation material are distributed and do not require anatomical convergence ([Rodriguez et al. 1999](#); [Metzinger 2000](#); [Varela et al. 2001](#)). [Baars \(1997\)](#) and [Dehaene et al. \(2006\)](#) propose that there is a workspace of consciousness whose neuronal correlate is a widely distributed network of neurons located in the superficial layers of the cortical mantle. As mentioned above, these neurons are reciprocally coupled through a dense network of cortico-cortical connections that have features of small-world networks. The proposal is that subjects become aware of signals if these are sufficiently salient to ignite coordinated activity within this workspace of consciousness. This is assumed to be the case for signals that either have high saliency because of the high physical energy of the stimuli or those that are made salient due to attentional selection.

Yet another, related proposal is that subjects become aware of contents, irrespective of whether they are triggered by sensory events or recalled by imagery from stored memories, if the distributed neurons coding these contents are organized into assemblies characterized by coherent, temporally-structured activity patterns. In this case, the critical state variable distinguishing conscious from non-conscious processing would be the spatial extent and the precision of coherence of temporally-structured neuronal responses ([Rodriguez et al. 1999](#); [Metzinger 2000](#); [Varela et al. 2001](#)).

In what follows, evidence will be reviewed in support of the latter hypothesis. However, before discussing this evidence we should briefly recall the reasons why temporal coherence should matter in neuronal processing.

4.4 The formation of functional networks by temporal coordination

Because of the small-world architecture of the cortical connectome, any neuron can communicate with any other neuron either directly or via just a few interposed nodes. Thus, efficient and highly flexible mechanisms are required, which permit selective routing of signals and assure that only the neurons that need to interact in order to accomplish a particular task effectively communicate with one another. Evidence from multisite invasive recordings and from non-invasive registration of global activity patterns with magneto-encephalography or functional magnetic resonance imaging indeed indicates that functional sub-networks are configured “on the fly” on the backbone of fixed anatomical connections in a task- and goal-dependent way. One mechanism that can accomplish such fast and selective association of neurons and gate neuronal interaction is the temporal coordination of oscillatory activity (Gray et al. 1989; Fries 2005). Since the discovery (Gray & Singer 1989) that spatially-distributed neurons in the primary visual cortex tend to engage in oscillatory responses in the beta and gamma frequency band when activated by appropriately configured contours, and that these oscillatory responses can synchronize over large distances within and across cortical areas and even hemispheres, numerous studies have confirmed that oscillations and their synchronization in different frequency bands are an ubiquitous phenomenon in the mammalian brain. The pace-makers of these oscillations are reciprocal interactions in local networks of inhibitory and excitatory neurons. The long-distance synchronization of this oscillatory activity appears to be achieved by several mechanisms operating in parallel: Long-range excitatory cortico-cortical connections, long-range inhibitory projections, and pathways ascending from nuclei in the thal-

amus and the basal forebrain (for a review of these see Uhlhaas et al. 2009). When neurons engage in oscillatory activity, they pass through alternating cycles of high and low excitability. At the peak of an oscillation cycle neurons are depolarized, highly susceptible to excitatory input, and capable of emitting action potentials. In the subsequent trough of the cycle, the membrane potential is hyperpolarized and membrane conductance is high because of strong GABAergic inhibition generated by the rhythmically-active inhibitory interneurons. During this phase, neurons are less susceptible to excitatory inputs, because excitatory postsynaptic potentials (EPSPs) are shunted and because the membrane potential is far from the threshold. Hence, neurons are unlikely to respond to presynaptic excitatory drive.

These periodic modulations of excitability can be exploited in order to gate communication among neurons. By adjusting oscillation frequency and phases of coupled neuronal populations, communication among those neurons can either be facilitated or blocked. To form a functional network of distributed neurons it suffices to coordinate their oscillatory activity in such a way that signals emitted by neurons of this network impinge on other members of the network at times when these are highly susceptible to input. One way to achieve this is to entrain the neurons that should be bound into a functional network to engage in oscillations of the same frequency, to synchronize these oscillations, and to adjust the phases such that neurons that ought to be able to communicate can communicate.

Evidence from multi-site recordings indicate that neurons are indeed bound together into sometimes widespread functional networks through synchronization of their oscillatory activity in a task-dependent way (Salazar et al. 2012; Buschman et al. 2012). This supports the hypothesis (Gray et al. 1989; Singer 1999; Fries 2005) that synchronization of oscillatory neuronal activity is a versatile mechanism for the temporary association of distributed neurons and the binding of their responses into functionally coherent assemblies—which as a whole represent a particular cognitive content. Such a dy-

dynamic binding mechanism appears to be an economical and highly flexible strategy for coping with the representations of a virtually unlimited variety of feature constellations characterizing perceptual objects. Taking the unified nature of conscious experience and the virtually infinite diversity of possible contents that can be represented, the formation of distributed representations, through response synchronization, offers itself as a mechanism that allows for the encoding of ever-changing constellations of contents in a unifying format.

Synchronization is also ideally suited to contribute to the selection of contents for access to consciousness. It enhances the saliency of signals by concentrating spike discharges into a narrow temporal window. This increases the coincidence of excitatory postsynaptic potentials (EPSPs) in target cells that receive input from synchronized cell groups. Because coincident EPSPs summate much more effectively than temporally dispersed EPSPs, synchronized inputs are particularly effective in driving postsynaptic target cells. It is thus not unexpected that entrainment of neuronal populations in synchronized gamma oscillation is used for attention-dependent selection of input configurations (Fries et al. 2001b; Fries 2009).

4.5 A prediction relating long-range synchronisation to consciousness

If activation patterns that subjects can become aware of are indeed characterized by globally coherent states of those cortical regions that process the contents actually appearing as unified, we expect these states of awareness to be associated with large-scale synchronization of neuronal activity. Candidate frequency bands are gamma and beta oscillations, as these have been shown to serve the temporal coordination of cortical networks. By contrast, if subjects are not aware of the presented stimulus material, processing should remain confined to smaller sub-networks, which operate in relative isolation and are not integrated into globally coherent states. In this case one should observe only local synchronization of more circumscribed neuronal populations (see Varela et al. 2001).

Finally, adjustments of oscillation frequency and phases fulfil the requirement that assemblies representing consciously processed contents need to be reconfigured at an extremely fast rate. The contents of which subjects are aware can apparently change at a rapid pace, at least four times a second, if one considers that this is the frequency with which the direction of gaze changes during the scanning of natural scenes. Thus, assemblies representing contents that are consciously perceived must be reconfigurable at similarly fast timescales. Evidence suggests that cortical networks operate in a regime of self-organized criticality close to the edge of chaos (Shew et al. 2009). Dynamical systems operating in this range can undergo very rapid state changes, which are characterized by shifts in oscillation frequencies, synchronization, and phase.

4.6 Methodological caveats in the search for the NCC

As discussed previously (Aru et al. 2012a) experiments designed to identify the neuronal correlates of consciousness are often fraught with ambiguities. The most frequently used strategy for the identification of NCC is contrastive analysis. One creates perceptual conditions in which targets are consciously perceived in only a subset of trials, while making sure that physical conditions are kept as constant as possible. This strategy implies that detection tasks have been designed, which operate close to the perceptual threshold. This can be achieved by reducing the physical energy of the stimuli or by masking them. While subjects are engaged in such detection tasks, neuronal responses are measured and then trials are sorted depending on whether the subjects did or did not perceive the stimulus. By subtracting the average responses obtained in the two conditions from one another, those neuronal responses that occur only in the condition of successful detection can be isolated, and these are then commonly interpreted as the neuronal correlate of conscious perception. This seemingly simple approach is not without ambiguity. Thus, noise fluctuations in afferent pathways are likely to lead to signi-

ficant differences in the available sensory evidence, especially because experiments are performed at the perceptual threshold. Therefore, those aspects of neuronal responses that truly reflect NCC may be contaminated by signals resulting from noise fluctuations at processing stages preceding those actually mediating awareness. In addition, once subjects have become aware of stimuli, there are a number of subsequent processing steps that need not necessarily be linked to NCC. These comprise the covert verbalization of stimulus material, the engagement of working memory, the transfer of information into declarative memory, and perhaps also the preparation of covert motor responses. The distinction between these various confounding factors is difficult because all the processes are intimately related to each other. A detailed discussion of this problem is given in [Aru et al. \(2012a\)](#). One distinguishing feature could be the latency of the electrographic signatures of these various processing steps. Noise-dependent fluctuations in sensory evidence should be manifested early on; responses related to NCC proper should have some intermediate latency; and the consequences of having become aware of a stimulus should have the longest latencies. In order to use these latencies as distinguishing criteria, it is of course required that we estimate the precise latency at which the mechanisms leading to conscious perception are likely to be engaged. Assuming that the time required to prepare and execute simple motor responses is generally constant, the interval of interest can be constrained and has been proposed as somewhere between 180 and a few hundred milliseconds, depending on the sensory modality and the difficulty of the detection task. Attempts to use latency criteria for the elimination of confounds is of course restricted to electroencephalographic and magnetoencephalographic data, and cannot be applied to results obtained with functional magnetic resonance imaging because of the limited temporal resolution of this technique.

Another option for the reduction of confounds is to combine manipulations that influence the conscious perception of a stimulus through different mechanisms and to compare

the electrographic responses between conditions ([Aru et al. 2012b](#)). We applied this strategy in investigations of patients with subdurally implanted recording electrodes located over the visual cortex. In one set of trials the visibility of stimuli, in this case faces, was manipulated by changing the sensory evidence of the stimulus material. In another set of trials visibility of the same stimuli was influenced by allowing the subjects to familiarize themselves with some of the stimuli. This also facilitated detectability, but now because of an expectancy-driven top-down process. The reasoning behind this was that neuronal responses reflecting NCC proper should be the same irrespective of whether stimuli are consciously perceived because of enhanced sensory evidence or because of top-down facilitation. As electrographic signature of interest we analyzed the neuronal activity in the gamma band. In a previous study ([Fisch et al. 2009](#)) had shown that category-specific gamma band responses in the visual cortex correlate with conscious perception. Conscious recognition leads to a phasic enhancement of the gamma-band response, thus supporting the notion that conscious perception arises locally within sensory cortices—which is in line with previous conclusions ([Zeki 2001](#); [Malach 2007](#)). In our study we found that the performance and the reports of the subject were clearly modulated both by changing sensory evidence *and* by prior knowledge of the stimuli, as expected; but the gamma-band responses solely reflected the sensory evidence. This suggests that the differential activation of specific areas of the visual cortex, in our case mainly the fusiform face area, reflect processes that prepare access to conscious perception but are not its substrate proper.

Another frequently used paradigm in the search for NCC is interocular rivalry. If the two eyes are presented with stimuli that cannot be fused into one coherent percept, subjects perceive only one of the two stimuli at a time, and these percepts alternate. There are various ways to label the stimuli presented to the two eyes, to trace the responses related to their processing in the brain, and then to see which brain structures have to get involved in order to

support conscious perception. Again, these studies have led to inconclusive results. Some claim that suppression of signals corresponding to the non-perceived stimulus occurs only at very high levels of visual processing, such as, for example, the temporal cortex, which is the highest stage of the ventral processing stream. The conclusion of these studies is that activation of this particular cortical network is a necessary prerequisite for conscious processing (Logothetis et al. 1996; Silver & Logothetis 2004). Others, by contrast, found diverging activity patterns already existing at the level of the thalamus and the primary visual cortex (Haynes et al. 2005; Fries et al. 1997). Recent correlations between the dynamics characterizing binocular rivalry and anatomical features of the primary visual cortex and the commissures linking the primary visual cortices of the two hemispheres provide compelling evidence that the rivalry phenomenon is based on processes occurring within V1 (Genc et al. 2014). However, none of these studies allows us to unambiguously locate the processes that lead to conscious perception. They only contribute to the identification of the earliest levels of processing, in which changes are detectable that correlate with conscious perception.

Interesting and of potential relevance for interpretations given in the next subsection is the observation that the access of sensory signals to conscious processing does not seem to be gated by modulation of the neurons' discharge rate, but rather by changes of the synchronization of their activity—at least in the early stages of processing. What matters is the degree of synchronicity of oscillatory activity in the gamma frequency range. Signals conveyed by well-synchronized neuronal assemblies have access to conscious processing, while signals conveyed by similarly active but purely synchronized neurons fail to do so (Fries et al. 2001c). Of interest in this context is the observation that stimuli access conscious perception more easily if they are attended to, and that attention enhances synchronization of neuronal responses in the gamma frequency band in early visual areas (Fries et al. 2001b). Again, however, this local increase in synchrony is likely to simply enhance

the saliency of the neuronal responses, facilitating their propagation across the cortical networks, and cannot per se be considered a neuronal correlate of consciousness.

4.7 Evidence relating long-range synchronization and consciousness

The results described in what follows were obtained in a study where we presented words that could be perceived in some trials and not in others (by adjusting the luminance of masking stimuli), and simultaneously performed electroencephalographic (EEG) recordings (Melloni et al. 2007). Several measures were analyzed: Time-resolved power changes of local signals; the precision of phase synchronization across recording sites, and over a wide frequency range; and event-related potentials (ERPs). A brief burst of long-distance synchronization in the gamma-frequency range between occipital, parietal, and frontal sensors was the first event that distinguished seen from unseen words at about 180ms poststimulus. In contrast, local synchronization was similar between conditions. Interestingly, after this transient period of synchronization, several other measures differed between seen and unseen words: We observed an increase in amplitude of the P300 ERP for visible words, which most likely corresponds to the transfer of information to working memory. In addition, during the interval period—in which visible words had to be maintained in memory—we observed increases in frontal theta oscillations. Theta oscillations have been related to maintenance of items in short-term memory (Jensen & Tesche 2002; Schack et al. 2005).

To test whether the increase in long-distance synchronization relates to awareness or depth of processing, we further manipulated the depth of processing of invisible words. It has previously been shown that invisible words can be processed up to the semantic and motor level (Dehaene et al. 1998). In a subliminal semantic priming experiment we briefly presented words (which were thus invisible) that were either semantically related or unrelated, alongside a second, visible word on which subjects had to carry out a semantic classification task. Invis-

ible words were processed up to semantic levels, as revealed by modulation of the reaction times, depending on the congruency between invisible and visible words: congruent pairs exhibited shorter reaction times than incongruent ones. We observed increases in power in the gamma frequency range for unseen but processed words. For visible words we additionally observed increases in long-distance synchronization in the gamma-frequency range (Melloni & Rodriguez 2007). Thus, local processing of stimuli is reflected in increases in gamma power, whereas long-distance synchronization seems to be related to awareness of stimuli. This suggests that conscious processing requires a particular dynamical state of the cortical network. The large-scale synchronization that we observed in our study could reflect the transfer of contents into awareness and/or their maintenance. We favour the first possibility, given the transient nature of the effect, and argue that the subsequent theta oscillations might support maintenance. It is conceivable that short periods of long-distance synchronization in the gamma band reflect the update of new contents, while the slower pace of theta oscillations might relate to sustained integration and maintenance of local results in the workspace of consciousness. The interplay between these two frequency bands might underlie the phenomenon of continuous but ever-changing conscious experience (see below).

More recently, Gaillard et al. (2009) have revisited the processing of visible and invisible words. In intracranial recordings in epileptic patients, they observed that invisible words elicited activity in multiple cortical areas, which quickly vanished after 300 ms. In contrast, visible words elicited sustained voltage changes, increases in power in the gamma band, as well as long-distance synchronization in the beta band and long-range Granger causality. In contrast to our study, Gaillard et al. observed a rather late (300–500 ms) rise of long-distance synchronization. However, it is important to note that in the study undertaken by Gaillard et al., phase-synchrony was analyzed for the most part over electrodes within a given cortical area, or at most between hemispheres. It is thus conceiv-

able that earlier synchronization events passed undetected because of incomplete electrode coverage. Despite these restrictions, this study provides one of the most compelling pieces of evidence for a relation between long-distance synchronization and consciousness.

Some results of the experiments on binocular rivalry point in the same direction. Several studies have shown increased synchronization and phase locking of oscillatory responses to the stimulus that was consciously perceived, and controlled behaviour (Cosmelli et al. 2004; Doesburg et al. 2005; Fries et al. 1997; Srinivasan et al. 1999). Cosmelli et al. (2004) extend the findings obtained in human subjects by performing source-reconstruction and analyzing phase-synchrony in source space. These authors observed that perceptual dominance was accompanied by co-activation of occipital and frontal regions, including the anterior cingulate and medial frontal areas. Recently, Doesburg et al. (2009) have provided evidence for a relation between perceptual switches in binocular rivalry and theta- and gamma-band synchronization. Perceptual switches were related to increments in long-distance synchronization in the gamma band between several cortical areas (frontal and parietal) that repeated at the rate of theta oscillations. The authors suggest that transient gamma-band synchronization supports discrete moments of perceptual experience, while theta oscillations structure their succession in time, pacing the formation and dissolution of distributed neuronal assemblies. Thus, long-range gamma synchronization locked to on-going theta oscillations could serve to structure the flow of conscious experience, allowing for changes in content every few hundred milliseconds. Further research is required to clarify the exact relation between the two frequency bands, their respective role in the generation of percepts, and the pacing of changes in perception.

Another paradigm in consciousness research exploits the attentional blink phenomenon. When two stimuli are presented at short intervals among a set of distractors, subjects usually detect the first (S1) but miss the second (S2) when it is presented 200–500 ms after S1. Increases in long-range neuronal synchrony in the beta and gamma frequency ranges have been observed when the S2

is successfully detected (Gross et al. 2004; Nakatani et al. 2005). Furthermore, Gross et al. (2004) observed that successful detection of both S1 and S2 was related to increased long-distance synchronization in the beta range to both stimuli, and this enhanced synchrony was accompanied by higher de-synchronization in the inter-stimulus interval. Thus, de-synchronization might have facilitated the segregation of the two targets, allowing for identification of the second stimulus (also see Rodriguez et al. 1999). Source analysis revealed, as in the case of binocular rivalry, dynamical coordination between frontal, parietal, and temporal regions for detected targets (Gross et al. 2004).

In summary, studies of masking, binocular rivalry, and the attentional blink support the involvement of long-range synchronization in conscious perception. Recent investigations have suggested further that a nesting of different frequencies, in particular of theta and gamma oscillations, could play a role in pacing the flow of consciousness. Furthermore, the study of Gross et al. (2004) suggests that de-synchronization could serve to segregate representations when stimuli follow at short intervals. These results are encouraging and should motivate further search for relations between oscillatory activity in different frequency bands and consciousness, whereby attention should be focused not only on the formation of dynamically-configured networks but also on their dissolution.

4.8 Conclusions on putative mechanisms supporting consciousness

Of the numerous proposals on NCC, those favouring temporal coherence as the mechanism that integrates widely distributed processes appear to be the least controversial. They account best for the apparent discrepancy between the unity of conscious experience and the distributed organization of the brain, because they allow for the dynamic integration of information generated in parallel by spatially segregated processing modules. Large-scale synchronization of oscillatory activity has been identified as a candidate mechanism for the flexible coupling of widely-distributed neuron populations, and hence as a likely NCC. This variable has the advantage that it can be meas-

ured relatively directly in humans who are able to give detailed descriptions about their conscious experience. However, oscillations and synchrony seem to be mechanisms that are as intimately and inseparably related to neuronal processing in general as the modulation of neuronal discharge rates. Thus, without further specification these phenomena cannot stand up as NCC—at least when we disregard the triviality that consciousness does not exist without them. We propose that the spatial scale and the precision and stability of neuronal synchrony might be taken as more specific indicators of whether the communication of information in the brain is accompanied by conscious experience or not. In this framework, conscious experience arises only if information that is widely distributed within or across subsystems is not only processed and passed on to executive structures but also bound together into a coherent, all-encompassing, non-local but distributed meta-representation. This interpretation is compatible with views that take consciousness to be the result of the dynamic interplay of brain subsystems; one that allows for a rapid and highly-flexible integration of information provided by the numerous distributed subsystems that operate in parallel. This view resembles a proposal from Sherrington, formulated in his book *The Integrative Action of the Nervous System* (Sherrington 1906): “[p]ure conjunction in time without necessarily cerebral conjunction in space lies at the root of the solution of the problem of the unity of mind.” The additive value of conscious processing would then be the possibility of establishing in a unified data format ever-changing relations between cognitive contents—irrespective of whether they are read out from memory or induced by sensory signals, and irrespective of the sensory modality providing the signals. By virtue of this dynamic definition of novel relations, non-local meta-representations of specific constellations could be established that have the status of cognitive objects. Just as with any other distributed representation of contents, these could then be stored as distributed engrams by use-dependent modification of synaptic connections, and thus influence future behaviour. Thus, conscious processing would differ from non-conscious processing because it allows for the versatile binding

of the previously unbound into higher-order representations. And if so, “conscious” processing would be functionally relevant and not merely an epiphenomenon. Further arguments supporting the functional role of conscious processing are presented in the following section.

5 Arguments supporting an adaptive value of conscious processing

5.1 Evolutionary considerations

Given the continuity of evolution and the gradual increase in complexity of brains that reached a (perhaps preliminary) maximum in human beings, it appears likely that the ability to be aware of cognitive contents, of one’s own cognitive operations, and finally of oneself as an intentional agent, is not an all-or-none phenomenon but an ability that gradually emerged as we evolved. Paleoanthropological evidence supports this hypothesis by documenting correlations between increasing brain volume and increasingly refined artefacts that reflect gradual increases in cognitive abilities. Not much direct data are available on the evolution of the human brain, because our immediate ancestors are all extinct. Thus, we have to rely on evidence of comparative studies with brains of other species. In less evolved brains the paths from sensory to executive areas of the cerebral cortex are short. These relatively short sensory-motor loops are of course much more elaborate than simple reflex loops, because signals are processed extensively and transmission is made conditional on input from other systems, on past experience, and on context. As evolution proceeds and brains become more and more complex, one observes the addition of new cortical areas. A distinctive feature of this evolutionary process is the way in which these new areas are embedded in already-existing networks. These newly-added areas no longer communicate directly with the periphery, neither on the executive nor on the receptive side (see [figure 3](#)). Instead they receive their input exclusively from the phylogenetically older areas, and also distribute their computational results solely to other cortical areas and not to effector systems. This process is iterative, with more and more areas constantly

added that communicate only with other higher areas. A neuron located in these more recent areas is connected exclusively with other partners in the cerebral cortex. Evidence indicates that all cortical areas, including older and more recent ones, operate according to the same basic principles, because they share the same intrinsic organization. These purely anatomical considerations suggest that the evolutionary-recent areas process the results of the older areas similarly to how they process signals from the outer world. This iteration of “cognitive” processes across several hierarchical levels could thus generate representations of representations, i.e., meta-representations. Information that has already been processed by the already existing areas becomes the object of yet another cortical computation, i.e., of a secondary cognitive operation. These iterative operations can even be circular, because all these areas are interconnected reciprocally. Thus, higher-order areas feed back to lower, order areas and can have their results reprocessed. In principle this recursive process should permit the generation of meta-representations of increasingly higher order. In other words, highly evolved brains can apply their cognitive functions not only to the outer world but also to processes that occur within the brain. Brain processes can therefore become the object of the brain’s own cognitive operations. This could be the basis of phenomenal awareness, the awareness of perceiving, to create a protocol for what one perceives, and in the case of human beings to create symbols for the perceived and for internal states and to communicate them to others. Animals probably share some of these abilities, because their brains are organized in a very similar way.

Curiously, the ability to be aware of the results of cognitive operations provides no clue concerning the computational processes underlying these cognitive functions. We have no insight into the neuronal processes that bring about cognition. We are aware only of the results—just as we are aware of an action without being able to tell which neuronal processes in the motor centers of our brains caused this action. This fact is at the origin of most discrepancies between our intuitions and neurobiological evidence concerning the nature of agency, the experience of Free Will, and

the ontological status of qualia and consciousness (see [final](#) paragraph).

These evolutionary considerations may provide some plausible explanation of the emergence of higher cognitive functions—including consciousness—but they do not suffice to counter the argument that the emergence of consciousness is an epiphenomenon without adaptive value. To address this problem, one must identify functions that can only be realized by conscious processing.

Emergence of phenomenal awareness

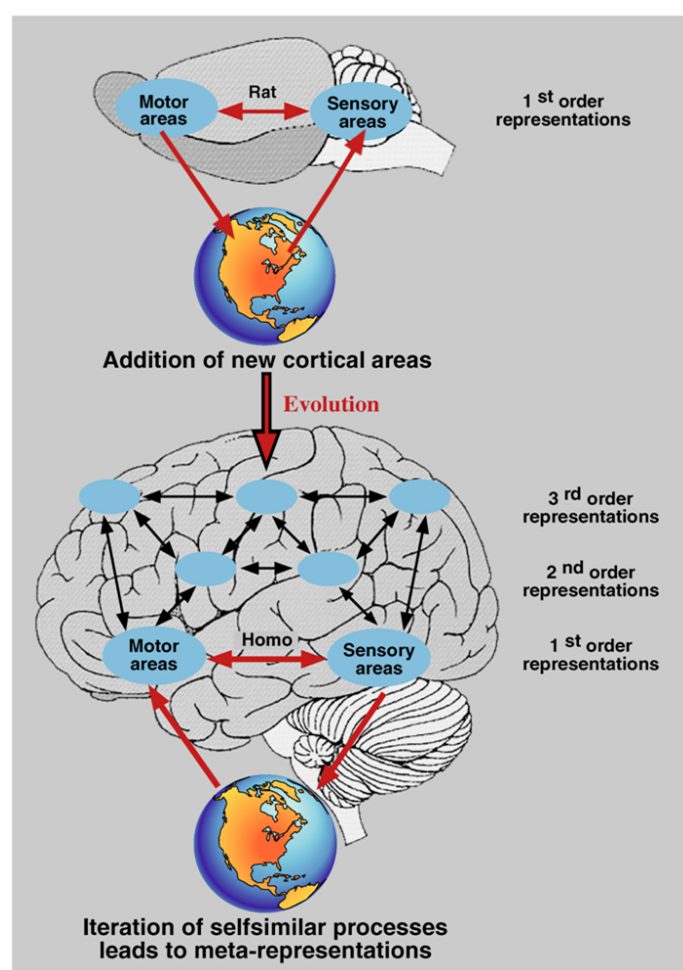

Figure 3: The evolution of complex brains is characterized by a massive increase of cortical areas. This renders responses to stimuli increasingly dependent on intracerebral processes and permits generation of meta-representations.

5.2 Functional considerations

Is the ability to be conscious of one's own cognitive operations a fitness factor? And would it

make any difference if brains lacked this ability? The philosopher of mind, David Chalmers, once stated: “[n]o, that wouldn’t make a difference. It’s just an epiphenomenon and if we wouldn’t have it we would do as well because the underlying brain processes would be the same and get us through life without us having to be aware of them.” I tend to disagree with this view for a number of reasons. The common denominator, however, is that there is something very special about the nature of conscious processes, and that this uniqueness does indeed constitute a fitness factor—in particular with respect to the ability to develop symbolic communication systems, a theory of mind, differentiated social systems, and, ultimately, culture.

As has been argued above, conscious processing allows for abstraction and symbolic representations due to its versatile binding of virtually all results of lower order cognitive operations in a unified representational space, capitalizing on the lingua franca (the homogeneous data format) of communication among cortical areas. This permits implementation of very effective—we call them rational—strategies for deliberation and decision-making that differ from and complement those of subconscious processes. The question then remains whether the results of these special processes affect brain functions and thereby affect behaviour.

It is difficult to see how the outcome of a conscious deliberation, that is, of an argument-based decision, could not affect future behaviour. A conscious decision leaves traces in declarative memory and so must the consequences of this decision. These traces are inscribed as modifications of the functional architecture of the respective networks. If a decision has averse or beneficial consequences, the experience of these consequences will also alter network properties, and the novel activation patterns generated by the modified networks will enter as a novel argument, or as a change of goal in future deliberations. Eventually, the newly-set goal, which initially had the status of a conscious rational argument, may change its status and become a habit that henceforth influences behaviour without having to appear as an explicit argument in consciousness. It can become one of

the variables that act at a subconscious level. One then refuses another glass of wine not because one recapitulates all the rational arguments against alcohol consumption but simply because it does not feel right to drink too much.

Another, and probably the most important fitness factor of conscious processing is its capacity to support complex societies in cultural evolution. This suggests that there may have been a co-evolution of mechanisms supporting the emergence of conscious behaviour on the one hand and the formation of societies on the other, with the two developments mutually supporting each other.

Cognitive objects represented in consciousness are always bound together into a coherent experience. Whether this is also the case for subconsciously-processed contents is obviously difficult to ascertain, but the following argument suggests that subconscious processing may be less integrated, more modular, and confined to subsystems. We subconsciously orient towards salient stimuli irrespective of their modality, visual, auditory, or tactile qualities, and these stimuli may be analyzed in the subconscious with respect to their behavioural relevance and thus give rise to action. However, if several stimuli compete for processing, usually the most salient will win. Compared to orienting responses, which are guided by conscious processing, there seems to be little evaluation of the embedding context here. Stimuli are processed more independently than they would have been had they entered consciousness, been bound together, and formed a unified coherent percept.

In order to achieve this integration and to relate the signals from various sensory systems to one another at the semantic level, the signals have to be encoded in a sufficiently abstract and homogenous format. As mentioned above, when describing brain evolution, the substrate for this integration of signals preprocessed by segregated sensory systems may be the evolutionary-recent cortical areas. By virtue of integrating and comparing signals from different modalities, it becomes possible to detect the similar in the seemingly different, and hence to extract invariant properties and to arrive at ab-

stract descriptions. Thus the addition of the novel, so called “association areas” of the neo-cortex prepared the ground not only for a more unified, polymodal representation of cognitive contents but also for symbolic coding—which in turn is a prerequisite for the development of a symbolic language system and abstract reasoning. Thus one might consider consciousness, or the state of conscious processing, as a state where distributed computational results can be bound together into a coherent whole, establishing multiple, simultaneous relations between the various distributed items. This obviously allows for a more abstract, more symbolic, and more comprehensive description of conditions. By itself this is an advanced processing strategy, whose adaptive or fitness value is obvious. However, if this unified, condensed, and abstract information can be routed to a versatile communication system, as seems to be the case with contents that are processed consciously, the evolution of cooperating societies will be greatly facilitated. Not only will it be easier to communicate what one has perceived if the numerous signals from different sensory modalities have already been bound together into coherent wholes but, because of the reflexive nature of awareness, it will also be easier to convey information about one’s internal state. This, in turn, is an important prerequisite for society-building, because it nurtures trust in and predictability of the respective other. A condensed report of the actual contents of one’s conscious state and its storage in the episodic memory of the listener is an effective and parsimonious way to couple brains with one another, to share experiences, and to foster cooperation. This interaction will modify the brains of the communicating partners and thereby act on their behaviour. In a sense this is an example of mental or top-down causation. The results of an information-processing strategy that can only be realized in the workspace of consciousness are stored in declarative memory—in this case not only in a single brain but in those of communicating partners—and henceforth influence future cognitive processes and behaviour. These considerations suggest that it might be useful and perhaps even necessary in consciousness re-

search to consider the phenomena ascribed to consciousness not solely in the context of cognitive functions of individual brains but in the larger context of social interactions. In the following section this strategy is applied in an attempt to approach the “hard problem of consciousness”.

6 Consciousness as a social phenomenon

6.1 Is the hard problem resolvable by considering cultural rather than only biological evolution?

The hard problem in consciousness research, the epistemic difficulty of devising bridging theories between subjective phenomena available only from a first-person perspective and the underlying neuronal mechanisms analyzable only from the third-person perspective, may not be resolvable by considering only the cognitive abilities of isolated brains. In addition, more recent concepts of embodiment that consider the embedding of the nervous system in a body endowed with receptor and effector organs may not suffice. Rather, it may be necessary to reconsider the problem in the context of social phenomena or social realities that emerged during cultural evolution. Through social interactions, realities have been created that can readily be experienced as such but that transcend the reality that existed before humans added cultural to biological evolution. These new realities have the quality of relations. They are immaterial, not tangible, not visible, not directly accessible to our senses—and yet they are perceived as real, as mental objects that humans can agree upon, that can become the object of shared attention and influence behaviour—just like the equally immaterial contents of belief systems.

What seems to pose the epistemic—the hard—problem in philosophy of mind is not so much that we perceive and have feelings and emotions, since we readily grant such abilities to animals and seem to be quite successful in identifying the neuronal substrate of these functions. The real problem appears to be our meta-awareness of having these abilities. It is

this meta-awareness that has mental connotations that appear to be so difficult to relate to neuronal processes. However, this meta-awareness—which is so intimately related with what we address when we talk about consciousness—in all likelihood does not emerge naturally from the functions of an individual brain. Rather, it appears to be the consequence of experiences resulting from social interactions, just as is the case for the experience of individuality, agency, and intentionality. These are attributions that have their roots in interpersonal interactions and are probably appropriated by individuals while they are developing their self-image. Without being embedded in a differentiated socio-cultural environment, without the option of mirroring oneself in the perception of others, without reflexive interactions between persons endowed with a theory of mind, and without an exchange of reports about inner states, formulated in a symbolic language-system, we would probably not be aware of our being conscious.

Thus the phenomenon that we call consciousness has the ontological status of a social reality. It is a construct, just like all the other social realities that our cultures have brought into this world. However, this construct differs in an important respect from other social realities, such as norms, beliefs, and values, in that it is an attribution that we ascribe to ourselves. We learn from social interactions that we are endowed with the ability to be aware of being aware. After conceptualization of this novel experience it becomes an integral part of our self-image—we exchange reports on this shared experience and coin words for it.

Regarded in this way the “hard problem” may not be as hard as it seems. Analyzing individual brains will not unravel the “correlates” of the many semantic connotations of what we term consciousness, because they emerged from a reflexive interaction *between individuals*. But we should eventually be able to identify the neuronal mechanisms underlying the cognitive abilities that allowed human beings to create the socio-cultural environment that itself allowed for the experience of being conscious.

7 Culture-specific, epigenetic shaping of brains and the concept of tolerance

As suggested in the preceding section, inclusion of the social dimension may be indispensable for defining the status of higher cognitive functions such as consciousness. But it may also help us to bridge gaps between naturalistic approaches and first-person phenomenology. Thus, surprisingly, the joint consideration of neurobiological evidence on the dependence of perception of priors and of the epigenetic modification of priors by socio-cultural factors has normative consequences for concepts of tolerance.

Human beings have a similar genetic outfit, and therefore usually agree on what they perceive—in particular when priors suffice for the interpretation of the perceived, which had been acquired during evolution in a pre-cultural world. However, this may not apply to the perception of social realities. Humans raised in different cultures may perceive social realities quite differently. Cultures may differ radically with respect to social conditions, concepts of fairness, justice, and aesthetics, as well as moral criteria, and so on. Thus, epigenetically-installed priors are likely to exhibit considerable culture-specific differences. As a consequence, the ways in which the world is perceived will also differ. Another culture specific variable likely to influence perception is the attachment to caretakers. The nature of early bonding experiences determines whether the world appears as hostile or as peaceful and secure, and whether others can be approached with confidence or scepticism. The ways in which these early attachments to other members are secured differ dramatically among different cultures and, as such, so will the perception of signals that inspire confidence or aggression. Since these early-acquired priors are implicit, and since one is unaware that perceptions are influenced by these early imprinting processes, human beings take what they perceive as “real” and see no reason to question its validity. Thus, two persons raised differently, while observing the same social situation may perceive it in completely different ways. They may come to grossly diverging ethical or moral judgments,

unable to convince the other through argument that he or she is wrong, because both experience what they experience as reality—just as one experiences optical illusions as real. The problem is that, in the case of the perception of social realities, there are no “objective” measuring devices. There are different perceptions, and there is no right or wrong. This has far-reaching consequences for our concepts of tolerance. Solving such problems with majority votes is clearly not a fair solution. Assuming that one’s own position is correct and granting others the right to retain their “wrong” perceptions—so long as they do not disturb the peace—is humiliating and denies them respect. Still, this is often considered to be tolerant behaviour. What should be done, instead, is to grant everybody that her or his perceptions are correct and to postulate that this attitude be reciprocated. Only if this agreement on reciprocity is violated have the dissenting parties the right to exert sanctions.

8 Concluding remarks

In this paper only a selection of concepts currently under discussion in the field of cognitive neuroscience could be reviewed in any detail. The selection criterion was their relatedness to consciousness studies and to some extent their relevance for epistemic issues. This led to the neglect of important domains, some of which have equally relevant bearing on philosophical questions and societal issues. Thus, no consideration was given to developmental aspects that illustrate the close correlation between the maturation of particular brain structures and the emergence of specific cognitive and social functions. Equally neglected were research on executive functions and associated concepts on intentionality, agency, mental causation, and free will. No attempts were made to explore the vast field devoted to the analysis of genuinely “psychic” phenomena, such as memories, emotions, motivations, drives, and aesthetic judgement. Finally, a much more elaborate review would have been required of research that analyzes brain functions that can only be assessed in conditions where brains interact with one an-

other in a social context. This is the domain of the relatively recent field of social neuroscience, which studies phenomena such as confidence, greed, generosity, fairness, parasitism, altruism, compassion, and collective beliefs. This would have been particularly important in view of the attempt made at the end of this contribution to demystify some of the immaterial connotations of consciousness, in particular by redefining some aspects of consciousness as belonging to the domain of social realities, i.e., as a relational construct emerging from reciprocal interactions among brains endowed with the cognitive abilities of humans. The research agendas of these “neglected” fields are the same as those of the domains reviewed above. They all attempt to identify the neuronal mechanisms that are responsible for a particular cognitive or executive function, such that it becomes less and less important whether a cognitive phenomenon is accessible from the third-person perspective—such as the orienting behaviour of an animal—or whether it is accessible only from the first-person perspective—such as in the famous example of the hue of a rose or an emotion. As long as these qualia can be operationalized and rated on some subjective scale, they are amenable to neuroscientific inquiry. In case of the social neurosciences, the agenda is somewhat enlarged, since the objects of studies are phenomena that emerge from social interactions and exist as relational constructs only in interpersonal space. Here the objects of study are the mechanisms underlying the cognitive functions enabling the respective social interactions such as, for example, the ability to have a theory of mind and the mechanisms that permit individual brains to represent social realities. This agenda of the neurosciences may appear bold and, as the reader will have noticed, while we already know much about the component functions in our brains, we are still very far from understanding the distributive processes underlying higher cognitive and executive functions. In fact, the more data that sophisticated analytical tools allow us to accumulate, the more we are humbled by the mind-boggling and no longer intuitively graspable complexity of the brain’s dynamics. However, at least the author and probably the ma-

jority of his colleagues believe that there should be no principle epistemological barriers to the pursuit of this research agenda. The greatest problem in the near future will be that the description of the dynamics of neuronal processes underlying higher functions will take the form of abstract mathematical formulations that lack any resemblance to the experienced or observed result of these functions.

Nevertheless, the naturalistic stance taken by the neurosciences has already in these early days provided some insights, whose relevance goes beyond the research agenda of the neurosciences proper. The data on mechanisms mediating perception discussed at the beginning of this chapter clearly support constructivism and thereby provide arguments for or against particular philosophical positions. Likewise, these epistemic considerations, to the author’s surprise, led to normative consequences in the context of notions of tolerance. Similar normative consequences arise from data on mechanisms responsible for decision-making, motivation, response suppression, conscious versus subconscious processing, personality traits, and so on, as these insights are all consequential for the definition of behavioural norms and the distinction between normal and pathological behaviour. It is foreseeable, therefore, that the neurosciences will become more involved in philosophical, normative, ethical, and societal issues. This should be beneficial for all parties involved, since the communication process is likely to lead to bridging theories, new terms for mutual understanding, and amendments to discipline-specific idiosyncrasies.

It's Not Just About the Contents: Searching for a Neural Correlate of a State of Consciousness

A Commentary on Wolf Singer

Valdas Noreika

Global gamma band synchronisation is perhaps the most extensively studied candidate for a Neural Correlate of Consciousness (NCC). Yet despite numerous studies confirming its association with consciousness, it seems to be neither sufficient nor necessary for the presence of all subjective experiences. Analysis of gamma synchronisation studies suggests that it is a correlate of the initial binding of expected, attended, task-dependent contents of consciousness, whereas task-irrelevant contents do not seem to require gamma synchronisation. While discovery of such a content-related NCC is a remarkable achievement for the neurophysiological research of consciousness, it does not fully explain some of the fundamental structural properties of consciousness, namely the temporal and spatial integration of all available experiences into a coherent stream of consciousness. As an alternative, instead of focusing solely on the selected contents of consciousness, the neural mechanisms of the fundamental properties of consciousness could be studied by contrasting states of (un)consciousness. Recent research into the states of consciousness suggests that, for instance, informational complexity is a highly sensitive predictor of the presence of consciousness, possibly reflecting background structural properties of the unity of subjective experiences. As a limiting factor, though, such a state-related NCC does not seem to reflect the phenomenal diversity of the contents of consciousness. Arguably, these limitations could be overcome by devising experimental setups that would simultaneously probe the neural correlates of the contents and the state of consciousness.

Contents of consciousness | Gamma band synchronisation | Neural correlate of consciousness (NCC) | Neural correlates of consciousness | Nonconscious states | Spatial binding | State of consciousness | Stream of consciousness | Temporal binding | Unconscious states

1 Introduction

Even though the search for the neural correlates of consciousness is still an unresolved challenge of astonishing complexity (Crick 1994), the continuous efforts to crack the mystery are not expended in vain. Each year brings an increasing number of cognitive neuroscientific studies that reveal yet another piece of the puzzle of the neural basis of subjective experience. However,

it often seems that individual findings are too diverse and sparse to form a coherent picture. In addition to the fundamental problem of the binding of conscious experiences (Singer 2001), we increasingly face the problem of how to bind the findings of consciousness-related studies. The present target paper by Prof. Wolf Singer serves such a discovery-binding function, bring-

ing very diverse findings into a unified picture of how the neural correlates with the subjective.

In an impressively erudite manner, [Singer \(this collection\)](#) integrates a very broad range of anatomical and functional findings of the organisational principles of the brain, concluding that the high-level cognitive functions are supported by densely coupled, recurrent neural networks, interacting under the principles of non-linear dynamics. In the proposed framework, perception is treated as an active process, whose self-organisation is initially determined by genes, and later modified by post-natal development, learning, social interactions, and cultural influences. At the neuronal networks level, high-level integration and communication are achieved through synchronisation of oscillations in different electroencephalography (EEG) frequency bands, the most notable of which is gamma band ($>30\text{Hz}$) synchronisation ([Engel et al. 1999](#)). Given that an association between the widespread gamma-band synchronisation and conscious awareness is found in rather different experimental paradigms, such as visual masking ([Melloni et al. 2007](#)), binocular rivalry ([Doeburg et al. 2009](#)), and attentional blink ([Gross et al. 2004](#)), gamma synchronisation is often regarded as the main NCC ([Singer this collection](#)).

Yet the candidature of gamma synchronisation as the correlate of consciousness is challenged by some findings from research into the behavioural states of the brain. If gamma-range activity correlates with consciousness, it should diminish when consciousness ceases. Contrary to this, gamma band activity seems to increase rather than decrease in response to certain general anaesthetics, such as ketamine ([Steriade et al. 1996](#)). Furthermore, gamma synchronisation seems to be absent in some conscious brain states. For instance, it has been reported that large-scale neocortical gamma-band coherence is virtually absent during rapid eye movement (REM) sleep in cats ([Castro et al. 2013](#)), a state typically marked by the most intense dreaming in humans ([Hobson et al. 2000](#)) as well as in felids ([Jouvet 1979](#)).

The target paper briefly mentions neural mechanisms supporting overall brain states, but

dismisses them as modulatory systems that are too general to be considered the NCC ([Singer this collection](#)). In the following, I will argue that the relation between the neural mechanisms of the contents and states of consciousness is not straightforward, and that the puzzle of the neural mechanisms of consciousness cannot be completed without studying the neural mechanisms of conscious states.

2 Contents vs. states of consciousness

An important distinction in consciousness research is that between the contents and a state of consciousness ([Chalmers 2000](#)). The concept of the contents of consciousness refers to individual subjective experiences that occur in phenomenal consciousness, such as reading a word or hearing birdsong, and as such they are sometimes referred to as the phenomenal contents of consciousness ([Revonsuo 2006](#)). Most neural experiments on consciousness, especially in the dominant field of visual awareness studies, are concerned with the neural basis of such specific contents of consciousness, i.e., they select one or two subjective experiences within an overall stream of consciousness. In this type of experiment, participants may be presented with stimuli close to their perceptual threshold ([Del Cul et al. 2009](#)) or they may be instructed to observe ambiguous stimuli that may lead to perception of several alternating contents of consciousness ([Kornmeier & Bach 2012](#)). The brain responses are then contrasted between trials that differ in awareness of these stimuli. Notably, while participants in such experiments report being unaware of some contents of consciousness, they still maintain awareness of other experiences: such as seeing the edges of a computer screen, hearing the background noise of the Magnetic Resonance Imaging (MRI) scanner, or letting their thoughts wander away from the experimental task. Typically, such experiences are ignored as task-irrelevant, and consequently the so-called “unaware” or “unconscious” trials still bear very rich phenomenology.

Contrary to the selective contents of consciousness, the concept of the state of consciousness refers to an overall pattern of subjective

psychological functioning that includes the totality of phenomenal contents of consciousness (Rosenthal 1986; Tart 1972). In addition to the relaxed waking state of consciousness in a healthy volunteer, which could be also regarded as a *baseline state*, altered, unconscious, and non-conscious states can be distinguished. In *altered states of consciousness*, such as dreaming or Lysergic Acid Diethylamide (LSD) psychomodulation, subjective experiences may undergo various perceptual and cognitive alterations, the neural basis of which can be studied by contrasting them with a baseline state of consciousness, e.g., by comparing brain activity before and after hallucinogen intake (Carhart-Harris et al. 2012). Given that there is no widely accepted definition and criterion for an altered state of consciousness (Móro 2010; Revonsuo et al. 2009), a rather common approach is to describe, classify, and study states that are traditionally called *altered*, avoiding a single definition that would grasp the core of all altered states of consciousness (Vaitl et al. 2005).

Contrary to the baseline and altered states of consciousness, unconscious states are deprived of subjective experiences, but they may still maintain the potential to become conscious. For instance, an unconscious state of dreamless sleep may turn into a conscious sleep once a sleeping participant begins to dream (for an alternative interpretation of dreamless sleep, see Thompson this collection). Finally, non-conscious states are those completely deprived of a capacity to support phenomenal consciousness, such as an irreversible coma. In clinical neuroscience, the most extensively studied contrast between a pathological altered state of consciousness and an unconscious or non-conscious state is a comparison between minimally conscious and vegetative state patients (Sitt et al. 2014). When states of (un)consciousness are contrasted, neural representations of specific experiences are typically ignored, making it difficult or even impossible to assess the phenomenal specificity of findings, e.g., if participants were aware of particular external stimuli or what internally generated experiences they had. Nevertheless, research into these states may re-

veal neural patterns that are common to all subjective experiences without individuating them.

It is possible that these two lines of research may eventually reveal rather different, if not independent, NCC systems: a neural correlate of the state of consciousness and a neural correlate of the contents of consciousness (Chalmers 2000). If these exist, any neuroscientific program of consciousness research would be incomplete without searching for a state NCC. Furthermore, even if a separate state NCC did not exist, there is currently no evidence for this, and thus NCC research is incomplete if it does not investigate this possibility. This view is often dismissed on the basis that some of the most plausible candidates for a state NCC, such as the brainstem reticular formation (Merker 2007; Parvizi & Damasio 2001), are rather low-level neural systems, whereas converging evidence shows that consciousness is a cortical process (Singer this collection). Furthermore, it could be argued that a conscious state may be nothing more than the sum of individual experiences, in which case revealing the NCC of specific contents would automatically explain the state NCC. Yet a brief analysis of the fundamental structural properties of consciousness—see the following section—shows that the necessary and sufficient NCC cannot be revealed by an exclusive focus on the contents of consciousness. Notably, the arguments presented in this commentary will be confined to the biological nature of human and animal consciousness, and as such they are not applicable to the problem of machine, extraterrestrial, or silicon-brain consciousness.

3 Unity as the fundamental property of the stream of consciousness

Given that subjective experiences can accompany almost any sensory, cognitive, emotional, and behavioural function of the brain, phenomenal consciousness turns out to be an extremely complex and multi-dimensional process. Nevertheless, introspection shows that despite its qualitative richness, phenomenal consciousness appears to us as a unified and coherent model

of the external and internal environment (Bayne 2010; Revonsuo 2006). The continuity in the diversity of subjective experiences is famously referred to as the stream of consciousness (James 1890). This metaphor points to the unification of experiences occurring at different points in time and space, which is achieved through temporal and spatial binding.

At the cognitive level of description, temporal binding, i.e., integration of subjective experiences over time, is realised through the perception of simultaneity, duration, and successiveness (Kiverstein 2010; Pöppel 1997). Perception of simultaneity may integrate several experiences, e.g., seeing a cat and hearing a birdsong in the park, as occurring at the same time. Perception of duration of selected experiences may extend them in time, e.g., the birdsong might seem to last for a certain period of time. Finally, perception of successiveness may signal the end of one temporally-extended experience, and the beginning of another one, e.g., as the cat reaches the bush and the birdsong ceases, we may notice a cone under the bush. Notably, the change does not typically involve all experiences, and as we are aware of some changing contents, some other experiences continue to endure in time, e.g., we still see the same bush. In addition to the timing-specific functions, temporal binding seems to depend on the iconic memory that contains the just-experienced contents of consciousness, and on the anticipation of subsequent ones, forming the temporally-extended phenomenal experience of now, sometimes referred to as the *specious present* (Dainton 2006; Kelly 1882). Temporal extension of subjective experiences have a simple, yet very important and often overlooked implication for NCC research: if there is a single neural mechanism generating phenomenal consciousness, it should be present as long as we are conscious of at least one single content. Given that our experiences do not cease at a fixed rate, i.e., some are shorter and some longer, and that the change does not happen abruptly for all experiences at once, the NCC should persist for the duration of the stream of consciousness. Thus, a temporary-confined correlate of awareness, such as a negative Event Related Potential (ERP)

waveform briefly peaking at about 200ms from the onset of visual stimuli (Railo et al. 2011), cannot be a sufficient correlate of consciousness, as awareness of visual contents lasts for a much longer period of time.

Spatial binding, i.e., integration of subjective experiences in space, is realised through several complimentary processes, through which each subjective experience occupies a specific location in relation to other experiences, which is sometimes referred to as *location binding* (Treisman 1996). In the baseline state of consciousness, one experience never occurs in isolation from other experiences; and when some experiences cease, we do not experience emptiness, because other experiences fill in their place. Furthermore, individual experiences are spatially integrated not only with respect to each other in phenomenally external space, but also with respect to the common egocentric reference point (Revonsuo 2006). The reference point is typically located in the phenomenal head or chest, and all other experiences are realised in the space as taking a certain distance and angle from this point. While typical phenomenological analysis of 3D space considers visual and auditory experiences, it has recently been shown that emotions and feelings are also experienced as taking certain location with respect to our body parts (Nummenmaa et al. 2014). For instance, anger is overrepresented in hands and arms when compared to sadness. Arguably, even thoughts, which are often regarded as non-spatial entities (Clarke 1995), are usually experienced as occurring within the head rather than somewhere else. Given that the whole phenomenal space is bound together, the NCC should also represent awareness of the whole space rather than, for instance, selected regions on the computer screen. That is, a promising candidate for an NCC should not cease when a specific experience vanishes as long as the spatial and temporal unity of the stream of consciousness is maintained.

So, what type of neural processes should we be looking for when searching for the NCC? If we take the unity of consciousness seriously, we should be looking for a neural process that steadily represents the whole phenomenal space,

and sustains its activity over periods of time longer than the existence of a single experience. Arguably, the neural correlate of unified consciousness cannot be discovered by studying and contrasting only isolated contents of consciousness, as the unity of spatiotemporal interactions simply cannot be derived from solitary experiences. Thus, while continuing to search for the neural mechanisms of the contents of consciousness, the NCC program should be extended by carrying out systematic contrasts between unconscious, baseline, and/or altered states, which would consider the whole stream of consciousness. A possible objection to this proposal is that the unity of consciousness is not fundamental in the strong form of fundamentalism, i.e., some forms of consciousness may still exist despite the possible disintegration of its unity, which seems to happen in states like schizophrenia, sleep onset, or a minimally conscious state. For instance, the stream of consciousness may occasionally undergo a sudden, unpredictable alteration in terms of inner speech and imagery (Noreika et al. 2014). Nevertheless, if one aims to explain the neural mechanisms of normal waking consciousness, the unity thesis, with its NCC-related implications, cannot be ignored. With these considerations in mind, let us examine now the proposal of global gamma synchronisation as the NCC (Singer this collection).

4 Is gamma band synchrony sufficient and necessary for consciousness?

A sufficient and necessary NCC (or perhaps a set of NCCs) should be generic enough to cover all conscious contents and states, and should also be specific enough to cover only conscious contents and states. Notably, gamma synchronisation does not meet the second specificity requirement, as it can be associated with almost any perceptual and cognitive function that depends on the formation of temporary associations of distributed neuronal networks. Among numerous cases, increased gamma-band synchronisation is found to be associated with such tasks as perceptual learning (Gruber et al. 2002), self-paced movement (Pfurtscheller et al.

2003), mental rotation (Bhattacharya et al. 2001), viewing of unpleasant stimuli (Martini et al. 2012), deductive reasoning (Zhang et al. 2014), auditory attention control (Doesburg et al. 2012), face integration (Kottlow et al. 2012), and memory encoding and retrieval (Osipova et al. 2006). Gamma-band synchronisation thus seems to be a generic process that contributes to complex cortical computations involved in most if not all of the higher cognitive functions (Fries 2009).

Singer (this collection) proposes that only global, widespread synchronisation of gamma oscillations is associated with consciousness, whereas local, spatially-restricted synchronisation is not necessarily related to conscious awareness. This might refute studies reporting local synchrony; however, some of the above-mentioned studies found increased global gamma-synchrony when observing unpleasant stimuli (Martini et al. 2012) or carrying out a mental rotation task (Bhattacharya et al. 2001). It could be argued, though, that gamma synchronisation is present in these experiments as a correlate of task-related subjective experiences, such as awareness of memory retrieval. In fact, even though most of these studies did not even mention consciousness or awareness, their participants were not unconscious, and gamma synchronisation could have been associated with the task-dependent subjective experiences. Yet, this line of reasoning is challenged by the simple fact that participants remained conscious in all contrast conditions throughout the experiments. Why would consciousness-related gamma synchronisation increase in some, but not other conditions? This leads us to the question of what exactly gamma synchrony correlates with in studies that specifically manipulate awareness? Let us take a closer look at two key studies, also examined by Singer (this collection).

Melloni et al. (2007) presented pairs of words and asked participants to report on whether both words were the same. Visibility of the first word was manipulated by adjusting the luminance level of the forward and backward masks, which rendered the words visible only in some of the trials. Global gamma-phase synchronisation between the fronto-centro-parietal

electrodes was observed within the 40–182ms time-window after the presentation of the first word only in visible trials, which coincides with the time when conscious perception of the words is expected to emerge. In the latter time-windows, visible words were marked by more localised gamma synchronisation, higher P300 amplitude, and higher amplitude of frontal theta oscillations than invisible words. These findings confirmed that gamma synchronisation is a correlate of visual-semantic awareness, and showed that other electrophysiological processes may also correlate with consciousness.

Doesburg et al. (2009) investigated the role of gamma-phase synchronisation in conscious awareness using a binocular rivalry paradigm, in which a different visual stimulus is presented to each eye. Instead of seeing both stimuli at the same time, people report perceiving only one of the stimuli that continues switching in time. An increase in the gamma-band synchronisation over the fronto-parietal regions was observed in the 600–540ms and 280–220ms time-windows before responses indicating a perceptual switch. Assuming that reaction time was about 250ms, the synchronisation increase coincided with a new percept reaching awareness. Interestingly, gamma synchronisation oscillated at the theta rhythm, suggesting a cross-frequency interaction.

In both of these experiments (Doesburg et al. 2009; Melloni et al. 2007), gamma synchrony peaked around the time when participants began experiencing a new content of consciousness, following which Singer (this collection) draws the well-justified conclusion that gamma synchronisation is associated with a transfer of the new contents into awareness. Given that increased synchronisation may reflect the neural and phenomenal binding required for the fundamental unity of consciousness to emerge, it seems to be an ideal candidate for the NCC. Yet the duration of increased synchronisation is relatively brief and seems to last a much shorter time than the awareness of stimuli. For instance, P300 distinguished visible and invisible words around 300ms post-stimulus, whereas gamma-band synchronisation became local during this time-window (Melloni et al. 2007). Such

brevity of synchronisation suggests that it is involved only in the initial binding of the new contents of consciousness, while a further maintenance of these contents is supported by other neural mechanisms, in particular theta oscillations (Doesburg et al. 2009; Melloni et al. 2007; Singer this collection). Given that the global gamma synchronisation correlates with a spatially- and temporally-local change in the stream of consciousness, its association with an overall unity of consciousness is uncertain and, at least currently, it cannot be accounted as the only or even as the major NCC. If it were such, it would not cease as long as the participant were aware of a particular content of consciousness.

Furthermore, gamma synchrony does not seem to increase in response to each of the new contents of consciousness. In each trial, Melloni et al. (2007) presented a series of stimuli, including a fixation cross, a masking noise, a target word, and a blank screen. Each of these stimuli should have entered consciousness, and even when the target word was unreadable, participants should have perceived something, e.g., an unreadable word, incoherent letters, or a flashing mask. However, the global gamma synchronisation increased only in response to perceived visible words, suggesting that it is a correlate of the initial binding of a selected, expected, attended, coherent, task-relevant content of consciousness. As such, in addition to the lack of specificity, gamma synchrony does not seem to be generic enough to cover all the different contents of consciousness, even within the paradigmatic visual modality. Thus, it seems that the global gamma synchronisation is neither necessary nor sufficient for consciousness to emerge, as subjective experiences may exist without gamma synchronisation, and even when synchronisation is involved in the generation of awareness, other neural processes are needed to maintain its presence.

As discussed in the previous section, the unity of consciousness emerges from the interaction of all experiences available at a time. Gamma synchronisation cannot account for the unity of a state of consciousness, simply because it is involved only in the generation of new task-

dependent contents, and it does not seem to bind these contents within the broader stream of consciousness. Arguably, instead of focusing on selected stimuli, we may be able to detect the neural correlates of the unity of consciousness by contrasting states of consciousness with unconsciousness, since such a contrast would consider the whole stream of phenomenal contents, including their structural unity.

5 Studying the contents and states of consciousness: Let's probe them together!

Perhaps the most powerful contrast conditions for studying a neural correlate of a state of consciousness are comparisons between wakefulness and slow-wave sleep, as well as between wakefulness and general anaesthesia. A notable clinical contrast is a comparison between vegetative state and minimally conscious state patients. Furthermore, new paradigms are available for comparing consciousness with unconsciousness when an overall physiological state of the brain is controlled, such as dreamless vs. dreamful non-rapid eye movement sleep (NREM sleep; Noreika et al. 2009; Siclari et al. 2013) or dreamless vs. dreamful anaesthesia (Noreika et al. 2011). Let us examine several exemplary papers that compare an overall stream of consciousness with its absence.

Sitt et al. (2014) studied auditory-evoked potentials and endogenous fluctuations of EEG signal in 75 vegetative state and 68 minimally-conscious patients. None of the studied evoked potentials (P1, MMN, P3a, P3b, CNV) were able to discriminate patient groups, indicating that task-dependent brain activity does not necessarily distinguish between conscious and unconscious states. Contrary to this, analyses of spontaneous EEG activity showed that unconscious patients had higher power of delta and lower power of theta and alpha oscillations, especially over parietal regions. Furthermore, EEG complexity indices derived from the compressibility of a sequence of data points indicated increased signal complexity over the parietal region in the minimally conscious patients compared to the vegetative state patients. Fi-

nally, electrode connectivity measures derived from information theory showed that vegetative-state patients had lower-weighted symbolic mutual information exchange in the range of theta and alpha oscillations than minimally-conscious patients. Interestingly, none of the EEG connectivity measures in the gamma frequency range, including phase lag index and imaginary coherence, could discriminate patient groups, coinciding with other independent observations that gamma synchrony does not necessarily differentiate conscious and unconscious states of the brain (Castro et al. 2013; Steriade et al. 1996).

The finding that the presence of consciousness is associated with an overall complexity of EEG signal and the magnitude of inter-electrode information exchange (Sitt et al. 2014) seems to support the information integration theory of consciousness (Tononi 2012), which predicts that consciousness depends on information complexity and integration in the system. The information integration theory was recently tested by Casali et al. (2013), who investigated the consciousness-related electrodynamics of the distributed cortical networks in a wide range of states of (un)consciousness, including wakefulness (eyes open, eyes closed), sleep (NREM sleep, REM sleep), anaesthesia (midazolam, xenon, propofol), and consciousness disorders (locked-in syndrome, minimally conscious state, patients who have emerged from a minimally conscious state, vegetative state). In a series of experiments, transcranial magnetic stimulation (TMS) pulses were delivered to different cortical sites, which perturbed spontaneous EEG activity (Massimini et al. 2010). Complexity of such TMS-induced EEG perturbations was then calculated, and its index successfully differentiated the states of consciousness and unconsciousness, even at the individual participant's level (Casali et al. 2013). As predicted, the presence of consciousness was associated with a higher level of information complexity.

In these and similar experiments, the contents of consciousness were not systematically manipulated or controlled for, and conscious participants probably underwent very diverse experiences. Consequently, the reported EEG

complexity as the NCC seems to be independent of particular phenomenal contents, and it may reflect some structural aspects of the whole stream of unified subjective experiences. It seems that phenomenal consciousness emerges in a state of the brain that is capable of generating the required level of information complexity and integration. As requested in the previous sections, such an NCC is stable in time and does not depend on an experience isolated from the rest of phenomenal space. Arguably, this type of study tackles the fundamental unity of consciousness much more directly than typical paradigms for studying the selected contents of consciousness. However, approaching one side of the bridge takes us further away from the other side, and the better characterization we have of the neural mechanisms of the state of consciousness, the less we can say about the neural mechanisms of particular contents of consciousness. For instance, the perturbational complexity index can differentiate conscious and unconscious states, but it is extremely insensitive when it comes to distinguishing between different contents of consciousness. For instance, the values of the complexity index did not systematically differ between the “eyes closed” and “eyes open” conditions in the standard waking state (Casali et al. 2013; Noreika 2014). Arguably, any NCC that cannot distinguish between experiences occurring in the “eyes closed” and “eyes open” conditions cannot be fully satisfactory, as the quality of subjective experiences is the core of the scientific problem of consciousness. Yet even though informational complexity does not reflect qualities of phenomenal contents, it is a promising candidate for an NCC of the background properties of consciousness that enable the emergence of subjective experiences and/or necessitate their structural unity.

We are thus left with studies of the contents NCC, such as focusing on the gamma synchrony, and studies of the state NCC, such as focusing on the information complexity. The first group of studies seems to explain the neural binding of concrete selected contents of consciousness, but it does not have a capacity to address the unity of consciousness. The second group seems to capture neural processes

involved in the whole stream of consciousness, but it ignores differentiation or phenomenal diversity of consciousness. Ideally, research into the NCC would combine both of these complementary approaches. Unfortunately, a systematic combination of the contents- and states-focused paradigms is almost never tested in cognitive neuroscientific studies of consciousness.

The combined *contents-states paradigm* would contrast baseline and altered states, or consciousness and unconsciousness, or the transition between the two, while participants carry out experiments that tackle the neural mechanisms of the contents of consciousness. For instance, one could study binocular rivalry while participants lose consciousness in response to an anaesthetic agent. This could, for instance, provide data to investigate how global gamma synchrony as a correlate of the binding and transfer of new contents to awareness depends on or interacts with a changing level of neuronal information complexity. Another promising avenue is research into awareness-related performance in the transition from wakefulness to sleep (Goupil & Bekinschtein 2011). In a recent attempt, Bareham et al. (2014) demonstrated that healthy individuals show neglect-like loss of awareness of the right side of their space in a drowsy state of consciousness. Thus, spatial awareness and unity seem to depend on the state of alertness, as defined by the relative amplitude of theta and alpha oscillations, which confirms that the contents are not wholly independent of the state. That is, despite the external physical stimuli and environment remaining stable, phenomenal contents may appear, disappear, or reorganise depending on the overall state of consciousness. More such studies are expected to be carried out in future, aiming to integrate the content NCC, the state NCC, and altered states of consciousness research programs under one unified framework of the content-state NCC research.

6 Conclusion

Global gamma-band synchronisation, research into which was largely triggered and continues to be advanced by Prof. Wolf Singer, is one of

the most promising NCCs. Synchronisation seems to increase in most cases when a new, task-dependent content of consciousness is formed. Yet a larger number of complications prevents its acceptance as the main NCC, namely: gamma synchronisation does not persist for as long as the contents of consciousness, some of the contents of consciousness emerge without gamma synchronisation being modulated, and, finally, gamma synchronisation may increase in unconscious or unresponsive states of mind. These complications show that gamma-band synchronisation cannot fully account for the existence of a unified stream of consciousness. Given that consciousness is integrated over cognitive time and space, a sufficient and necessary NCC should persist even when some but not all of the experiences cease to exist in time, or change their location. Nevertheless, even though gamma-band synchronisation seems to be neither necessary nor sufficient for all contents of consciousness to arise, it should be regarded as one of the NCCs specifically involved in the binding of new attended experiences. Future research may also develop more accurate characterization of gamma synchronisation, including its spatial scale, precision, and stability (Singer [this collection](#)), and certain forms of synchrony might be necessarily accompanied by consciousness; yet such evidence is not currently available.

Given that gamma synchronisation cannot be the only NCC, research efforts and resources should be distributed to search for the other NCCs, some of which might be responsible for the maintenance of already-bound single contents, and some of which might contribute to the unity of the whole stream of consciousness. Research paradigms should be developed that allow simultaneous manipulation and testing of both the contents and the states of (un)consciousness. Most likely, none of the discovered NCCs alone will be necessary and sufficient for all forms of subjective experiences to exist. How many of the neural correlates will be sufficient for the stream of consciousness to flow, and whether the sufficient ones will also be necessary, remains to be studied in future. For now, an exciting program of NCC research should

continue searching for the new avenues. Among various proposals, such as a focus on how social interactions and culture modulate neural networks supporting phenomenal contents (Singer [this collection](#)), the present one claims that it's not just about the contents, and that a state of consciousness deserves a treatment of its own.

State or content of consciousness?

A Reply to Valdas Noreika

Wolf Singer

An attempt is made to distinguish between brain states required to support consciousness and the neuronal underpinnings of conscious versus non-conscious processing in an awake, attentive brain, respectively. It is argued that brain states supporting consciousness are characterised by high dimensional dynamics exhibiting a high degree of complexity, implying that conscious states are graded. Different mechanisms determine whether signals are processed at the conscious or sub-conscious level. Thus, there is no unique neuronal correlate of consciousness.

1 Introduction

My sincere thanks go to Valdas Noreika for having identified with succinct clarity the weaknesses in our current attempt to identify the neuronal correlates of consciousness (NCC). I would have sincerely appreciated these comments before finalising my manuscript, as they would have forced me to distinguish more clearly between the neuronal underpinnings of the conscious state and the neuronal correlates of conscious versus unconscious processing.

Noreika is absolutely right in pointing out that the search for the mechanisms permitting access to conscious processing falls short of

identifying the NCC proper and, likewise, that the determination of variables required for the maintenance of a conscious state is insufficient if pursued without considering the contents of conscious processing. The mere fact that one can distinguish between the “conscious state” and the conditions required for “conscious processing”, yet also consider both as targets in the search for the NCC, suggests that the explanandum is ill-defined. Presently, both studies devoted to the distinction between conscious and unconscious processing and those investigating the brain states required for conscious pro-

cessing are considered as investigations of the NCC, although they clearly target different neuronal mechanisms. Thus, studies on consciousness are fraught with the problem of a lack of a clear definition of “the” consciousness for which we wish to find a neuronal correlate. Another problem is that we are still far from fully understanding the neuronal mechanisms underlying higher cognitive functions. Behavioural studies suggest, for example, that perception involves probabilistic Bayesian-matching operations in which sensory evidence is compared with stored knowledge about the probability of occurrence and the features of the respective perceptual objects. However, it is entirely unknown where and how the huge amount of priors are stored, how the specific priors can be retrieved on the fly within the few hundreds of milliseconds sufficient for recognition, and how the matching operations are realized in neuronal networks. Thus, at the present stage it is even impossible to precisely define the signatures of neuronal activity that could be considered the result of a perceptual process or as the neuronal representation of a percept.

In the light of these uncertainties, the distinctions between conscious and unconscious processing or between states compatible with conscious and unconscious processing, respectively, appear to be exploited primarily in order to learn more about mechanisms underlying pattern recognition, decision making, and intentionality, rather than serving the search for the neuronal underpinnings of the ill-defined phenomenon that we address as “consciousness”. In contrast to NCC research, these more humble approaches have been quite successful, probably because the explananda are well-defined and can be operationalised.

2 The conscious state

The analysis of the neuronal prerequisites required for the maintenance of consciousness has a long history and has only recently been considered part of consciousness research. The reason for this is that the criteria used for distinctions between conscious and non-conscious states or altered states of consciousness can be

tested in both humans and animals. Examples of these criteria are reactivity to noxious stimuli, the ability to move intentionally, and the ability to accomplish a number of well-defined cognitive tasks, involving attention, short and long term memory, recognition, and decision making. Thus, the plethora of studies performed both on animals and humans on the neuronal mechanisms underlying arousal, attention, wakefulness, sleep, anaesthesia, and coma all contribute to our understanding of the neuronal prerequisites of states permitting conscious processing. Accordingly, it is well-established that brain functions characteristic of the conscious state require that neuronal networks operate in a critical dynamical range. This range is regulated by half a dozen globally-acting modulatory systems that originate in deep and evolutionary ancient brain structures. The adjustable neuronal parameters are essentially the balance between excitatory and inhibitory effects and the time- and length constants of dendritic integration. These adjustments lead to marked modifications of the system’s dynamics. These modulations are reflected by changes in the prevailing frequencies of oscillatory activity, the degree and spatial granularity of synchronisation (also addressed as correlation length), and the propagation of signals across the network.

Classical brain theories have not attributed much attention to the significance of these dynamic variables for processing and assume that loss of consciousness in sleep and anaesthesia is essentially due to reduced excitability and signal transmission. However, in more recent theories, brain dynamics are thought to play a crucial role in information processing. This novel framework provides much more specific explanation of the breakdown of consciousness in sleep, anaesthesia, and coma. These theories posit that oscillations and the concomitant variables, such as synchronisation, phase locking, phase relations, and cross frequency coupling, are relevant for signal selection by attention, binding operations, and the representation of nested semantic relations (for review see [Singer 1999](#); [Buzsáki et al. 2013](#)). In addition, these complex dynamics have been proposed as a substrate for the generation of the high-di-

mensional coding space required for the storage and superposition of priors, the matching of stored information with sensory evidence, and the segregation of patterns for classification (for review see [Singer 2013](#)). The basis of these operations is the transformation of low-dimensional input patterns into high-dimensional dynamic states, in order to perform the necessary computations in this space and to then retransform the results into low-dimensional output signals. The advantages of performing computations in high-dimensional dynamic space are currently explored in the conceptual framework of “reservoir computing” or “liquid state or echo state machines” ([Bertschinger & Natschläger 2004](#); [Buonomano & Maass 2009](#); [Jaeger 2001](#)).

Recent analysis of the properties of recurrent networks, such as those realized in neuronal systems and in particular the cerebral cortex, indicate that such high-dimensional dynamic states can indeed be generated in delay-coupled networks ([Lazar et al. 2009](#); [Buonomano & Maass 2009](#); [Soriano et al. 2013](#); for review see [Singer 2013](#)). In the present context it is important to recall that the dynamics required for such computations can emerge only when the networks are in the appropriate state. The optimal state has been identified as the edge of chaos, slightly below self-organised criticality, the so-called SOC state, because in this state the dimensionality or the complexity of the system are very high. Computationally this range is optimal because it offers a maximum of possible bifurcation points and storage capacity. ([Plenz & Thiagarajan 2007](#)). In this conceptual framework, computational results should consist of substates with reduced dimensionality. Experimental evidence indicates that the high-dimensional resting states are actually reduced by sensory input, imagery, recall of memories, or focused attention. These processes are all associated with enhanced correlation between neuronal responses due to the induction of synchronized high-frequency oscillations—where enhancing correlations reduces dimensionality (for review see [Singer 2013](#)). The notion that SOC states are optimal prerequisites for processing also fits with the robust evidence that states compatible with consciousness are characterized

by “desynchronized” brain activity, i.e., states characterized by uncorrelated activity, such as are typical for wakefulness and arousal. If, and evidence suggests this to be the case (for review see [Singer 1999, 2013](#)), establishment of lower-dimensional synchronous substates, e.g., the formation of transiently-synchronized assemblies of neurons, is an integral part of the computations, then dynamic states characterized by global, large scale synchrony would be inappropriate as background for computations underlying higher cognitive functions.

As outlined in the target paper and above, higher cognitive functions require fine-grained binding operations among semantically-related contents that need to be encoded in ad hoc-formed neuronal assemblies. Such concatenation of multiple assemblies by partial correlations and perhaps also cross-frequency coupling would be impossible in networks that are already highly synchronized to begin with and hence exhibit low complexity and dimensionality. The well-established notion that deep sleep, anaesthesia, and most forms of coma are associated with brain states that exhibit slow oscillations synchronized over considerable distances agrees with this interpretation. In agreement with the prediction that low-dimensional brain states are incompatible with sophisticated processing are also the recent stimulation experiments cited by Noreika. It is to be expected that stimulation of a dynamic system that is in a low-dimensional state and at an overall reduced level of excitability will elicit only a spatially-restricted responses of low complexity—in particular if the stimulus is itself very low-dimensional, as is the case for a TMS pulse.

Considering more recent theories on brain functions, it appears as if the prerequisite or the NCC of a conscious state is a dynamic state that assures a high degree of complexity and high-dimensionality of resting-state dynamics. It is only in this state that the higher cognitive functions can be realized that one expects from a conscious brain.

It should be noted, however, that this operational definition of consciousness makes no inferences about the subjective contents of consciousness or the awareness of particular qualia

of experience. According to this definition, consciousness is simply a brain state that allows animals and humans to accomplish higher cognitive functions that include not only perception but also decision making, planning of actions, generation of procedural and episodic memories, and last but not least intentionality and reasoning. Thus, one would expect consciousness, defined in this way, to be a graded phenomenon. If the state of the brain changes towards reduced complexity and dimensionality, there should be a graded deterioration of functions. Those requiring integration of widely-distributed assemblies should become impeded first, while simple reactions to salient sensory stimuli would persist for much longer. This seems to be in perfect agreement with the gradual deterioration of cognitive functions as the brain state shifts from high levels of alertness to drowsiness and sleep.

3 Conscious versus subconscious processing

As Noreika points out, “consciousness” defined by the status of phenomenal content is something very different from a conscious state, as this connotation of consciousness can only be investigated in human subjects. The reason for this is that the distinguishing criterion is the degree of subjective awareness of a cognitive content, and this variable can only be assessed through verbal report. It is simply not possible to know whether a monkey trained to press a lever to signal that it has recognized a particular pattern has the subjective experience that we equate with conscious perception. The monkey brain has the same mechanisms as humans for the allocation of attention, the selection of objects for perception, and the routing of experiences to the different storage modes (working memory, procedural and episodic memory). Thus it is very likely that monkeys are aware of their perceptions in a similar way to us, and that the distinction between conscious and non-conscious processing holds for them as well—but we have no way of knowing. Conditioned lever presses in response to stimuli do not require conscious perception of the stimuli, just as

stopping at a red light while being engaged in a conversation does not require conscious recollection of having perceived the light. It is for this reason that the criterion for conscious processing is the reportability of the perceived stimulus, and hence this aspect of consciousness can only be studied in humans.

Attempts to identify the differences between the neuronal processes that accompany non-conscious and conscious processing, respectively, are of course interesting in their own right. The expectation is that they will provide answers to the question of why certain processes are reportable and have access to working and episodic memory while others are excluded, or the question of why certain forms of reasoning and decision-making require conscious deliberations while others do not. However, as pointed out so stringently by Noreika, these attempts fall short of identifying the NCC proper, and at best cover some aspects of conscious processing while being fraught with problems. The most difficult problems are related to the distinction between the processes that are essential for subjective awareness and reportability and those that are the consequence of having become aware of something or that simply provide favourable conditions for becoming aware, such as the allocation of attention or the saliency of stimuli. So far the only neuronal signatures distinguishing between reportable and non-reportable processes have been found to be transitory, lasting at most a few hundred milliseconds. Noreika argues rightly that this disqualifies these events as NCCs because the stream of consciousness is continuous and the awareness of contents can persist for quite some time.

4 Conclusion and outlook

We need to be more cautious when using the term NCC and to define precisely, each time we perform a search for underlying neuronal mechanisms, which of the many aspects of “consciousness” we actually intend to investigate. We need to differentiate between processes assuring access to conscious processing, which are expected to be transient, and processes necessary for sustaining the stream of consciousness

that has longer time-constants. And finally, we need to distinguish processes assuring sustained awareness of contents that are most likely related to the transfer of material to short- and long-term memories. If we proceed in this way, subdividing “consciousness” into subfunctions including reportability and defining these as explananda, some of the present problems may dissolve. However, the consequence is that we shall have to give up the search for “the” overarching NCC.

If we pursue this agenda, it is to be expected that correlates will be found for all aspects of consciousness except those associated with the “hard” problem, which appears to be a specific human problem. As I argued in the target paper, searching for the neuronal correlates of qualia in individual brains is unlikely to be successful because the immaterial and therefore somewhat mysterious connotations of qualia are likely to have the status of social realities. What we can achieve, however, is an identification of brain processes that underlie those cognitive functions required for generating social realities. These would be the ability to engage in social interaction, to develop a theory of mind, to find symbolic descriptions of internal states, and to reach consensus on the “reality” of these through communication with others.

To conclude this brief reply to the extremely inspiring commentary on my target paper, I want to express my sincere gratitude to Noreika for having pointed out the critical issues in our research on the NCC. The reply forced me to engage with this research again and helped me substantially in clarifying my own position in the debate.

Dreamless Sleep, the Embodied Mind, and Consciousness

The Relevance of a Classical Indian Debate to Cognitive Science

Evan Thompson

One of the major debates in classical Indian philosophy concerned whether consciousness is present or absent in dreamless sleep. The philosophical schools of Advaita Vedānta and Yoga maintained that consciousness is present in dreamless sleep, whereas the Nyāya school maintained that it is absent. Consideration of this debate, especially the reasoning used by Advaita Vedānta to rebut the Nyāya view, calls into question the standard neuroscientific way of operationally defining consciousness as “that which disappears in dreamless sleep and reappears when we wake up or dream.” The Indian debate also offers new resources for contemporary philosophy of mind. At the same time, findings from cognitive neuroscience have important implications for Indian debates about cognition during sleep, as well as for Indian and Western philosophical discussions of the self and its relationship to the body. Finally, considerations about sleep drawn from the Indian materials suggest that we need a more refined taxonomy of sleep states than that which sleep science currently employs, and that contemplative methods of mind training are relevant for advancing the neurophenomenology of sleep and consciousness.

1 Introduction

Many neuroscientists and philosophers today think of dreamless sleep (see [glossary](#)) as a blackout state in which consciousness is entirely absent. Indeed, they often appeal to this apparent fact in order to define consciousness:

Everybody knows what consciousness is: it is what vanishes every night when we fall into a dreamless sleep and reappears when we wake up or when we dream. (Tononi 2008, p. 216)

Consciousness consists of inner, qualitative, subjective states and processes of sentience and awareness. Consciousness, so defined, begins when we wake in the morning from a dreamless sleep and continues until we fall asleep again, die, go into a coma, or otherwise become “unconscious”. (Searle 2000, p. 559)

I will call the view that consciousness vanishes or ceases in dreamless sleep the *default view* of the relationship between consciousness and dreamless sleep. One aim of this paper is to argue that the

default view is not as obvious or strong as it is often thought to be. Another aim is to propose that we need a finer taxonomy of sleep states than that which sleep science currently employs, in order to allow for the possibility of states or phases of dreamless sleep in which consciousness is present. There are forceful reasons, if not decisive ones, for describing certain kinds of dreamless sleep as modes of consciousness rather than as the absence of consciousness. These reasons derive from the debate about dreamless sleep between the Advaita Vedānta and Nyāya schools of Indian philosophy (see [glossary](#)). Examining this debate in the light of cognitive science raises important conceptual and methodological issues for the cognitive neuroscience of consciousness. Furthermore, considerations about sleep drawn from Indian philosophy suggest new experimental questions and protocols for the cognitive neuroscience of sleep and consciousness. By weaving together these different traditions—Western cognitive science and Indian philosophy—I hope to show the value of cross-cultural philosophy of mind for cognitive science.

2 The experience of waking up

Before turning to the Indian debate, I would like to motivate the examination of dreamless sleep and consciousness by considering the experience of waking up from deep sleep and what this experience reveals about our experience of the self.

One of the best descriptions of waking up comes from Marcel Proust. In a long passage at the beginning of the first volume of *In Search of Lost Time*, the unnamed narrator describes awakening from sleep:

A sleeping man holds in a circle around him the sequence of the hours, the order of the years and world. He consults them instinctively as he wakes and reads in them in a second the point on the earth he occupies, the time that has elapsed up to his waking; but their ranks can be mixed up, broken. If towards morning, after a bout of insomnia, sleep overcomes him as he is reading, in a position too different from

the one in which he usually sleeps, his raised arm alone is enough to stop the sun and make it retreat, and, in the first minute of his waking, he will no longer know what time it is, he will think he has only just gone to bed. If he dozes off in a position still more displaced and divergent, for instance after dinner sitting in an armchair, then the confusion among the disordered worlds will be complete, the magic armchair will send him travelling at top speed through time and space, and, at the moment of opening his eyelids, he will believe he went to bed several months earlier in another country. But it was enough if, in my own bed, my sleep was deep and allowed my mind to relax entirely; then it would let go of the map of the place where I had fallen asleep and, when I woke in the middle of the night, since I did not know where I was, I did not even understand in the first moment who I was; all I had, in its original simplicity, was the sense of existence as it may quiver in the depths of an animal; I was more bereft than a cave-man; but then the memory—not yet of the place where I was, but of several of those where I had lived and where I might have been—would come to me like help from on high to pull me out of the void from which I could not have got out on my own; I passed over centuries of civilization in one second, and the image confusedly glimpsed of oil lamps, then of wing-collar shirts, gradually recomposed my self's original features. ([Proust 2003](#), p. 9)

Proust depicts the moment of awakening from deep sleep as one where we have lost all sense of the self derived from memories of the episodes of our lives. Instead of the autobiographical or narrative sense of self as a person with a storyline through time, there remains only the sensation of existing at that moment. What marks the first instant of awakening is not the self of memory but the feeling of being alive, or what Proust calls “the sense of existence as it may quiver in the depths of an animal.”

The moment of awakening thus reveals two kinds of self-experience. The first kind is the embodied self-experience of being alive in the present moment, or the experience of being sentient. The second kind of self-experience is the autobiographical experience of being a person with a storyline, a thinking being who mentally travels in time. The first kind of embodied sense of self we experience immediately upon awakening, but as we reach automatically for the second kind of autobiographical sense of self, it sometimes goes missing.

This distinction between two modes of self-experience, one of which remains present in the sleep–wake transition even if the other is lost, suggests the following tentative phenomenological line of thought leading towards the idea of consciousness being present in certain phases of dreamless sleep.

Consider that although deep sleep creates a gap or a rupture in our consciousness, we often feel the gap immediately upon awakening. Our waking sense that we were just asleep and unknowing is not outside knowledge—like the kind we have when we know about someone else’s having been asleep; it is inside, first-hand experience. We are aware of the gap in our consciousness from within our consciousness. Although we may forget many things about ourselves when we first wake up—where we are, how we got there, maybe even our name—we do not have to turn around to see who it was who was just asleep and unknowing, if by “who” we mean the sense of self as the embodied subject of present-moment experience in contrast to the sense of self as the mentally represented object of autobiographical memory. This intimate and immediate bodily self-awareness that we have as we emerge from sleep into waking life suggests that there may be some kind of deep-sleep awareness, operative at least for some stretch of time prior to waking up, a taste of which we retain in the waking state, despite there being no specific mental content to recall. If there is a deep-sleep awareness we can retain in this way, then there may, at least for certain phases of deep sleep, be a phenomenal character to deep sleep or something “it is like” (Nagel 1974) to be deeply asleep—in which case consciousness

cannot be entirely absent from deep sleep (Sharma 2001).

This line of thought finds its strongest philosophical expression in classical Indian philosophy, so if we wish to see whether we can sharpen it into a more compelling argument, we need to look at the Indian discussions.

3 A classical Indian debate

In the earliest texts of the *Upaniṣads*, dating from the seventh century B.C.E., dreamless sleep is singled out as one of the principal states of the self, along with the waking state and the dream state. Various characterizations of dreamless sleep are given. Some texts characterize it as a state of oblivion, while other texts describe it as a mode of unknowing or non-cognitive consciousness that lacks either the outer sensory objects of the waking state or the inner mental images of the dream state (Raveh 2008). It is this second characterization that we find in the later texts of the Yoga and Vedānta schools. These texts also present a basic form of philosophical argument for dreamless sleep being a mode of consciousness. The argument runs as follows: When you wake up from a dreamless sleep, you are aware of having had a peaceful sleep. You know this directly from memory, so the argument asserts, not from inference. In other words, you do not need to reason, “I feel well rested now, so I must have had a peaceful sleep.” Rather, you are immediately aware of having been happily asleep. Memory, however, presupposes the existence of traces that are themselves caused by previous experiences, so in remembering that you slept peacefully, a peaceful feeling must have been experienced. To put the thought another way, the memory report, “I slept peacefully,” would not be possible if awareness were altogether absent from deep sleep; but to say that awareness is present in deep sleep is to say that deep sleep is a mode of consciousness.

To my knowledge, the earliest version of this argument comes from Vyāsa’s third or fourth century C.E. commentary on Patañ-

jali's *Yoga Sūtras*.¹ Patañjali defines yoga as the stilling or restraining of the “fluctuations” of consciousness (*Yoga Sūtras* I:2). When this stilling is accomplished, the “seer” or “witness” can abide in its true form, namely, pure awareness; otherwise the “seer” identifies with the fluctuations of consciousness—with the movements of thought and emotion (I:3–4). Patañjali identifies five kinds of fluctuations or changing states of consciousness: correct cognition, error, imagining or conceptual construction, sleep, and memory (I:5–6), and he defines sleep as a state of consciousness that is based on an “absence” (I:10).

As the traditional commentaries indicate, “absence” does not mean absence of consciousness; it means absence of an object presented to consciousness.² Deep and dreamless sleep is a kind of consciousness without an object. When we are awake we cognize outer objects, and when we dream we cognize mental images. When we are deeply asleep, however, we do not cognize anything—there is no object being cognized and no awareness of oneself as knower. Nevertheless, according to Yoga, we feel this peculiar absence while we sleep and we remember it upon awakening, as evidenced by our saying, “I slept peacefully and I did not know anything.”

Before we examine the debate arising from this argument, let me mention an obvious objection that would occur to us today, especially given what we know from sleep science. The objection is that retrospective subjective evaluations of sleep may be unreliable (Baker et al. 1999), so we cannot assume that the subjective feeling upon awakening of having slept peacefully is based on a veridical memory of a peaceful sleep. An extreme case of the unreliability of self-reports about sleep comes from insomnia patients (Perlis et al. 1997; Rosa & Bonnet 2000; Zhang & Zhao 2007). These patients frequently display sleep-state misperception; that is, their subjective

assessments of the quantity and quality of their sleep deviate strongly from the objective, polysomnographic measures. For example, they often identify themselves as having been awake when they are woken up from polysomnographically-defined sleep, they tend to overestimate sleep-onset latency (the length of time it takes to go from full wakefulness to sleep), and to underestimate total sleep time as compared with polysomnographic measures (Perlis et al. 1997). Even in healthy individuals, the feeling of having slept well could sometimes deviate from objective measures. One could feel refreshed upon awakening, yet the objective measures might show that one's sleep was physiologically restless or intermittent; or one could feel fatigued upon awakening, yet the objective measures might show that one's sleep was physiologically deep and undisturbed. In short, although it is conceptually true that a veridical episodic memory implies having undergone an experience whose content corresponds, to some degree, to that of the memory, it is an empirical matter whether or to what degree any given waking memory impression of sleep is veridical. It is also an empirical question whether episodes of peaceful sleep typically lead to the awareness of having slept peacefully and whether this feeling can occur even when sleep is disturbed.

This line of thought, however, is not decisive against the Yoga argument. Strictly speaking, all this argument needs is the possibility of there being veridical waking memories of having been deeply and dreamlessly asleep in order logically to establish that awareness can be present in at least certain phases or types of dreamless sleep. The argument does not need to establish that waking memory impressions are typically veridical, only that they can be. Indeed, as we will see later, the Yoga viewpoint can allow that ordinary sleep-state perception and retrospective subjective sleep-state evaluations may be unreliable. I will come back to this point at the end of the paper.

A more direct objection to the argument, however, is to challenge the premise that wak-

¹ For a translation of the *Yoga Sūtras* with Vyāsa's commentary, see Āraṇya (1983). Other useful translations can be found in Arya (1989); Bryant (2009); Chapple (2008); Iyengar (1996); and Phillips (2009).

² Arya (1989, pp. 178–184); Bryant (2009, pp. 41–43); Iyengar (1996, pp. 59–60).

ing retrospective reports of sleep are ever memory reports. The philosophers of the Nyāya school (Naiyāyikas) make this challenge. They maintain that the statement, “I slept peacefully and I did not know anything,” expresses an inferential cognition, not a memory report, and that consciousness is entirely absent in dreamless sleep. Given how one feels upon awakening, one infers one had a peaceful sleep and no memory of any dreamless sleep awareness is involved.

Advaita Vedānta, in turn, argues against the Nyāyan viewpoint. The debate between them focuses in particular on the ignorance occurring in dreamless sleep, and specifically on how we know or establish the waking report, “I knew nothing.” While we are asleep we know nothing of this ignorance; we come to know it only upon waking up. Yet given that we do not remain ignorant of our own ignorance, how is this knowing of not-knowing possible? The Naiyāyikas claim that we infer we were ignorant because we do not remember anything, but the Advaitins argue that retrospective oblivion is no proof of a prior lack of consciousness. Moreover, when we wake up we have the feeling of having been asleep and having not known anything. This feeling, the Advaitins claim, is better regarded as a kind of memory brought about by the traces of previous experience. So, in some sense, we must experience our ignorance—the unknowing stillness of our mind—in dreamless sleep.

In reply, the Naiyāyikas claim that we have no consciousness in dreamless sleep, and that when we wake up we make an inference by reasoning in the following way: “While I was in deep sleep, I knew nothing, because I was in a special state (I was not awake) and I lacked the necessary means for knowledge (my senses and mental faculties were shut down).” Of course, the Naiyāyikas are not saying that we explicitly make this inference when we wake up. What they are saying is that what looks like memory is really a case of implicit reasoning taking this inferential form.³

³ My account of the Nyāyan position and of the Advaita Vedānta rebuttal relies heavily on Gupta (1995, pp. 56–66, 99), and Gupta (1998, pp. 84–86). My account simplifies a number of the complexities on both sides of the debate.

In order to understand the kind of inference that the Naiyāyikas think we make, as well as why the Advaitins reject the Nyāyan position, it will be helpful to state the inference in the form of the standard Nyāyan syllogism, which forms an important part of the Nyāyan theory of inferential knowledge.

Suppose we are looking at a hill and you say to me, “There is fire on the hill.” I doubt what you say, however, so you need to convince me. You point to the hill and say, “There is smoke on the hill.” I see the smoke and I am convinced. According to the Nyāya, if we want to unpack how perception and inference have worked together to convince me that you are right, we need to formulate the inferential cognition in the following five steps:

1. There is fire on the hill.
[This is the proposition to be proven. It is what you think when you look at the hill, and it is what you want to convince me is the case.]
2. Because there is smoke on the hill.
[This is the reason you give to support what you say.]
3. Wherever there is smoke there is fire.
[This step states the universal concomitance between the presence of smoke and the presence of fire.]
4. As in the case of the kitchen.
[This step provides an example or actual case of the concomitance, to which we both agree.]
5. There is fire on the hill.
[This step states the conclusion, which is the proposition with which we began, but now stated as established and generated by the preceding inferential process.]

Let us now take this five-step syllogism and apply it to the case of dreamless sleep.⁴ The Nyāya view is that our knowledge that we knew nothing in dreamless sleep is based on the following sort of inference:

1. While I was in dreamless sleep, I knew nothing (there was an absence of knowledge in my self).

⁴ The following inference is my reconstruction of the Naiyāyikas’ reasoning as understood by their Advaita Vedāntin opponents. See Gupta (1995, pp. 56–66, 99), and Gupta (1998, pp. 84–86).

2. This is because (i) I (my self) was in a special state (that is, not awake) or (ii) I (my self) lacked the necessary means for knowledge (that is, my senses and mental faculties were shut down).

3. Whenever (i) I (my self) am in a special state (whenever I am not awake) or (ii) I (my self) lack the necessary means for knowledge (whenever my senses and mental faculties are shut down), I know nothing (there is an absence of knowledge in my self).

4. As in the case of fainting or a blow to the head.

5. While I was in dreamless sleep, I knew nothing (there was an absence of knowledge in my self).

Notice the parallel between the previous inference concerning fire and the present inference concerning dreamless sleep. In the previous case, our concern is to establish the presence of fire on the hill. In the present case, our concern is to establish the absence of knowledge in the self during dreamless sleep. Nevertheless, the form of reasoning is the same.

Again, the Naiyāyikas are not saying that we explicitly go through this inference step by step when we wake up. What they are saying is that we know by inference that we were ignorant during dreamless sleep, and that our inference can be shown to be correct when we make explicit all the steps that it contains. So there is no need to suppose that there is any kind of consciousness during dreamless sleep.

The Advaitins respond by arguing that this inference is faulty and cannot be how we know that there is an absence of knowledge during sleep. The problem is that I need some way to know or establish the reasons for inferring that I knew nothing—namely, that I was in a special state and that I lacked the means for knowledge—and there seems to be no way for me to do this without my relying on the kind of memory these reasons were supposed to obviate.

The first reason the Naiyāyikas give for me to infer that I knew nothing is that I was in a special state, that is, a state different from the waking state. But how do I know that I was

in a special state? If I say, “Because I knew nothing in this state,” then I am reasoning in a circle.

The second reason the Naiyāyikas give for me to infer that I knew nothing is that the means for knowledge were lacking—that is, that my senses and mental faculties were shut down. But here too we need to ask, how do I know that these means were lacking? How do I know my senses and mental faculties were inactive?

Suppose I say, “I infer my senses were shut down because they feel refreshed when I wake up.” But here the same basic problem repeats itself. How do I know or establish that there is a relationship between my senses feeling refreshed and their previously having been inactive? Would I not need to have some experience of knowing that my senses were inoperative together with an experience of knowing I feel refreshed in order to establish a relationship between the two? But while I am asleep I do not have any experience of knowing my senses are inactive; I know this only upon awakening. So how do I establish this relationship? If I appeal to yet another inference, then it looks like I am headed off on an infinite regress.

More generally, the only way I can know that the means for knowledge were absent in deep sleep is by knowing that there was no knowledge present in this state. Only by knowing the effect—my not knowing anything—can I infer the cause—the absence of the means for knowledge. So unless I already know what the inference is trying to establish—that I knew nothing—I cannot establish the reason on which the inference relies.

The Advaita Vedānta conclusion is that I know on the basis of memory, not inference, that I knew nothing in deep sleep. In other words, I remember having not known anything. But a memory is of something previously experienced, so the not-knowing must be experiential.

It is important to highlight the larger metaphysical disputes about the self and cognition that drive this debate. For the Naiyāyikas, the self is a non-physical substance. Unlike Descartes, however, who held that consciousness is the essence of the non-physical mind, the

Naiyāyikas maintain that the self is the substratum of consciousness and that consciousness is an adventitious quality of this substratum that is present only given the appropriate causal conditions, namely when the sensory and mental faculties are functioning to cognize objects. In addition, cognition consists in the taking of a separate object as content and never in taking itself as its own content.⁵ (In the case of introspection, a second-order cognition takes a separate first-order cognition as its object.) For the Advaitins, however, the self is pure consciousness, that is, sheer witnessing awareness distinct from any changing cognitive state. Thus, unlike the Naiyāyikas, the Advaitins cannot allow that consciousness disappears in dreamless sleep, since they think (as do the Naiyāyikas) that it is one and the same self who goes to sleep, wakes up, and remembers having gone to sleep. In addition, for the Advaitins, cognition consists in a reflexive awareness of its own occurrence as an independent prerequisite for the cognition of objects (Ram-Prasad 2007). In other words, the defining feature of cognition is reflexivity or self-luminosity, not intentionality (object-directedness), which is adventitious. Thus, during dreamless sleep, although object-directed cognition is absent, consciousness as reflexive and objectless awareness remains present.

It may help to use the modal notions of necessity and possibility to describe the difference between these views. For the Naiyāyikas, to be in a conscious state is to be in an object-directed state. Given that dreamless sleep is not an object-directed state, it is necessarily the case that consciousness is absent from this state. Nevertheless, if it could be shown that object-directed cognition can occur in dreamless sleep, then the Nyāya could allow for the possibility of consciousness during dreamless sleep. Such consciousness, however, would have to be intermittent or episodic, since object-directed cognitions come and go. What the Nyāya cannot allow is that consciousness is intrinsically reflexive or self-revealing (self-luminous), or that it can occur without an object. Furthermore, for the Nyāya, consciousness requires a

substratum, since consciousness is a mental quality, and mental qualities require the substratum of the self. Therefore, although the self continues to be present during dreamless sleep, consciousness is absent. The Advaitins agree with the Naiyāyikas that the self remains continuously present during dreamless sleep, but they maintain that the self is pure consciousness—consciousness as intrinsically reflexive and self-revealing, not as contingently and adventitiously object-directed. So, for the Advaitins, consciousness cannot ever be absent from dreamless sleep, which is to say that it is necessarily the case that consciousness is present throughout dreamless sleep.

Given these differences, the Nyāya might be thought to be more flexible than Advaita Vedānta with regard to the specific issue about dreamless sleep, since the Nyāya can allow for the possibility of intermittent consciousness during dreamless sleep, whereas Advaita Vedānta cannot allow for any absence of consciousness in this state.

Despite this limitation of the Advaita Vedāntan view, it is possible to extract a key phenomenological idea from its metaphysical commitments. This idea is that when I wake up from a dreamless sleep, it seems that I can sometimes knowingly say I have just emerged from a dreamless sleep, and this saying seems to be a reporting of my awareness, not the product of having to reason things out (Kesarcordi-Watson 1981). It is this thought that provides a premise of the Advaita Vedāntan argument for consciousness continuing in dreamless sleep, and this thought is logically distinct from the Vedāntan belief that the self is essentially pure consciousness.

This phenomenological thought, however, is open to the objection that, given an apparent memory, it does not follow that the state apparently remembered was consciously experienced. For example, we may have apparent memories of childhood events, yet their presence does not imply that these events were consciously experienced, for the memory impressions may have been acquired from other sources of information, such as things our parents told us or family photographs. Similarly, during dreamless

⁵ See Ram-Prasad (2007, Ch. 2) for discussion of the different Indian views about the nature of cognition and consciousness.

sleep, information may accumulate non-consciously from a variety of interoceptive and exteroceptive sources, and upon awakening we may realize that something was going in our mind while we were asleep, though at the time we had no experience of it.

At one level—the level of the empirical psychology of memory—we can make the same reply here that we made above to the objection to the Yoga argument, namely that all the argument requires is the possibility of there being genuine veridical episodic memories upon awakening of having been peacefully asleep; the argument does not need to establish that every apparent waking memory is such a memory. Unlike remote memory (of the sort we have for childhood events) or semantic memory (memory for learned facts or words), episodic memory is standardly taken to require that the events “encoded” in memory are experienced at the time of encoding. So, if there are possible cases upon awakening in which there is any kind of genuine episodic memory “retrieval” of the dreamless-sleep state, it follows that in such cases something about the state of being dreamlessly asleep must have been experientially encoded.

At another level—the level of cross-cultural philosophy of mind—we can see in the Vedāntan phenomenology the basis of a transcendental argument. Transcendental arguments aim to deduce what must be the case in order for some aspect of our experience to be possible. In the present case, the aspect of experience with which we are concerned is not simply that we sleep but that we know that we sleep. What are the necessary conditions of possibility for this kind of self-knowledge? To put the question in a more phenomenological way, how is it possible for you as a conscious subject to experience yourself as one and the same being who falls asleep, who does not actively know anything in being asleep, and who emerges from sleep into waking life? The Vedāntan view is that a retrospective inference across the gap of a complete absence of consciousness will not suffice to make this kind of unified self-experience possible. Rather, you must have some kind of experiential acquaintance with dreamless sleep as a mode of your conscious being.

We can take a further step and think about the Vedāntan argument not just from a Kantian transcendental perspective but also from a Husserlian transcendental phenomenological perspective. From this perspective, the core of the Vedāntan argument concerns not so much episodic memory in the sense of the distinct mental act of recollection but rather what Husserl calls “retention”—the holding onto the just-past as an intentional content belonging to our consciousness of the passage of time, including our own mental lives as flowing in time. The Advaita Vedāntan thought is that, at the moment of waking up, I can experience by retentional awareness my having just been asleep and my having not known anything. What Nyāya fails to see, according to Vedānta, is that I need this kind of retentional awareness in order to have the first-person knowledge that I slept and to ground any retrospective inference I may subsequently make.

Of course, even if we suppose that there is or can be such a direct memory in the form of a retentional awareness of the deep sleep state, the presence of such a memory would not suffice to prove the continuous presence of consciousness throughout the entirety of dreamless sleep. After all, the presence of such a memory seems compatible with there having been moments or periods during which consciousness vanishes completely, with the sleeper remembering only the later smoothed-out and mentally-merged, conscious parts of sleep. Nevertheless, if dreamless sleep allows for or includes phases in which awareness is present, then this state cannot be defined as one in which consciousness is absent.

Another important Advaita Vedāntan thought is that when I say I just woke up from a dreamless sleep, the first-person pronoun does not refer to my autobiographical self—my self as I represent it in personal memory. Rather, it picks out my consciousness or subjectivity itself. To use a phenomenological idiom, it picks out the “ipseity” or minimal selfhood of consciousness in contrast to the ego as a mentally represented object of memory or reflection. But whereas the Advaitin takes this minimal selfhood to be a transcendental “witness consciousness” (Gupta 1998), it is open to us today to

maintain that it is my embodied self or bodily subjectivity, or what phenomenologists would call my “pre-personal lived body.” In this way, we may be able to remove the Advaita Vedāntan conception of dreamless sleep from its native metaphysical framework and graft it onto a naturalist conception of the embodied mind—a conception that should also appeal to the Cārvāka or naturalist school of Indian philosophy (see [Ganeri 2012](#), pp. 69–97), besides being tractable for cognitive science.

Cognitive science is also relevant to an interesting disagreement between Yoga and Advaita Vedānta concerning cognitive activity during dreamless sleep. Advaita Vedānta maintains that cognitive activity ceases during dreamless sleep and only consciousness remains, whereas Yoga maintains that cognitive activity continues during dreamless sleep (see [Dasgupta 1922](#), pp. 460–61). To understand this difference it is important to note that both traditions distinguish between consciousness, which is the self-luminous (reflexive) and passive witnessing awareness, and the mind, which is the intentional or object-grasping cognitive system. Moreover, in the Yoga view, the mind is material, and so is not different from the body (see [Schweizer 1993](#)). According to Yoga, deep sleep is a subtle or reduced state of the mind, specifically of the “inner sense” (*antaḥkaraṇa*), which includes both mental cognition (*manas*, which processes and integrates sensory material, and *buddhi*, which intellectually discriminates and judges) and the sense of ego (*ahaṃkāra*, the feeling, “I am”). Thus, for Yoga, cognitive activity, particularly the formation of memories, continues subliminally in deep sleep, and this process is physical or physiological. According to Advaita Vedānta, however, the mind, specifically the inner mental sense, shuts down entirely in deep sleep, leaving only the passive “witness consciousness” and the life processes of the body. If we set aside the question of consciousness and ask whether cognitive activity, specifically memory formation, occurs during deep sleep, the answer from cognitive science is unequivocal, for evidence from psychology and neuroscience indicates that memory processes are strongly present in deep sleep ([Diekelmann & Born 2010](#); [Walker 2009](#)).

These processes include both passive and active forms of memory consolidation (the strengthening of newly-acquired memories and the integration of them with older ones). Of course, this kind of memory consolidation is thought to occur in the absence of consciousness, so this evidence does not support the Yoga and Vedāntan view that consciousness continues in dreamless sleep. Nevertheless, the evidence does support the Yoga view that physiologically-instantiated cognitive processes continue in dreamless sleep, contrary to both Advaita Vedānta and Nyāya, which believe the mind shuts down in dreamless sleep.

The claim that mental activity ceases in dreamless sleep while consciousness remains creates another difficulty for the Advaita Vedāntan view. If the inner sense stops functioning in dreamless sleep, then how is the waking memory, “I slept peacefully and I did not know anything,” formed? Episodic memory requires the encoding of experience, so if there is no experience of “I” in dreamless sleep, then how can I remember that I slept well?

The Advaita Vedānta answer is clever (see [Dasgupta 1922](#), pp. 460–461). In deep and dreamless sleep, ignorance completely envelops the mind. Since the ego sense is inoperative, it doesn’t appropriate this ignorance to itself, so there is no feeling of the ignorance belonging to an “I.” At the moment of awakening, however, the ego sense, grounded on the felt presence of the body, reactivates, and the mind starts up its cognitive workings. Immediately, the ego sense appropriates the lingering impression or retention of not-knowing and associates this retention with itself, thereby generating the retrospective thought, “I did not know anything.”

From the Vedānta perspective, this “I” is not the true self; it consists in a mistaken superimposition of the self onto the mind-body complex. The true self is the egoless “witness consciousness” (egoless, because it is not a function of the ego sense). The Advaitin takes this “witness consciousness” to be transcendental and not essentially embodied. It is open to us today, however, to suppose that if there is some kind of egoless and basal consciousness that can continue to be present in dreamless sleep, then it is a funda-

mentally embodied consciousness, perhaps a minimal mode of sentience consisting in the feeling of being alive. This thought provides another example of how it may be possible to separate the Advaita Vedāntan conception of consciousness in dreamless sleep from its original metaphysical framework and graft it onto a contemporary naturalist conception of the embodied mind.

If we project some terminology from contemporary philosophy of mind onto Yoga and Advaita Vedānta, then we can say that dreamless sleep counts for these Indian philosophers as a “phenomenal state” or a state of “phenomenal consciousness”—a state that has a phenomenal character or for which there is something it is like to be in that state. What is it like? Yoga and Vedānta describe deep and dreamless sleep as peaceful, as one undifferentiated awareness not divided up into a sense of being a distinct subject aware of a distinct object, and as blissfully unknowing. From a contemporary naturalist perspective, this conception could be taken as a description of a quiescent and tranquil form of sentience or the feeling of being alive. Under this description, dreamless sleep would not count as a state of “access consciousness”—a state whose phenomenal content or character we can cognitively access, hold in working memory, and use to guide our attention and thinking. We seem to have no cognitive access to being asleep during sleep; rather, we gain access retrospectively in the waking state. On this conception, in dreamless sleep we are phenomenally aware but we have no cognitive access to that awareness at the time.

Ultimately, however, this way of conceptually parsing the Yoga and Vedāntan view will not work. A central commitment of Yoga and Vedānta, as well as Indo-Tibetan Buddhism, is that we can gain access to the state of dreamless sleep through meditative mental training. I will come back to this idea at the end of this paper. But first we need to consider the default view of consciousness and dreamless sleep in cognitive neuroscience.

4 Assessing the default view

Why have neuroscientists thought that consciousness disappears during dreamless sleep?

One reason comes from the reports that people give when they are woken up from NREM (non-Rapid Eye Movement) sleep, especially when the EEG shows slow waves in the delta frequency range (0.5–4 Hertz) during sleep stages 3 and 4 (so-called slow-wave sleep). When given the instruction, “report anything that was going through your mind just before waking up,” people tend to report short and fragmentary thoughts or not being able to remember anything at all (Nielsen 2000; Tononi & Koch 2008, p. 243). On the basis of such reports, scientists conclude that the sleepers were aware of little or nothing at all prior to being woken up, and hence that slow-wave sleep is a state of reduced or absent consciousness.

We need to be cautious here, however. The fact that one has no memory of some period of time does not necessarily imply that one lacked all consciousness during that time. One might have been conscious—in the sense of undergoing qualitative states or processes of sentience or awareness—but for one reason or another one was not able to form the kind of memories that later one can retrieve and verbally report.

This point is familiar to scientists who study the effects of anaesthetics (Alkire et al. 2008). At certain doses, some anaesthetics prevent memory formation while sparing awareness. Near the threshold of unconsciousness, some anaesthetics block working memory, but patients may still be aware and fail to respond because they immediately forget what to do. At lower doses, patients under general anaesthesia can sometimes carry on a conversation using hand signals, but after the operation they deny ever being awake.

Although dreamless sleep and anaesthesia are not the same condition, the general point that retrospective oblivion does not prove a prior lack of consciousness must be kept in mind whenever we are tempted to infer that consciousness is absent in deep sleep because people report not being able to remember anything when they are woken up.

We also need to think about the kinds of verbal reports that people are asked to make when they are woken up in the sleep lab. The instruction to report “anything going through

your mind just before waking up” encourages you to direct your attention and memory to the objects of your awareness—to anything you might have been thinking about. But what about the felt qualities or phenomenal character of your state of awareness? A different instruction would be to report “anything you were feeling just before waking up.” This instruction encourages you to direct your attention and memory to the felt quality of your sleep. Did you have any feeling of being aware? Was your sleep peaceful and clear, or was it agitated, restless, or sluggish? Or do you have no impression of any feeling or quality of awareness? The point here is to guide people away from focusing exclusively on the intentional objects of consciousness, which may be absent in deep sleep, and to orient them towards the felt qualities or phenomenal character of awareness itself.

Another reason neuroscientists think that consciousness fades away in deep sleep comes from comparing brain activity during slow-wave sleep with brain activity during waking consciousness. For example, during wakefulness, when an electrical pulse is used to stimulate a small region of the brain, the pulse generates an EEG response that lasts for 300 milliseconds and that is made up of rapidly changing waves that propagate in specific directions over long distances in the cortex (Massimini et al. 2005; Tononi & Massimini 2008). During deep sleep, however, although the initial EEG response to the stimulation is stronger than during wakefulness, the response remains localized to the stimulated region instead of travelling to distant regions, and it lasts only 150 milliseconds. In short, whereas the waking brain responds to stimulation with a complex pattern of large-scale activity across many interconnected regions, the deeply sleeping brain responds with localized and short-lived activity. These findings are interpreted as showing that “effective connectivity”—the ability of neural systems to influence each other—breaks down in deep sleep. As a result, “large-scale integration” (Varela et al. 2001) in the brain cannot happen—that is, the brain cannot generate the kinds of dynamically-changing large-scale patterns of activity that are known to characterize consciousness in the waking state.

But what is it about the loss of effective connectivity and large-scale integration that makes neuroscientists think that consciousness disappears in deep sleep? To put the question another way, what is the connection between the presence of consciousness and the presence of effective connectivity and large-scale integration?

To answer this question, neuroscientists usually rely on the idea that a content of consciousness is a reportable content, and that reportable contents are ones that can be attentionally selected, held in working memory, and used to guide thought and action. Such cognitive processes—selective attention, working memory, sequential thought, and action guidance—require the large-scale integration of brain activity.

One of the more theoretically-principled versions of this idea is Giulio Tononi’s “integrated information theory” of consciousness (2008). According to this theory, any typical conscious experience has two crucial properties. First, it is highly “informative,” in the technical sense that it rules out a huge number of alternative experiences. Even an apparently simple conscious experience, such as lying on your back and seeing the clear blue sky throughout your whole visual field, is richly informative in the sense that it rules out a vast number of other experiences you could have had at that moment. Second, the experience is highly “integrated,” in the sense that it cannot be subdivided into parts that you experience on their own, such as the top and bottom portions of your visual field, or the color and the space of the sky.

Given this model of consciousness as “integrated information,” Tononi proposes that the level of consciousness of a system at a given time is a matter of how many possible states (information) are available to the system as a whole (integration). In the waking state, many possible states are available to the whole system (the system is rich in integrated information), whereas in deep sleep this repertoire drastically shrinks to just a few states (the system is poor in integrated information). Transposed onto the brain, the idea is that during slow-wave sleep

there is a massive loss of integrated information in the brain. Effective connectivity breaks down, leaving isolated islands that cannot talk to each other (loss of integration), while the repertoire of possible states contracts to a few largely uniform states (loss of information). Hence, according to the integrated information model, deep sleep is a state where consciousness reduces to a very low level or disappears entirely.

Although the integrated information theory offers a useful way of thinking about the qualitative richness and coherence of consciousness in informational terms, the theory has serious limitations as a theory of phenomenal consciousness, so it would be a mistake to use the theory to rule out the possibility of consciousness during dreamless sleep.

Despite Tononi's bold claim that "consciousness is one and the same thing as integrated information" (2008, p. 232), integrated information does not seem sufficient for consciousness. On the one hand, even simple systems have some degree of integrated information, so the equation of consciousness and integrated information implies that even simple systems, such as a photodiode, have some degree of consciousness. On the other hand, complex digital computers can possess a high amount of integrated information. Yet neither system is conscious (at least the attribution of consciousness to such systems seems highly implausible) (see Searle 2013). As Ned Block (2009) points out, the integrated information theory fails to distinguish between intelligence, in the sense of being able to solve complex problems by integrating multiple sources of information, and consciousness, in the sense of sentience or felt awareness (phenomenal consciousness). Since integrated information does not seem sufficient for consciousness—let alone identical to it—the presence or absence of integrated information cannot be the crucial mark of whether a state is conscious or not conscious.

We also need to keep in mind the distinction between "phenomenal consciousness" and "access consciousness." To be phenomenally conscious means to be in a state that has some subjective or phenomenal character. To be ac-

cess conscious means to be in a state where there is cognitive access to the contents of awareness. Whether a state's being phenomenally conscious requires that it be cognitively accessible is currently a matter of debate (Block 2011; Cohen & Dennett 2011). Although large-scale integration in the cortex is crucial for cognitively accessed or reported conscious experience, it may not be crucial for every kind of phenomenal consciousness; for example, it may not be crucial for the kind of cognitively unaccessed consciousness that Yoga and Vedānta maintain is present in dreamless sleep (though they also maintain, as we shall see, that this kind of consciousness is accessible if one is highly trained in certain types of meditation).

The upshot of this critical assessment of the default view is that neither the subjective report data nor the objective neurophysiological data suffice to rule out the possibility of a subtle mode of phenomenal consciousness occurring in certain phases of dreamless sleep. To put the point another way, the sleep science construct of "dreamless sleep," defined electrophysiologically as slow-wave sleep, may need phenomenological refinement. We need to allow for the possibility that certain types of slow-wave sleep may have a phenomenal character—a possibility that could in turn lead to refinements in the physiological construct of slow-wave sleep. It follows from these considerations that the standard neuroscientific definition of consciousness as "that which disappears in dreamless sleep and reappears in waking and dreaming states" is not acceptable. At the very least, it needs qualification in light of the present considerations, and it may need to be either substantially revised or abandoned in light of further research.

The case of dreamless sleep suggests that we need to allow at least for the possibility of there being modes of phenomenal consciousness that may not be cognitively accessible in the usual ways. At the same time, Yoga and Vedānta, as well as Indo-Tibetan Buddhism, maintain that aspects of the mind in deep and dreamless sleep can become cognitively accessible through meditative mental training. This is the last topic I wish to discuss. My main point

will be that considering sleep from this contemplative angle suggests new experimental questions and protocols for the cognitive neuroscience of sleep and consciousness.

5 New experimental questions and protocols

In juxtaposing the Indian and neuroscience conceptions of deep sleep, I have proceeded so far as if the Indian notion of dreamless sleep corresponds to NREM slow-wave sleep. But we can now see that this correspondence is too simplistic. The Indian conception of dreamless sleep suggests that we need a finer taxonomy of sleep states—a taxonomy that is not just physiological but also phenomenological, and that accommodates the ways that sleep may be culturally variable as well as flexible and trainable through meditative practices.

Consider that the fourth century C.E. author, Vyāsa, in his commentary on Patañjali's *Yoga Sūtras*, distinguishes three types of sleep that are recalled upon awakening—peaceful sleep, disturbed sleep, and heavy sleep. According to the cosmology that informs Yoga, these three types of sleep result from whichever one of the three qualities or tendencies (*guṇas*) predominates in the psychophysical complex. Overall, the quality of dullness or the tendency to inactivity (*tamas*) dominates the mind in ordinary sleep. Sleep is heavy or stupefying when this quality is not modified by either of the two other qualities or tendencies. Sleep is disturbed and restless when the quality of excitation or tendency to activity (*rajas*) is present. And sleep is peaceful and refreshing when the quality of lightness or tendency to clarity (*sattva*) is present. When the Vedānta philosophers describe deep and dreamless sleep as blissful, it is deep sleep, with this quality of clarity, that they have in mind.

When sleep-lab participants are roused from NREM sleep, however, they sometimes report that they have been thinking while they were asleep, and often they describe going around in a repetitive loop of rumination. Although this kind of thinking probably occurs mainly in stage 2 NREM sleep, it is also repor-

ted during awakenings from deeper slow-wave sleep.

Owen Flanagan appeals to this finding to argue that there is no such thing as dreamless sleep and hence no sleep completely lacking in consciousness (2000). Contrary to the standard neuroscience view, Flanagan thinks we are always conscious while asleep because we are always dreaming. Dreaming, he proposes, is any conscious mental activity occurring during sleep, not just mental activity involving sensory imagery. If ruminative thinking occurring in NREM sleep counts as dreaming, and if this kind of mental activity can happen during slow-wave sleep, then all sleep stages involve dreaming and at least some degree of consciousness.

From the Indian perspective, however, we need to distinguish clearly between two things. One is whether there is such a thing as dreamless sleep; the other is whether we are conscious while we sleep. Yoga and Vedānta agree that consciousness is present while we sleep, but this is not because we are always dreaming, even if we define “dreaming” widely to mean any kind of thinking during sleep. On the contrary, what Yoga and Vedānta mean by “dreamless sleep,” as we have seen, is that sleep state in which there are no sensory or mental objects of awareness, that is, no images and no thoughts. Nevertheless, they maintain, there is awareness, so this state is a conscious state; it is a mode of consciousness without an object.

In the Yoga framework, reports of ruminative thinking upon awakening indicate a coarser or shallower sleep state—one closer to the surface of thinking consciousness—and a state with a strong quality of excitation or tendency toward movement of the mind.

Consider now the reasons that sleep scientist J. Allan Hobson gives for doubting the reliability of waking reports of ruminative thinking during slow-wave sleep:

Reports of antecedent mental activity elicited following awakenings from deep sleep are rendered unreliable by the brain fog through which they must pass [...]. Even if the deeply sleeping brain were capable of

the low-level ruminations sometimes implied by experimental reports, it is unlikely that they would survive the inertia of awakening. It may even be that the tumult of the awakening process triggers the chaotic and fragmentary mentation that is reported. And even when deep sleepers are sufficiently aroused to be interviewed, they may still generate huge slow waves in their EEGs, indicating that they are in a semituporous state quite different from either sleeping or waking. Indeed, they may even hallucinate, become anxious, and confabulate as if they suffered from delirium. This is precisely what happens in the night terrors of children. (1999, pp. 142–143)

Clearly, this too is a far cry from the Indian conception of dreamless sleep. Neither reports of ruminative thinking nor waking hallucinatory confabulations correspond to the Yoga and Vedāntan descriptions of dreamless sleep as a peaceful or blissful state free of mental activity, from which one awakens feeling alert and refreshed. From the Yoga perspective, what Hobson describes are sleep states strongly marked by a quality of dullness combined with mental excitation upon awakening.

My point here is not at all that sleep science should refine its taxonomy using the Yoga framework. It is rather that ultimately we cannot map the Indian notion of dreamless sleep using already-established scientific categories, especially the physiologically-defined sleep stages, which, even from a scientific perspective, are now recognized as too crude to capture the moment-to-moment dynamics of electrical brain activity during sleep, let alone the experiences with which they may be correlated (Nir & Tononi 2009). Not only is the Indian notion phenomenological and metaphysical, rather than physiological, it is also embedded in a normative framework that understands sleep in contemplative terms. So, to bridge from sleep science and the neuroscience of consciousness to the Indian conception of dreamless sleep, we need to view sleep as a mode of being that is trainable through meditation.

From the Yoga perspective, entering a state of blissful dreamless sleep on a regular basis requires leading a calm and peaceful life guided by the fundamental value of nonviolence (*ahimsā*), practicing daily meditation, and treating going to sleep and waking up as themselves occasions for meditation—for watching the mind as it enters and emerges from sleep.

In addition, from a yogic perspective, we need to distinguish between ordinary dreamless sleep and lucid dreamless sleep. Ordinary dreamless sleep is the sleep of ignorance, in which awareness is described as being in total darkness. Lucid dreamless sleep is described as a state in which awareness is luminous and without an object (free of thoughts and images). Whereas lucid dreaming consists in knowing that you are dreaming, lucid dreamless sleep is said to consist in being able to witness the state of dreamless sleep and recall its phenomenal clarity upon waking up. Although the background metaphysics of Yoga, Vedānta, and Indo-Tibetan Buddhism differ in significant ways, they all describe lucid dreamless sleep as disclosing a basal level of pre-personal consciousness that lies deeper than the modes of awareness that characterize the ego-centred waking and dreaming states.⁶

At this point you may wonder whether we have strayed back into the realm of metaphysics. Does this conception of dreamless sleep really have any descriptive phenomenological content or is it simply a consequence of the Indian metaphysical views that identify the true self with pure consciousness (as in the case of Vedānta) or that maintain that there is no self but only an ownerless stream of consciousness that continues in dreamless sleep (as in Indo-Tibetan Buddhism)?

From a purely textual perspective, the metaphysical and the phenomenological are thoroughly intertwined in the Indian discussions. From a cognitive science perspective, however, we can ask whether the idea of inducing lucid dreamless sleep through certain types of meditation is experimentally testable,

⁶ For further discussion, see Thompson (2014).

and, more generally, whether meditation is associated with altered sleep patterns or has measurable effects on sleep. Two neuroscience studies of sleep in relation to meditation are suggestive in this regard.

One recent study comes from the laboratories of Giulio Tononi and Richard Davidson (Ferrarelli et al. 2013). They examined slow-wave sleep in highly experienced Theravāda Buddhist and Tibetan Buddhist meditation practitioners. They found that the long-term meditators, compared to non-meditators, had significantly increased fast-frequency gamma activity, as recorded by high-density EEG, in a parietal-occipital region of the scalp during NREM sleep. In addition, the higher gamma activity was positively correlated with the length of meditation training. This finding is notable because gamma-frequency electrical brain activity is a well-known neural marker of conscious cognitive processes (Tononi & Koch 2008), including certain types of meditative states in long-term meditation practitioners (Lutz et al. 2004). Gamma activity has also been shown to distinguish lucid dreaming from non-lucid dreaming in REM sleep (Voss et al. 2009; see also Voss & Hobson this collection). During NREM sleep, however, gamma activity tends to decrease, so the higher gamma activity in the meditators could reflect a capacity to maintain some level of awareness. More generally, the study suggests that there may be distinct slow-wave sleep states associated with meditation practices.

Another older study examined long-term practitioners of TM (Transcendental Meditation) who reported what they called the subjective experience of “witnessing” during sleep (Mason et al. 1997). They described this experience as one of feeling a continuous and peaceful awareness without dreams while one sleeps and as resulting in one’s feeling refreshed upon awakening. The main finding was that the long-term meditation practitioners, compared to short-term practitioners and non-meditators, showed a unique EEG pattern during slow-wave sleep, one in which faster alpha and theta waves were superimposed on the slower delta waves. Although we cannot draw clear conclusions

about what these distinctive physiological patterns mean, including whether they are due to TM practice or some other cause, the authors of the study interpret them as supporting the presence of a different kind of slow-wave sleep state in individuals who report witnessing of sleep.

These two studies reinforce the point that we cannot use already established categories from sleep science to map the Indian conception of dreamless sleep. This conception, besides being closely tied to a specific phenomenology, which in turn reflects a specific metaphysics, is embedded in a normative cultural framework that aims to bring about and promote certain kinds of contemplative sleep states. Instead of trying to fit these states into a physiological scheme derived from studying the way twentieth-century Americans and Europeans sleep in the sleep lab, we need to enlarge the conceptual framework of sleep science to include contemplative ways of training the sleeping mind. This project will require that sleep scientists, cognitive neuroscientists, cognitive anthropologists, and Western and Indian philosophers work together to map the sleeping mind. In short, we need a cross-cultural cognitive science and neurophenomenology (Lutz & Thompson 2003) of the wake–sleep cycle, one that draws on the combined expertise of Western and Asian theoretical traditions.

One benefit of such a cross-cultural cognitive science is that it could offer new data relevant to our guiding question about consciousness and dreamless sleep. Consider the following testable, neurophenomenological hypothesis: In highly-experienced practitioners of certain types of meditation, compared to individuals without this kind of experience, we should observe a stronger correlation between subjective reports of phenomenal qualities of sleep and various objective measures of brain activity. Specifically, if highly experienced meditators were able to provide reports upon awakening about qualities of their experience of the state they call dreamless sleep, and if cognitive neuroscientists were able to relate these reports to fine-grained features of sleep physiology and to familiar aspects of the neural correlates of consciousness, then we would have new evidence

from experimental science that a certain type of dreamless sleep in certain individuals counts as a mode of phenomenal consciousness whose felt qualities can be made accessible to verbal report.⁷

This hypothesis also cast lights on our earlier discussion of sleep-state misperception. From a contemplative perspective, when little attention is given to sleep as an occasion for the practice of mindfulness, it is not surprising that sleep-state perception will be unreliable, even in ordinary individuals, let alone patients suffering from insomnia or other sleep disorders. In contrast, sleep-state perception may be more reliable when sleep is valued in a contemplative way and is treated as an opportunity for cultivating mindfulness. Whether these assumptions are correct is something that neurophenomenology should test.

6 Conclusion

The definition of consciousness as “that which disappears in dreamless sleep and reappears when we wake up or dream” is unsatisfactory. It rules out the possibility of states or phases of dreamless sleep in which some kind of consciousness is present. A strong case for taking seriously this possibility can be constructed by combining resources found in Indian philosophy, Western philosophy of mind, the neuroscience of consciousness, and sleep science. The main message of this paper—besides that of needing to revise the above definition of consciousness—is that we need a more refined taxonomy of sleep states than the one that sleep science and the neuroscience of consciousness currently employ, and that contemplative methods of mind training are relevant for advancing the neurophenomenology of sleep and consciousness.

Just in Time—Dreamless Sleep Experience as Pure Subjective Temporality

A Commentary on Evan Thompson

Jennifer M. Windt

In this commentary, I propose a strategy for extending Evan Thompson's argument on the existence of dreamless sleep experience. My first aim is to show that the Indian debate on reports of having slept peacefully is importantly similar to debates in scientific dream research and contemporary Western philosophy on the trustworthiness of dream reports. This analogy leads to a surprising conclusion: the default view of conscious experience as that which disappears in dreamless sleep, though widely accepted in cognitive neuroscience, is in fact inconsistent with the methodological background assumptions of scientific dream research. Importantly, the methods already used in scientific dream research, as well as the theoretical justification on which they are based, can be extended to the investigation of dreamless sleep experience. Second, I sketch the outlines of a conceptual model of dreamless sleep experience as involving pure subjective temporality, or phenomenal experience characterized only by the phenomenal *now* and the sense of duration, but devoid of any further intentional content. I suggest that understood in this manner, dreamless sleep experience is a candidate for minimal phenomenal experience, or the simplest form in which a state can be phenomenally conscious. This model also extends existing work on minimal phenomenal selfhood in dreams. Third, I discuss three empirical examples that I take to be particularly promising candidates of dreamless sleep experience. These are certain forms of minimal or imageless lucid dreams, white dreams, and sleep-state misperception of the type most dramatically seen in subjective insomnia.

Keywords

Dreaming | Dreamless sleep | First-person reports | Insomnia | Lucidity | Minimal phenomenal experience | Minimal phenomenal selfhood | Sleep-state misperception | Time consciousness | White dreams

1 Introduction

The default view in philosophy of mind and cognitive neuroscience has long been that the very notion of phenomenal experience occurring during dreamless sleep is nonsensical and involves a conceptual contradiction.¹ In this view, consciousness is „that which disappears in dreamless sleep and reappears when we wake up or dream” (Thompson 2015, this collection, p. 1), and dreamless sleep is simply characterized by the absence of conscious experience.² In his target article, Evan Thompson casts doubt on this view. Drawing from classical Indian philosophy as well as evidence from sleep and dream research, he argues that dreamless sleep experience is a theoretically coherent and empirically tractable target for future research. Yet, in order to even begin to make sense of dreamless sleep experience, a more fine-grained taxonomy

of sleep states and new experimental protocols integrating disciplined first-person reports as well as neuroscientific methods are needed.

Here, I take up this challenge and attempt to sketch the outlines of a positive account of dreamless sleep experience. This commentary has three main aims. The first is to propose that Thompson’s case for dreamless sleep experience can be strengthened by constructing a rough analogy between the historical Indian debate on dreamless sleep and contemporary Western debates from scientific dream research and philosophy on the epistemic status of dream reports. Based on this analogy, I argue that the default view is inconsistent with the methodological background assumptions of scientific sleep and dream research. This internal inconsistency lends additional urgency to Thompson’s demand for a more fine-grained taxonomy of sleep states. I then use the Indian debate as a foil to sketch the outlines of an integrated theoretical position on the trustworthiness of first-person reports of dreams and dreamless sleep experience. I take this approach to be in the spirit of the type of cross-cultural approach recommended by Thompson and hope to show that valuable lessons can be learned on both sides.

My second aim is to sketch the outlines of a positive account of dreamless sleep experience. Here, my key claim is that dreamless sleep experience can be described as pure temporal experience. By this I mean phenomenal states that aside from their temporal structure are devoid of any further intentional content and characterized only by the subjective experience of time. Pure temporal experience (or pure subjective temporality, as I will also sometimes call it) is not structured around perceptual objects, events or emotions; it is the experience of being *just in time*.³ This account of dreamless sleep

¹ In some readings of the term dreamless sleep, the default view is not just obviously false, but it is also unclear that it is actually endorsed by many researchers working on dreaming and sleep. Most would acknowledge, for instance, that hypnagogic imagery during sleep onset or repetitive and non-progressive types of sleep thinking involve phenomenal experience during sleep; yet, because they are also commonly distinguished from full-fledged dreaming, they can be said to occur in dreamless sleep. This, however, is different from the type of dreamless sleep experience that Evan Thompson has in mind and that is the focus of this commentary. As will become clear later, in the narrower reading endorsed by Thompson, dreamless sleep “is that sleep state in which there are no sensory or mental objects of awareness, that is, no images and no thoughts” (p. 14); the question, denied by the default view, is whether this state of sleep can sometimes involve phenomenal experience. Dreamless sleep experience of this type, if it exists, is also distinct from experiences occurring during sleep-wake transitions in that it is thought to occur during deep sleep. In the context of this commentary, I will always, unless explicitly noted otherwise, use the term dreamless sleep experience in this narrow sense. In other readings, the default view may be thought to be trivially true: if one defines dreams as involving *any* kind of phenomenal experience during sleep (Flanagan 2001), then the occurrence of phenomenal experience during dreamless sleep is indeed ruled out by conceptual considerations. This reading, however, is too permissive in that it fails to acknowledge the distinction between different types of experiences occurring during sleep, ranging from imagistic, narratively complex, and often emotional dreams to thought-like activity. For now, this suggests that the default view is too simple: the question is not whether there are experiences during sleep that fall short of full-fledged dreaming in some particular sense but whether there is a further group of experiences—call them dreamless sleep experience in the narrow sense—that is distinct from *any* of the established forms of conscious experience during sleep, including hypnagogic imagery and sleep-thinking. Thompson acknowledges this issue (p. 14) and I only emphasize it here to avoid misunderstanding.

² Note that throughout this commentary, I will use the terms “experience”, “subjective experience”, and “consciousness” interchangeably to describe states that have phenomenal character, or for which there is something it is like to have them.

³ At first sight, there is an inherent ambiguity in the concept of pure subjective temporality in that it can refer to the experiential character of *nowness*, but also to the experience of duration and of succession. In section 4, it will become clear that in the account defended here, the two aspects of *nowness* and duration are not strictly dissociable: the simplest forms of temporal experience are characterized by both a phenomenal *now* and the experience of duration, because

experience is attractive, or so I claim, because it offers a way of spelling out not just what is distinctive about dreamless sleep experience, but also how dreamless sleep experience can be integrated into a broader theoretical framework describing different kinds of sleep experiences, including dreams. The key idea is that while even the simplest forms of dreaming are characterized by phenomenal selfhood, or the experience of being or having a self, the transition from dreaming to dreamless sleep experience occurs when even this minimal form of phenomenal selfhood is lost. While the analysis of dreaming can help identify the conditions for minimal phenomenal selfhood, the analysis of dreamless sleep experience may provide a glimpse of an even simpler (and perhaps even minimal) form of phenomenal experience. In the final part of the commentary, I identify what I take to be the three most promising candidates for a future research program on dreamless sleep experience. These are lucid dreamless sleep, white dreams, and sleep-state misperception of the type most commonly seen in subjective insomnia. These examples broaden the scope of the target phenomenon by suggesting that the theoretical and experimental investigation of dreamless sleep experience extends beyond the case of expert meditators discussed by Thompson.

2 From the classical Indian debate to a new taxonomy of experience during dreamless sleep

In *Dreamless Sleep, the Embodied Mind, and Consciousness*, Evan Thompson retraces the steps of the classical Indian debate between the Advaitins and the Nyāyīyikas on the occurrence of conscious experience during dreamless sleep (see also Thompson 2014, chap. 8). The classical Indian debate is important, according to Thompson, because if the Advaita Vedānta

and Yoga claims about the persistence of consciousness during dreamless sleep are correct, the default view of consciousness as that which disappears during dreamless sleep is false and requires revision. In this section, I briefly reconstruct Thompson's main arguments and sharpen the precise points of agreement and disagreement in the classical Indian debate, as well as their overlap with questions raised in cognitive science and contemporary philosophy of mind. I also introduce three challenges to Thompson's view.

Thompson's reconstruction of the classical Indian debate starts out from a deceptively simple question: How, after awakening from sleep, do we know that we have slept peacefully? The Yoga and Advaita Vedānta schools argue that retrospective reports of having slept peacefully are memory reports: we directly and non-inferentially remember (and hence are able to report) a state in which we were phenomenally conscious, but did not experience any particular thoughts or images. Dreamless sleep experience is, in this view, devoid of intentional content; it is a state of knowing nothing and at least in principle, it can be remembered and accurately reported upon awakening. The Nyāyas disagree, arguing that reports of having slept peacefully are inferential. Their point is that if dreamless sleep involves a particular form of ignorance, or of not-knowing, this not-knowing cannot itself be known, either during sleep or retrospectively. Because the means for knowledge are lacking during dreamless sleep, we can at best infer, when we wake up feeling refreshed and remember nothing, that we must have slept peacefully.

As Thompson (sec. 3) points out, the classical debate about conscious experience during dreamless sleep has to be seen in the larger context of how these schools construe the relationship between consciousness and the self. For the Nyāyas, consciousness is an adventitious property of the self, meaning that the self can persist throughout sleep even when consciousness ceases. They also claim that cognition always involves taking something as its object, where this object is necessarily distinct from the cognitive state itself. This view is compatible with

the phenomenal *now* itself is temporally stretched. Though for reasons of space, I cannot discuss this any further here, note that once the distinction between the phenomenal *now* and the experience of duration collapses, the experience of seriality or of succession disappears as well: if the phenomenal *now* is no longer embedded within a larger temporal reference frame, then there will be no separate events that can be experienced as succeeding each other.

the occurrence of object-directed thought and dream-related imagery during sleep, but prohibits the occurrence of objectless cognitive states. For the Advaitins, the situation is different. Because for them, the self is pure, reflexive (or self-luminous) consciousness, they cannot allow that consciousness can disappear altogether even during sleep, because this would entail a disappearance of the self. Unlike the Nyāyas, the Advaitins do not, however, take consciousness to be necessarily object-directed. Instead, they regard the essentially reflexive and self-luminous character of consciousness and the self as separate from and indeed as the very condition of object-directed thought. A prediction would be that “pure” cases of reflexive, self-luminous consciousness should occur even in the absence of object-directedness, for instance during sleep.

Despite these differences, the debate on dreamless sleep experience unfolds before a background of mutual agreement. Both schools agree, for instance, that object-directed consciousness can (and does, for instance in the form of dreams) occur during sleep, but also that it does not persist throughout sleep. Both also agree that dreamless sleep is a state in which object-directedness is lost. And finally, both agree that the self persists throughout dreamless sleep, even in the absence of object-directedness. Their disagreement thus hinges, first, on what exactly it means to say that the self persists during dreamless sleep, understood in the sense of a state in which object-directed thought is lost, and second, on how to construe the relationship between consciousness, the self, and memory reports. Both points are relevant, as we will see, for assessing the relationship between the Indian debate and contemporary research as well.

How, then, to adjudicate between the two sides in the debate? Thompson (p. 6) reconstructs the Nyāya claim that our knowledge of dreamless sleep is inferential as involving a five-step syllogism. His discussion of the Nyāya syllogism is already so clear that nothing would be gained from rehearsing it once more here. Instead, I want only to recall to readers’ attention that Thompson’s reconstruction of the Advaitin re-

sponse shows the Nyāya syllogism to be inherently fallacious: it is either circular or results in an infinite regress. In order to infer from the fact that I was in a special state that I knew nothing in this state, I must first have a reason for saying that I was indeed in a special state; and if this reason is that I knew nothing in this state, I am presuming what is supposed to be shown and the argument is circular. Alternatively, if I say that the means for knowledge were lacking in this special state, for instance because the mental faculties and the senses were inactive, then this further claim has to be backed up by independent evidence. Saying that I felt refreshed upon awakening will not do—for in order to know that feeling refreshed after awakening is correlated with the inactivity of the mental faculties and the senses during sleep, I would either once more have to appeal to memory (which, on pains of circularity, I cannot do), or I would be headed for an infinite regress. Thompson sums up his critique of the Nyāya syllogism by formulating a general principle:

More generally, the only way I can know that the means for knowledge were absent in deep sleep is by knowing that there was no knowledge present in this state. Only by knowing the effect—my not knowing anything—can I infer the cause—the absence of the means for knowledge. So unless I already know what the inference is trying to establish—that I knew nothing—I cannot establish the reason on which the inference relies. (p. 7)

The Advaitin view offers an easy way out. As Thompson points out, it can be reconstructed as involving the phenomenological claim

that when I wake up from a dreamless sleep, it seems that I can sometimes knowingly say I have just emerged from a dreamless sleep, and this saying seems to be a reporting of my awareness, not the product of having to reason things out. (p. 8)

At least in principle, the subjective impression of having awakened from dreamless sleep can be

reflected in veridical reports of awareness during dreamless sleep.

It is important to see that Thompson's assessment of the Indian debate does not lead to a whole-hearted endorsement of the Advaitin view; the view he promotes is in fact much more subtle, and also more humble. Thompson's main goal is to establish the logical possibility of dreamless sleep experience. For this, it is sufficient that veridical memories of having slept dreamlessly are possible in principle (p. 5, p. 9). He also explicitly allows that there could be cases in which one's memory of having slept peacefully and dreamlessly is mistaken. Thompson's view is also weaker than the Advaitin position in that it is not committed to the persistence of conscious experience throughout sleep, but leaves room for periods of unconsciousness during sleep. According to Thompson, the mere possibility of dreamless sleep experience challenges the default view and highlights the need for a refined taxonomy of sleep states, because such a refined taxonomy is the condition for investigating dreamless sleep experience experimentally (p. 3).

To be sure, Thompson also offers some factual evidence for thinking that dreamless sleep experience actually exists: experienced meditators report witnessing or becoming lucid during dreamless sleep, and they show a changed pattern of EEG activity during slow wave sleep. Meditative training may, as Thompson suggests, facilitate cognitive access to the state of dreamless sleep (p. 11) and with it, more accurate reports. But his main point is that conceptual and empirical questions about dreamless sleep experience are well worth asking and that in order to do so, prominent theories of sleep, but also of consciousness (such as Tononi's *Integrated Information Theory*; see [Tononi 2008](#)) should at least make room for the possibility of its occurrence and require revision.

While I find Thompson's case for the logical possibility and conceptual coherence of dreamless sleep experience compelling, I worry that its humility makes it vulnerable to three related objections. A proponent of the default view could acknowledge that veridical reports of dreamless sleep experience are logically possible

but could insist that unless such veridical reports are identifiable and can be distinguished from nonveridical ones, such reports cannot be used for the experimental investigation of dreamless sleep experience, or only in a very small and admittedly special group of highly trained subjects. Thompson's own suggestions for the future investigation of dreamless sleep experience assume that this basic problem has been solved. For instance, he proposes that because dreamless sleep experience is supposed to be devoid of intentional objects, asking participants to report anything that was going through their minds before awakening, which is a question about the objects of awareness or the contents of consciousness, might be poorly suited to the target phenomenon. A good alternative, he suggests, would be to direct participants' attention to the phenomenal character of sleep itself, for instance by asking them to report any feelings or any qualitative states experienced before awakening (p. 12). Here, the proponent of the default view might object that this strategy falls short of a methodology for investigating dreamless sleep experience: In order to use reports of dreamless sleep experience as evidence, some rationale for distinguishing veridical reports from nonveridical ones is needed. Without this, the large-scale revision of standard sleep-state taxonomy demanded by Thompson may seem premature; Thompson's case for the mere possibility of dreamless sleep experience lacks the empirical grounding and research methodology to justify such a move.

A related problem is that in order to empirically investigate the occurrence of dreamless sleep experience, it is not enough to identify veridical reports of such experiences and distinguish them from nonveridical ones. Instead, in order to determine the frequency of dreamless sleep experience, one has to determine whether subjects can reliably report not just the presence of dreamless sleep experience, but also its absence. This problem is especially pronounced because Thompson's claim is not that experience persists throughout sleep. As we saw earlier, his view departs from the Advaitin claim in that he thinks that dreamless sleep experience occurs only occasionally and contrasts

with periods of genuine unconsciousness during sleep. A report-based methodology for investigating dreamless sleep experience will consequently have to assume not only that reports of dreamless sleep experience reliably indicate the presence of such experience during the preceding sleep period, but also that the absence of such experiences can be reliably reported, or at least that it can be inferred from the absence of reports of dreamless sleep experience. Unless this second condition is fulfilled, reports of dreamless sleep experience could be highly reliable in that they occur only when dreamless sleep experience was in fact present during the preceding sleep period, but could nonetheless fail to be sensitive to its actual frequency, for instance by only following a small proportion of such sleep experiences (for a discussion of the reliability and sensitivity of first-person reports, see [Fink unpublished manuscript](#)).

Thompson himself shies away from both commitments. In fact, he casts doubt on the assumption, common in cognitive neuroscience, “that a content of consciousness is a reportable content, and that reportable contents are ones that can be attentionally selected, held in working memory, and used to guide thought and action” (p. 12). Relatedly,

the general point that retrospective oblivion does not prove a prior lack of consciousness must be kept in mind whenever we are tempted to infer that consciousness is absent in deep sleep because people report not being able to remember anything when they are woken up. (p. 11)

Here, he might be read as effectively denying the possibility of using retrospective reports as a source of evidence for the scientific investigation of dreamless sleep experience. Moreover, given these doubts about the reliability and sensitivity of retrospective reports, Thompson’s (p. 17) proposal that meditation makes positive occurrences of dreamless sleep experience accessible to verbal report is not enough; a proponent of the default view could object that expertise of the relevant type is acquired only if meditation enables periods of unconscious sleep

to be retrospectively reported as well (or at least to be measured indirectly through the inability to report conscious experiences from the preceding sleep period).

Finally, a proponent of the default view might grant that reports of expert meditators are more trustworthy than those of laypeople in both respects: meditators can report both when dreamless sleep experience was present and when it was absent.⁴ Yet, it could still be objected that the example of expert meditators is simply too remote to justify the large-scale revision of sleep-state taxonomy that Thompson has in mind. For all practical purposes, or so the objection might go, the default view of consciousness and dreamless sleep as diametrically opposing and mutually exclusive states stands.

To be clear, I do not think these objections are particularly worrisome; but I do think they help set the agenda for how best to develop Thompson’s view, defend it against skeptical objections, and place it on broader empirical grounding. The first step, taken in the next section, is to introduce a stronger defense of the trustworthiness of reports of dreamless sleep experience, as well of reports of its absence. If successful, this provides a sound methodological basis for the experimental investigation of dreamless sleep experience. The second step is to provide a broader theoretical and empirical basis by proposing a conceptual framework of dreamless sleep experience as well as additional candidates for its future investigation.

3 Are reports of dreamless sleep experience trustworthy? The analogy between the Indian debate on dreamless sleep and the contemporary debate on dream reports

In this section, I draw an analogy between the Indian debate on dreamless sleep experience and the contemporary debate on the trustwor-

⁴ It remains controversial whether different forms of meditation actually enhance introspective accuracy. While there is some evidence in support of this claim ([Fox et al. 2012](#); [Sze et al. 2010](#)), at least one study has suggested that meditators may feel more confident than controls about their ability to successfully perform interoceptive tasks (such as heartbeat detection), but that this confidence is not paralleled by an actual improvement in task performance ([Khalsa et al. 2008](#)).

thiness of dream reports. This analogy provides the resources for overcoming the first two challenges to Thompson's argument. In particular, it reveals the default view to be inconsistent with the methodological background assumptions of scientific sleep and dream research. Given their own methodological commitments, researchers in these fields should reject the default view.

3.1 The methodological background assumptions of scientific dream research: Lessons for the investigation of dreamless sleep experience

The first step towards seeing why the default view is inconsistent with scientific dream research is to realize that this field, at least implicitly, relies on the assumption that reports of conscious experience during sleep are trustworthy: at least when they are given under certain (sufficiently) ideal conditions and immediately after awakening from sleep, such reports are taken to reflect what was experienced during the preceding sleep period, and indeed whether anything was experienced at all. What exactly the (sufficiently) ideal conditions for reporting sleep experiences consist in is an empirical question, and in scientific dream research, much work has been dedicated to its investigation (for discussion and further references, see Windt 2013, 2015, chaps. 3 and 4). There is widespread agreement that temporal proximity is a crucial factor: reports given immediately after awakening are commonly taken to be least vulnerable to forgetting. The sleeping environment (at home versus in the laboratory), method of awakening, interaction with experimenters, and precise wording of questions also play an important role (Domhoff 1996, 2003; Hall & Van de Castle 1966; Kramer 2013; Winget 1979). Different reporting techniques may be suitable for different research questions, and aside from being asked for verbal reports, participants may be encouraged to produce a dream drawing or compare the visual imagery in their dream with photographs with varying degrees, for instance, of color saturation or brightness (Rechtschaffen & Buchignani 1992). While there

may be uncertainty, in a given case, as to the sincerity of a report, this is a practical matter, not a deep theoretical problem.⁵ The key idea is that by improving reporting conditions and tailoring the reporting technique used in a given study to the specific research question, this risk can be minimized. For now, my main point is that this strategy, which is already well established in scientific sleep and dream research, only makes sense against a background of basic trust in at least a subset of dream reports.

This basic idea is very much in keeping with Thompson's proposal of asking participants to report any feelings or qualitative states experienced prior to awakening, rather than asking them to focus on the contents of conscious thought. By directing participants' attention to certain aspects of sleep experience or even introducing new experiential categories for their description (an excellent example of this strategy is Lutz et al. 2002), the expressive granularity⁶ of individual reports can be increased: types of experiences can be rendered reportable that would otherwise be forgotten. A compelling possibility is that in the case of dreamless sleep experience, such improvements in reporting conditions may not just supplement training, as suggested by Thompson, but may even facilitate the investigation of dreamless sleep experience in participants who lack any particular introspective training.⁷

Admittedly, this approach does not provide a fail-safe method for avoiding or even identifying nonveridical reports. Rather than fo-

⁵ Researchers occasionally worry, for instance, that participants may underreport embarrassing dream content; censorship of this type may be why sexual dream content is only rarely reported in laboratory studies (Hobson 1988); see also Rosen's (2013) discussion of willful narrative fabrication of dream reports. For the investigation of dreamless sleep experience, which is, after all, thought to be devoid of such content, such worries about censorship do not seem to apply.

⁶ I owe this term to Sascha Fink; see for instance Fink 2015, p. 23; for discussion, see Windt 2015, p. 92.

⁷ As Solomonova et al. (2014) note, it is important to distinguish questions about the range of possible experiences in dreams (or the "depth" of dreaming) from those about their typical characteristics in the general population (or the "breadth" of dreaming), and what counts as the ideal reporting conditions in the context of a given study depends on which of these questions is being addressed. For now, note that because expertise is likely most useful for answering questions about the depth of experience, and because expert reports may not be representative of the breadth of the target phenomenon, broadening the investigation of dreamless sleep experience beyond expert groups is an important goal for future research.

cusing on the veridicality of individual reports, the strategy is to identify which types of reports are best tailored to a given question and under which conditions they are most likely to be obtained. The problem of identifying individual reports of a certain type for which this strategy has failed is thus not obliterated, but minimized.⁸ What is more important is that there is, in this view, a distinction to be drawn between *general opinions* about experience and *reports of individual experiences*. Note that reports, in this context, are broadly construed as the product of (verbal or nonverbal) behaviors con-

ducted with the *sincere intent of conveying or recording certain relevant information about a specific dream* (for details, see Windt 2015, chap. 3.3) Questionnaires asking participants to assess the general frequency with which, for instance, they dream in color do not count as experience reports in this narrow sense. Indeed, there are good reasons for doubting the trustworthiness of responses to such general questionnaires, and in some cases, they have even been shown to be at odds with individual reports (Schwitzgebel 2002, 2011, chap. 1; Windt 2013, 2015, chap. 4.3). At best, such general questionnaires tap into opinions about experience, but whether these opinions match the phenomenal character of the corresponding experiences is a separate question. Importantly, questions about the relative trustworthiness of responses to general questionnaires can be meaningfully investigated only if the trustworthiness of at least a subgroup of dream reports is assumed (Windt 2015, chap. 4.4). This subgroup can then act as a baseline and can be used to determine the relative trustworthiness of answers to general questionnaires, but also of different types of reports. While the exact details continue to be debated (for instance on the laboratory effect), there is widespread agreement in scientific dream research that dream reports gathered immediately upon awakening, as is common in laboratory studies using timed awakenings from different sleep stages, are the gold standard against which other types of dream reports (such as home dream diaries compiled following spontaneous awakening) can be measured (again the debate on dream color is a good example; see Hoss 2010; Murzyn 2008; Schredl et al. 2008).

Importantly, as discussed earlier, the assumption that dream reports are trustworthy translates into a research strategy only if reports of nondreaming are taken to be equally trustworthy as reports of dreaming, at least when they are gathered under the same conditions. If the reporting conditions used in a given study are (sufficiently) ideal, it would, surely, be arbitrary to disqualify a subset of these reports on the basis of their content alone. In order to do so, some independent reasons for at-

⁸ Strictly speaking, it cannot be ruled out that even for reports obtained under seemingly ideal conditions—for instance immediately after awakening, and using appropriately worded questions—certain subject groups are particularly prone to memory failure or confabulation (Rosen 2013), or that results are distorted because of further disturbing factors that have so far been overlooked. The challenge will then be to identify such potentially disturbing factors, manipulate them experimentally, and derive certain predictions on how they will affect data obtained from the analysis of dream reports. These factors can then be integrated into a future, improved and more empirically plausible account of the ideal conditions of dream reporting. For now, my main point is that this strategy only makes sense if one already assumes that some subset of dream reports can be used as a baseline against which other, less trustworthy ones can be measured. The study of dream emotions is a nice example of how this strategy has been put to work in dream research. Views on the both the frequency and the types of emotions experienced in dreams have changed quite dramatically as new methods of collecting and scoring dream reports have been developed. Whereas older studies using classical dream content analysis suggested that dream emotions are relatively rare (Hall & Van de Castle 1966), the frequency of reported dream emotions increases tenfold when subjects are specifically asked to report their emotions on a line-by-line basis (Merritt et al. 1994). Affirmative probes of this sort suggest that dreams are “hyperemotional”, with emotions being mentioned in 95 percent of dream reports and the average dream report containing several different types of emotions. A plausible explanation is that dream emotions are underreported in free dream reports of the type used in older studies; free dream reports, in this view, are insufficient to capture the actual frequency of dream emotions. Until very recently, the accepted view was that the types of emotions experienced in dreams differ from those experienced in wakefulness in that dream emotions are predominately negative (Hobson et al. 2000). However, a recent study compared external ratings of emotions in dream reports to scores obtained when participants answered a standard emotion questionnaire themselves. Sikka et al. (2014) found that external ratings underestimate not only the frequency but also the types of emotions experienced in dreams. A particularly surprising result was that self-ratings showed positive dream emotions to be six times more frequent than negative ones. The systematicity of the differences is compelling and the same pattern was found in a number of follow-up studies (Sikka et al. 2014), suggesting that the use of self-ratings is a more reliable method for capturing the frequency and types of dream emotions than the use of external raters. This is not so say that the conditions for reporting and scoring dream emotions cannot be further improved. But this example does illustrate that theoretical views on dream emotions changed in tandem with changed and likely improved reporting and scoring conditions. Again, the idea is that methodological adjustments can obscure or render visible different aspects of the phenomenology of dreaming.

tributing reports of nondreaming to disturbing factors would be needed. It does not make sense to trust dream reports, but selectively distrust reports of nondreaming gathered under the same conditions and in the absence of any empirical evidence for distrusting them. Put differently, dreams will have to be regarded as reportable experiences, in the sense that given sufficiently ideal reporting conditions, their presence or absence, respectively, can actually be reported. Importantly, both assumptions are implicit in the scientific investigation of dreams. A brief excursion into the history of philosophical and scientific theorizing about sleep and dreaming illustrates this point.

The beginning of scientific dream research coincided with a new experimental paradigm: the practice of obtaining polysomnographic measurements of EEG activity, muscle tone and eye movements from subjects sleeping in the sleep laboratory and of obtaining mentation reports following timed awakenings. This methodology revealed reports of dreaming to be most frequent following awakenings from REM (rapid eye movement) sleep, whereas awakenings from NREM (non-REM) sleep were typically followed by an inability to recall any dreams. In their groundbreaking paper on the correlation between dreaming and REM sleep, [Aserinsky & Kleitman \(1953\)](#) optimistically claimed that that the method of timed awakenings from REM sleep “furnishes the means of determining the *incidence and duration of periods of dreaming*” ([Aserinsky & Kleitman 1953](#), p. 274; my emphasis).⁹ They very naturally took the reports given by their subjects to reflect conscious experience during the preceding sleep period, noting that “of 27 interrogations during [sic] ocular motility, 20 revealed detailed dreams usually involving visual imagery” ([Aserinsky & Kleitman 1953](#), p. 273; my emphasis). Because the method of obtaining reports following timed awakenings in the laboratory is, arguably, the backbone of scientific dream research, this assumption is not unique to Aserinsky and Kleit-

man’s original study. Instead, scientific dream research generally relies on the assumption that dream reports (at least when gathered under ideal reporting conditions, of which timed awakenings in the laboratory are taken to be a prime example) are epistemically transparent in the sense that they are trustworthy sources of evidence about the occurrence and phenomenal character of experience during sleep. I call this the *transparency assumption* ([Windt 2013, 2015](#)).¹⁰

It is important to see that on its own, the transparency assumption would be insufficient to establish the presumed correlation between dreaming and REM sleep. Claims about the sleep-stage or neural correlates of dreaming require that reports of dreaming and of nondreaming, when gathered under the same conditions, are equally trustworthy: if only reports of dreaming were trustworthy, but reports of nondreaming were not, then the analysis of dream reports would be insufficient to determine the occurrence and frequency of dreams during different sleep stages. Saying that dream reports are transparent is not quite enough: one will also have to assume that dreams are reportable experiences in the sense that had any dream occurred in a given sleep stage, one would in fact be able to report it, at least under sufficiently ideal reporting conditions. I call this the *reportability assumption* (for details, see [Windt 2015](#), chap.s 3 and 4). Only this added assumption casts reports of dreaming and of nondreaming as equally trustworthy and thus enables reports to be indicative of the occurrence and frequency of dreaming in different sleep stages. The emerging picture is that scientific dream research not just uses dream reports, *under the assumption of transparency*, to investigate *conscious experience during sleep*, but that in doing so, it is also *methodologically constrained by the space of reportable dreams*. Its implicit commitment to the

¹⁰ Here, I use the concept of epistemic transparency in a non-technical and metaphorical sense, intending to capture the intuition that dream reports are the closest researchers can come to “watching the sleeping mind” ([Cartwright 2010](#), p. 17). The choice of terminology also reflects the fact that dream reports are not identical with, but better conceived of as separate from dreaming. Finally, transparency is a nod to the historical situation that the theoretical problems raised by dream reporting were nearly invisible throughout most of the history of philosophical theorizing about dreaming.

⁹ Today, it is widely recognized that dreams can occur in all stages of sleep and are not exclusively a REM sleep phenomenon. Incidentally, this recognition may also lead to refined sleep-stage scoring systems and a blurring of the borders between REM and NREM sleep ([Nielsen 2000](#); see also [Windt 2015](#), chap. 2).

trustworthiness of reports of dreaming and of nondreaming means that it cannot go beyond what is in fact reported without risking internal inconsistency; it can only strive to render further aspects of dreaming reportable. Metaphorically speaking, the space of reportable dreams can be expanded; it can be broadened to cover more aspects of what characterizes typical dreams, or perhaps also to include more diverse types of dreams; and it can be deepened, by probing the unique aspects of certain types of dreams (such as nightmares) or the dreams of certain subject groups (such as meditators) in more detail (see [Solomonova et al. 2014](#)). Importantly, this reliance on dream reports is not a liability, a problem to be overcome: it is built into the very nature of dream research. Conversely, studies relying only on the polysomnographic analysis of sleep stages and/or neuroimaging data gathered independently of dream reports do not form part of dream research proper ([Windt 2015](#), chap. 3.2).

How does this account of dream reporting help address the objections to Thompson's argument discussed at the end of the last section? The strategy of focusing on reports gathered under (sufficiently) ideal reporting conditions and working towards a continuous improvement of these conditions is clearly relevant to the first objection, according to which the mere possibility of veridical reports is not enough. As soon as we broaden our focus from reports of dreamless sleep experience to reports of sleep experience (including dreams) more generally, it becomes clear that scientific dream research has long been centered on the project of identifying and optimizing the trustworthiness of such reports, as well as on determining the adequacy of different kinds of reports for addressing various research questions. Indeed, the very existence of scientific dream research hinges on the assumption that this can be done. Moreover, we have seen that the assumption that reports of dreaming and of nondreaming are equally trustworthy is implicit in this research strategy. This assumption is directly relevant to the second objection, according to which reports of dreamless sleep experience can be

used for the investigation of dreamless sleep experience only if they help detect both its presence and its absence.

Moreover, this proposal is, I think, compatible with Thompson's own strategy of focusing on reports from certain expert groups and improving the wording of questions. Indeed, this strategy of directing participants' attention to certain aspects of their experience rather than asking for a free report nicely parallels recent work suggesting that a self-scoring method, where participants respond to a standard questionnaire, for instance, about the emotions experienced in a particular dream, is a better measure of dream emotions than data obtained by external raters scoring free dream reports ([Sikka et al. 2014](#); see footnote 8 for discussion). This suggests that Thompson does not mean to reject, as a matter of principle, the claims that conscious experiences are reportable and that an absence of memory is sufficient to infer an absence of experience. Rather, I think his position involves the weaker claim that we should not easily and uncritically trust just any type of experience report to actually reflect the presence of such experience, nor should we easily and uncritically trust just any failure to remember previous experience as indicating an absence of such experience. But this weaker position is in keeping with the account of dream reporting outlined in this section. The challenge then becomes how to narrow the gap between experiences that are in fact reported and those that could (and would) be reported, given sufficiently ideal conditions. I think this is exactly the problem that large parts of report-based dream research are already trying to address.

Note that nothing I have said so far suggests that the transparency and reportability assumptions are theoretically justified (but see [Windt 2013, 2015](#)); if my analysis is correct, however, both are implicit in and in fact crucial for the entire field of scientific dream research. This shifts the burden of proof: while reports of dreamless sleep experience may seem to be an easy target, if only because of the novelty and alleged remoteness of Thompson's proposal for investigating dreamless sleep experience, we can now see that the proponent of the default view

will in fact have to take on the entire field of (report-based) scientific dream research as well. This raises the bar considerably; but first, more has to be said about how the methodological background assumptions of scientific dream research actually parallel questions asked in the classical Indian debate.

To begin with, note that the transparency assumption is analogous to the Advaitin and Yoga claim that upon awakening from dreamless sleep, we can veridically remember and report that we experienced nothing during sleep. To be sure, this type of report describes an experience marked by the absence of the complex imagery and narrative contents that characterize dreaming. Yet, in the Advaitin view, these are reports of an experiential state: in reporting having slept dreamlessly, we are reporting that we *experienced* nothing, in the relevant sense, during sleep;¹¹ we are not reporting the absence of experience. Thompson suggests that in order to turn the Advaitin view into a research strategy, the most reasonable and cautious approach is to assume that dreamless experience exists only intermittently, rather than persisting throughout dreamless sleep. The frequency with which dreamless sleep experience is reported to occur upon awakening will then be regarded as indicative of the actual occurrence of such experience. This is analogous to the reportability assumption. To endorse the stronger claim that dreamless sleep experience persists throughout sleep, at least prior to empirical investigation, would be to legislate an answer to the question of dreamless sleep experience. The weaker claim complements the assumption, implicit in scientific dream research, that periods of dreaming contrast with periods of nondreaming, which is quite different from saying that dreaming persists throughout sleep.

By combining my analysis of the methodological background assumptions of scientific dream research with Thompson's proposal on

the investigation of dreamless sleep experience, we can see that if we were to translate the Yoga and Advaitin view into a research methodology, we would find it to rely on assumptions that run parallel to those of scientific dream research. Dreamless sleep experiences, or so a modern-day, scientifically-minded Advaitin would be forced to admit, are reportable experiences; and if it should happen that (under sufficiently ideal reporting conditions, such as immediately after having awakened from sleep) one were unable to recall any such experience having happened during sleep, this would indicate that no such experience had occurred.

This also tells us that reports of non-dreaming should be further qualified: reporting the absence of experience during sleep is not the same as reporting dreamless sleep experience. The former is an instance of reporting an absence of experience, the latter is an instance of reporting a form of experience characterized by the absence of intentional objects; but it is still an experience report. Yet, while this requires terminological adjustments and shows that the concept of reporting a state of nondreaming is ambiguous, this adjustment is consistent with the familiar methodology; indeed, it falls out of the methods already used in dream research, when they are applied to the target of dreamless sleep experience.

From this, we can conclude that the default view of dreamless sleep as being characterized by the absence of subjective experience is intrinsically flawed for two related reasons. The first is that by treating dreamless sleep experience as a conceptual absurdity rather than as an open and empirically tractable question, it misconstrues the nature of the question of dreamless sleep experience. The second is that it stands in outright contradiction to the assumptions implicit in the scientific investigation of conscious experience during sleep. Dream research, understood as the scientific investigation of conscious experience during sleep, should be expanded to include dreamless sleep experience as well. And while this certainly will involve an adjustment of its conceptual resources, the good news is that its existing methodological background assumptions can remain largely intact.

¹¹ At this point, it might be objected that this formulation rides on a reification of the word "nothing", as if "nothing" itself could be turned into an object of experience. I return to this problem in section 4; as will hopefully become clear, my own positive model of dreamless sleep experience avoids this problem by introducing a qualified reading of what is described, in the Advaitin view, as experiencing or knowing nothing.

3.2 The Indian debate revisited: Lessons for the philosophical debate on the trustworthiness of dream reports

The analogy between the Indian debate on dreamless sleep experience and the background assumptions of scientific dream research not only highlights the inconsistency of the default view. There are also valuable lessons to be learned in the other direction, and considering the historical Indian debate can enrich contemporary debates on the status of dream reports as well. In particular, note that it is one thing to say that scientific dream research is implicitly committed to the transparency and reportability assumptions; but it is another to say that these assumptions are also theoretically justified. Elsewhere, I have defended the view that explanatory considerations justify the transparency and reportability assumptions: construing dream reports as (largely veridical) memory reports provides a *better explanation* of dream reporting behavior than skeptical alternatives that construe dream reports as the result of inference, misremembering or outright confabulation (Windt 2013, 2015, chap. 4). Here, I want only to point out that similar considerations apply to reports of dreamless sleep experience. In fact, Thompson's response to the Nyāya argument against dreamless sleep experience shows that casting reports of having slept dreamlessly as based on inference rather than memory is not a proper explanation at all. Instead, it leads to an argument that either results in an infinite regress or is circular. Again, there is a striking similarity to a similarly skeptical account of dream reporting from the 20th century. This time, the analogy with the historical Indian position will lend additional support to anti-skepticism about dream reporting.

To see why, another brief excursion into the history of theorizing about scientific dream research is instructive. Let us consider Norman Malcolm's (1956, 1959a) skeptical argument against the claims that dreams are conscious experiences occurring during sleep and that dream reports transparently show this to be the case. This argument was a direct reaction to early attempts, following the discovery of REM sleep,

to operationalize dreaming as a REM sleep phenomenon. Malcolm's argument hinges on the conceptual claim that "if a person is in *any* state of consciousness it logically follows that he is not sound asleep" (Malcolm 1956, p. 21). According to Malcolm, even though we use the same language to describe dreams and waking experiences, dreams (or at least such dreams as occur during sound sleep, which Malcolm, again for conceptual reasons, takes to be representative of dreaming proper) are not experiences, and for the same reason dream thoughts, feelings, and emotions are not real instances of their kind. As Malcolm puts it,

if a man had certain thoughts and feelings in a dream it no more follows that he had those thoughts and feelings while asleep, than it follows from his having climbed a mountain in a dream that he climbed a mountain while asleep. (Malcolm 1959a, pp. 51-52)

Malcolm's view is complex and a detailed discussion is beyond the scope of this commentary; suffice it to say that one of its more controversial upshots is that dream recall is not a real instance of remembering experience during sleep. Instead, "statements of the form 'I dreamt so and so' are always inferential in nature" (Malcolm 1959a, p. 65): one infers that one has dreamt when one realizes, upon awakening, that the events one seems to remember did not in fact occur. This claim struck many of his critics as contradicting both the common-sense understanding and the phenomenology of dream recall (see Dunlop 1977 for a collection of some of the most important critical essays; see Windt 2013, 2015, chap. 1 for discussion). Elsewhere, (Malcolm 1959b) explains that he takes dream recall to be inferential not in the psychological sense of actually drawing this inference when we notice that we have dreamt, but in the sense that we could give grounds for our belief that we dreamt if pressed to do so. However, because he fails to clarify what exactly these grounds are, his account remains sketchy. By applying Thompson's reconstruction of the Nyāya syllogism to Malcolm's claim, it quickly becomes

clear that even a more complete reconstruction of the inference would be intrinsically flawed. The result would be something like this:

1. While I was sound asleep, I had no experiences, including sensations, conscious thoughts, feelings, beliefs, or emotions.
2. This is because (i) I was in a special state (that is, not awake) or (ii) I lacked the necessary means for having experiences, including sensations, conscious thoughts, feelings, beliefs, or emotions (that is, my senses and mental faculties were shut down).
3. Whenever (i) I am in a special state (that is, whenever I am not awake) or (ii) I lack the necessary means for having experiences, including sensations, conscious thoughts, feelings, beliefs, or emotions (whenever my senses and mental faculties are shut down), I do not have experiences, including sensations, conscious thoughts, feelings, beliefs, or emotions.
4. As in the case of fainting or a blow to the head.
5. While I was sound asleep, I had no experiences, including sensations, conscious thoughts, feelings, beliefs, or emotions.

Malcolm concludes that sound sleep is comparable to other states of unconsciousness, and “to a person who is sound asleep, ‘dead to the world,’ things cannot even seem” (Malcolm 1956, p. 26).

If we follow this reasoning, then dream reports cannot ever be veridical experience reports: if we cannot have thoughts, feelings or emotions during sleep, then we also cannot have them during dreams, and we cannot actually remember (or veridically report) having had them after awakening. Rather, we sometimes awaken with the impression of having had such thoughts, feelings and emotions during sleep; and when we realize that they did not in fact occur, we infer that we dreamt.

To be fair, there might well be cases in which dream recall does have such an inferential nature. To use Malcolm’s example, it seems possible that I could awaken with the particularly vivid impression of having climbed a mountain

and then might realize, from the simple fact that I was lying in bed and nowhere near a mountain, that I had not actually climbed a mountain, but had been asleep. However, even if I was now quite sure that I had merely dreamt that I had climbed a mountain, it would not follow that the thoughts and feelings I remember having in the dream did not really occur. In order to draw this further inference, I would have to know that dreaming is a special state that is devoid of any experiences whatsoever.¹² As is the case for the Nyāya syllogism, this immediately invites the dual threats of circularity and of infinite regress: If I say I was in a special state because the thoughts and feelings I experienced in my dream were not real instances of their kind, I am reasoning in a circle. And if I say that I was in a special state because the mental faculties required for having thoughts and feelings were shut down (or because, as would better befit Malcolm’s argument, I had temporarily lost the capacity for producing the types of behavioral evidence that would enable another person to verify that I had been dreaming), then independent evidence would be needed—and so on. Again, without appealing to memory, no such evidence is available.

At this point it might seem that there is an easy solution: Perhaps, independent evidence for saying that dreaming is a special state has, in the meantime, become available. Malcolm’s analysis of dreaming was a direct reaction to early studies, discussed in section 3.1, on the correlation between REM sleep and dreaming, and his argument made much of the alleged impossibility of acquiring independent evidence,

¹² Incidentally, note that if it were the case that dreams are devoid of any experiences whatsoever, it would be utterly mysterious why we should awake with the vivid impression of having had such experiences in the first place. Indeed, Malcolm provides no explanation of why this happens. By contrast, my erroneous impression of having climbed a mountain during sleep is nicely explained by saying that during sleep, I had experiences that were sufficiently similar to their waking counterparts to create this impression. Again, this comes back to the idea that explanatory considerations favor the view that dream reports are actual memory reports, and not inferential. Perhaps, the difference between dreams that are belief-inviting beyond the borders of sleep, for instance by making us actually believe, if only for a moment, that the corresponding events actually occurred, and more commonplace dreams that do not induce such false beliefs can even be described in phenomenological terms (for a first proposal of how this might be done, see Windt 2015, chap. 10).

over and above dream reports, for the occurrence of dreams during sleep. Among Malcolm's critics, there was widespread agreement that he was simply mistaken about this latter point: sleep behavior, (for instance in patients with REM sleep behavior disorder, who are thought to act out their dreams due to a loss of REM sleep-related muscular atonia; see [Schenck 2005](#), [Valli et al. 2012](#)) sleep talking, and also polysomnographic measurements were (and continue to be) thought to provide exactly such independent evidence, perhaps even to the point of enabling researchers to verify dream reports (see for instance [Ayer 1960](#); [Rosen 2013](#); signal-verified lucid dreams are another example, as proposed by [Revonsuo 2006](#); see sec. 5.1 for a fuller discussion). Yet, even though the appeal to scientific dream research slightly changes the content of the argument, this merely restates the familiar syllogism, including its problems in a new guise.

To see why, let's say that rapid eye movements had indeed been found (as stated by the so-called scanning hypothesis; see [Dement & Kleitman 1957](#), to be directly related to visual dream imagery. Could we now analyze these eye movement patterns to diagnose the occurrence (and perhaps even the content) of dreaming even in the absence of (or in contradiction to) dream reports (see [Dennett 1976](#) for the discussion of this possibility)? Note that this is not an abstract philosophical issue: dream researchers have long dreamt the dream of moving beyond dream reports in the study of dreaming altogether. This ranges from science fictional visions of televising dreams ([Hall & Van de Castle 1966](#)) or of perhaps modeling them as an immersive, interactive virtual environment, as in [Antti Revonsuo's](#) (2006, pp. 300-303) dream catcher test, to real-world attempts to predict the content of dream reports from behavioral ([Leclair-Visonneau et al. 2010](#)) or neuroimaging ([Horikawa et al. 2013](#)) data. Again, the idea is that in the future, the analysis of neuroimaging data might be a way to verify dream reports, or even to move beyond their collection and analysis altogether. Elsewhere, I have argued that such attempts are circular: Dream reports, under the assumption of transparency, are used to

identify potential sleep-stage and neural correlates of dreaming; but the evidence such potential correlates provide is only as strong as the correlation, and so one cannot then turn around and use such measures as independent evidence to verify dream reports. Now, the Nyāya syllogism and its failure present a nice and crisp illustration of why this is the case. I think this is a nice example of the fruitfulness of a cross-cultural perspective on the methodological and conceptual issues involved in studying the occurrence of consciousness during sleep.

But there is another lesson to be learned. This is that the Nyāya syllogism is not an outdated problem, but one that persists even if we place it in the context of scientific dream research. The question of whether reports of having slept dreamlessly are experience reports or inferential is not of mere theoretical interest, but makes a real difference: assuming such reports, at least when given under ideal reporting conditions, to be veridical memory reports is the condition for a report-based scientific investigation of the relevant experiences in the first place. The historical debate, and [Thompson's](#) reconstruction of it, nicely highlights the need for acknowledging the relevance of first-person reports. Together, they also strengthen the theoretical case against skepticism about the trustworthiness of dream reports. With this anti-skeptical account in place, we can now move forward. In the next section, I sketch the outlines of a conceptual framework for describing dreamless sleep experience and its relation to dreaming.

4 From minimal phenomenal selfhood to minimal phenomenal experience: Towards a conceptual model of experience during dreamless sleep as pure subjective temporality

If what I have said so far is on the right track, then the question of whether dreamless sleep, at least on occasion, involves phenomenal experience is open to empirical investigation, and progress towards answering it can be made by applying the methods already used in scientific dream research, for instance by combining

timed awakenings in the sleep laboratory with questionnaires that are carefully calibrated to direct participants' attention towards the relevant features of such experiences and facilitate their reportability. Even occasional reports of dreamless sleep experience will support the claim that dreamless sleep experience exists. The next step towards turning the question of dreamless sleep experience into a scientifically tractable research project is to draw a more precise conceptual map of the territory. Sketching at least the rough outlines of such a conceptual map is my aim in this section.

Thompson's reconstruction of the classical Indian debate as well as his own positive proposals for how to study dreamless sleep experience provide a helpful point of departure. To begin with, as [Thompson](#) points out, the concept of dreamless sleep itself requires phenomenological refinement (p. 13). If dreamless sleep experience exists, then it is not enough to characterize dreamless sleep by the absence of dreaming or its electrophysiological correlates. Rather, dreamless sleep can now be seen to be a blanket term covering different types of conscious and nonconscious mental activity. Some forms of conscious mental activity that are commonly contrasted with dreaming (and in this simple sense can be said to occur in dreamless sleep), such as hypnagogic imagery during sleep onset or repetitive and non-progressive types of sleep thinking, are not candidates for the kind of dreamless sleep experience described in the Indian debate. Dreamless sleep experience in this narrow sense, if it exists, is a form of phenomenal experience characterized by nonintentional awareness ([Thompson 2015](#), p. 2): "When we're deeply asleep [...] we don't cognize anything—there's no object being cognized and no awareness of the 'I' as knower. Nevertheless, [...] we feel this absence while we sleep and remember it upon awakening" ([Thompson 2015](#), p. 238). Dreamless sleep experience is not just characterized by the absence of certain object-directed forms of conscious experience, but by the fact that this is an *experienced* absence. Moreover, it is not just the objects of experience that are absent, but also the subject of experience, or the "I". A very basic experiential fea-

ture, namely that of being an epistemic agent or a potential possessor of knowledge, has been lost (cf. [Metzinger 2013](#) for a fuller discussion of the term of an "epistemic agent model"). Dreamless sleep experience is characterized by a dissolution of subject-object duality, or, to put a more contemporary gloss on this, by a breakdown of even the most basic form of the self-other distinction ([Windt et al. 2014](#)).

This last point is important because it suggests a way of differentiating between dreaming and dreamless sleep experience. Many different definitions of dreaming exist—indeed, the lack of a uniform definition is an important desideratum for theoretical and experimental work on dreaming—but work on dreaming in philosophy of mind often focusses on a structural feature of dream experience. The assumption that dreaming involves the experience of a self in a world marks a point of convergence for philosophers of different stripes, ranging from contemporary philosophers of mind working towards an empirically informed theory of dreaming ([Metzinger 2003](#); [Revonsuo 2006](#)) to authors working in the tradition of classical phenomenology ([Husserl 2006](#); [Conrad 1968](#)).¹³ Studies have shown that an overwhelming majority of dream reports describe the presence of a dream self ([Strauch & Meier 1996](#)) though the precise way in which the dream self is represented is variable ([Occhionero et al. 2005](#); [McNamara et al. 2007](#)). The description of dreams as involving not just a self in a world, but an intersubjective world has even informed theories on the functions of dreaming (see for instance

¹³ Note that this way of thinking about phenomenal selfhood is quite different from the way the term "self" is used in the classical Indian literature. In his reconstruction of the Advaita Vedānta concept of witnessing, [Fasching \(2010\)](#) notes that the "witness" (sāksin) is not understood as an observing entity standing opposed to what it observes, but as the very taking place of 'witnessing' itself, and 'witnessing' is nothing other than the taking place of the experiential *presence* of the experiences, in which the experiences have their very being-experienced and thereby their existence." (p. 204) In this conception, "the 'self' is nothing other than becoming aware of experiential presence (consciousness) as such" (p. 207); it is "not a structural moment of what is given, but is the *very taking place of givenness itself*" (p. 210). Recall that one of the points of agreement between the Advaitins and the Nyāyas was that the self persists throughout sleep. But this is not the reading of the concept of "self" that [Thompson \(2014](#); see for instance chap. 10) has in mind when he says that in dreamless sleep experience, there is no longer an awareness of the "I", or what I mean when I speak of phenomenal selfhood.

Revonsuo et al.'s 2015 theory of dreaming as a simulation of social reality). Importantly, the description of dreaming as the experience of a self in a world also informs Thompson's own work on dreaming. In *Waking, Dreaming, Being*, he tells us that "the core feature of full-blown dreaming is the experience of immersion in the dream world" (Thompson 2014, p. 127), and also that this immersive quality is exactly what distinguishes hypnagogic imagery during sleep onset from dreaming (pp. 135ff.). The hypnagogic state is a state of absorption, in which attention is fully captured by a series of dynamically changing and often short-lived images; "the hypnagogic state blurs the boundaries between inside and outside, self and world" (p. 124).

This description coincides nicely with my own theoretical work on dreaming. Elsewhere, I have argued that the analysis of self-experience is the key towards understanding not just different types of dreaming (Windt 2010, 2015, chap.s 11 and 12), but also the relationship between dreaming and waking experience. In this view, the common denominator underlying different types of dreams, such as lucid and nonlucid dreams, but also nightmares and false awakenings is their immersive quality. Even in simple forms of dreaming, there is still a sense of presence, a phenomenal *here*, or the sense of being located at a specific point in space, as well as a sense of duration centered on a phenomenal *now*. This basic structure is preserved even when the features that characterize a majority of dreams, such as interaction with non-self dream characters, objects, emotions, or even visual imagery are lost. In such minimal dreams, phenomenal selfhood takes the form of pure spatiotemporal self-location, arising independently of more complex forms of phenomenal selfhood that involve the experience of being a thinking self and embodied agent. There may even be the experience of phenomenal disembodiment, or of lacking a body, and the dream self may be experienced (and later described) as an abstract, undefined volume of indeterminate extension or even as an unextended point in space. Even though this sense of identification with a phenomenal *here* and *now* in-

volves a drastically reduced form of phenomenal selfhood, it is still sufficient to ground retrospective claims of having had a self in dream reports. The basic structural feature of a self that is experienced as distinct from and located at a precise point within the world is preserved. To be sure, the locus of self-location and self-identification is more fluid in dreams than in wakefulness—the phenomenal *here* is subject to sudden shifts, and sometimes, we identify with a dream character or even a series of dream characters that are quite distinct from our waking self (Rosen & Sutton 2013). Yet, as long as there still is a world experienced as distinct from the self, at least a basic form of the self-other distinction continues to exist.

Within this framework, immersive spatiotemporal hallucination, or self-location with respect to a largely nonveridical, spatiotemporal reference frame, marks the cutoff line between dreaming and nondreaming. It also helps isolate and empirically ground minimal phenomenal selfhood (Blanke & Metzinger 2009), or the simplest conditions under which the experience of being or having a self arises. Here, I would like to suggest that this framework can be extended to dreamless sleep experience as well. A very basic point is that we can now sharpen the claim that dreamless sleep experience is a selfless state. Within the present framework, in order for dreamless sleep experience to count as selfless, even the basic form of self-other distinction that underlies spatiotemporal self-location must be lost. The next step is to consider the spatial and the temporal characteristics of self-location independently of each other and ask whether either of them, considered on their own, would be sufficient to give rise to phenomenal selfhood. An affirmative answer would mean that we had not yet identified the phenomenal signature of dreamless sleep experience; an even more simplified account would be needed.

Considering the spatial and temporal aspects of self-location separately, there seems to be a strong conceptual link between the phenomenal *here* and the sense of being located in and relative to a larger spatial expanse. A spatial reference frame, according to the present

theory, turns into an experienced world when it is centered on a phenomenal *here*, which in turn is identified as the self. The spatial variant of presence thus seems to have the self, or some rudimentary form of self-other distinction, written into it. Moreover, the attempt to conceive of an experience characterized by a phenomenal *here* but lacking any temporal characteristics whatsoever strains the limits of conceivability. Speaking of an experience that is both instantaneous, lacking any temporal extension, and fails to have temporal location seems to be a contradiction. It is not clear how this could count as an experience at all, and even less how it could count as a reportable one.

By contrast, the phenomenal *now* does not appear to carry the same conceptual commitments. At least intuitively, the notion of a form of temporal experience that is independent of and perhaps more basic than the experience of being or having a self seems more acceptable than that of an immersive but nonetheless selfless form of spatial experience. Moreover, we can at least conceive, it would seem, of a phenomenal *now* that fails to be differentiated from or clearly located relative to a larger temporal reference frame.¹⁴ And we can also, it would seem, conceive of an experience characterized only by temporal but not by spatial characteristics. Thinking, for instance, is not always experienced as having spatial location (as in thoughts occurring in one's head), but it certainly has temporal dynamics.¹⁵ Spatiality does not seem to be essential to phenomenality in quite the same way as temporality.

Note that I do not intend these conceptual considerations to carry too much weight. In the framework I am working towards, conceptual

distinctions are informed by differences in the structure of phenomenal experience and such differences should at least in principle be memorable and describable, for instance in dream reports or reports of dreamless sleep experience.¹⁶ I also think that the most empirically plausible view will allow for gradual transitions between states involving a phenomenal self and those retrospectively described as selfless; and the same may also be true for the emergence of the simplest forms of phenomenal experience. If this is correct, then we should expect there to be a certain amount of uncertainty when dealing with borderline cases. Where exactly to draw the cutoff line for minimal phenomenal selfhood in a given case may well be hard (if not impossible) to determine; but even so, it might still be useful to introduce a conventional cutoff line (for instance by saying that minimal phenomenal selfhood involves both the spatial and the temporal aspects of self-location) if this helps pick out a theoretically meaningful transition in the structural features of experience and guides future research in a constructive manner. We will also expect such a theoretical conception to be reasonably well aligned with the way such experiences are described in retrospective reports.¹⁷ I think that both types of considerations support the claim that spatiotemporal self-location can be meaningfully described as a minimal form of phenomenal selfhood, or at least as a theoretically salient point of transition on the trajectory from states described as

¹⁶ This is not to deny that experiences (or qualitative aspects of experiences) could exist that are beneath the cutoff line of memorability and reportability. Certain subtle aspects of phenomenal experience, such as hues of color, do seem to outrun our ability to categorize and reidentify them over time (Raffman 1995). Here, I am only claiming that such subtle aspects of experience are not candidates for the report-based type of scientific investigation I am interested in here.

¹⁷ This is a prediction, and different subjects may mean different things when they describe an experience as selfless. For some this may mean an experience characterized by spatiotemporal self-location, but in which they had the experience of being a disembodied entity (cf. Windt 2015, chap. 7); others may describe episodes characterized only by their temporal features as involving a self. There is also the familiar problem that reports of selfless experiences easily slip into a performative self-contradiction, of the type "I had a dream in which I was not present"; such episodes are clearly remembered and reported by someone. But we should not expect the folk-psychological use of terms such as "I" or "self" to align perfectly with a particular technical definition. This is a good example of where specific interview questions might increase the expressive granularity of retrospective reports.

¹⁴ In fact, if we conceive of temporal experience as involving a specious present, we might say that the phenomenal *now* simply is identical with a rudimentary form of a temporal reference frame. I return to this point later. Alternatively, if we conceive of temporal experience as consisting of a series of unconnected moments that themselves have no temporal extension, then again it would seem that each of these could occur in isolation and without being embedded in a larger temporal reference frame.

¹⁵ This phenomenological observation is reflected in the classical idea that the mind cannot be spatially located in the physical world. Mental states persist over time, but they do not have spatial characteristics such as expansion or separable parts. Perhaps, this phenomenological observation lies at the root of metaphysical claims about the relationship between mind and body.

selfless to states involving self-experience in a fuller sense. By contrast, the phenomenal *now*, when it arises independently of spatial self-location, is a candidate for a structural feature of phenomenal experience that provides the conditions of possibility for self-experience but that when occurring on its own is still prior to it. I would like to suggest, then, that pure subjective temporality is a candidate for minimal phenomenal experience; it is a condition for but still more basic than minimal phenomenal selfhood. It can be described as subjective only because it involves phenomenal experience; yet, it does not involve the additional experience of being a self, or a separate entity having the experience.¹⁸

There is, of course, a rich philosophical debate on the nature of time experience, as well as a large empirical discussion (for an introduction, see [Dainton 2010](#); [Arstila 2014](#); [LePoidevin 2015](#)). I cannot begin to do justice to this literature here, but want only to focus on one specific aspect. This is the idea, which we find in William James as well as in Husserlian phenomenology, but also in the neuroscience of time consciousness (see for instance [Pöppel 2003](#)), that even the smallest unit of temporal experience, the temporal *now*, is extended rather than instantaneous.¹⁹ Following this con-

ception, a rudimentary form of duration would be intrinsic to the phenomenal *now*; and neuroscientific work seems to suggest that this temporal *now* is itself variable ([Wykowska & Arstila 2014](#)). The window of simultaneity, or the maximum time-frame within which two different events are experienced as occurring *now*, is modality-specific. The cutoff line for two stimuli being experienced as simultaneous is, for instance, larger for visual stimuli than for auditory ones. As [Wykowska & Arstila \(2014, p. 443\)](#) note,

it might be that a relatively broad window of simultaneity is actually beneficial. The human brain needs to exhibit some degree of tolerance to asynchronous stimuli in order to be able to bind different sensory inputs into one event. The window of simultaneity can be seen as an integration window for stimuli and, as such, is a necessary mechanism for binding signals from different pathways into one single object or event.

Human temporal resolution is flexible, it is easily affected by attentional processes as well as by training and expertise ([Wykowska & Arstila 2014](#)). Duration perception might be state-dependent as well, showing characteristic changes in altered states of consciousness and psychiatric disorders ([Noreika et al. 2014](#)); and perhaps the same is true for the degree to which the experienced *now* itself is stretched in time. There also seems to be a close relationship between changes in time perception and alterations in self-experience. When the self becomes the focus of attention, when we attend to our current mental or emotional state, or to bodily sensations (such as hunger or pain), time seems to slow down; by contrast, when we are thoroughly absorbed in an activity, time contracts and seems to move faster ([Wittmann in press](#)). When self-experience is lost, as in selfless states, the loss of a reference point may be associated with feelings of timelessness ([Wittmann in press](#)); the phenomenal *now* is stretched indefinitely. There is a sense of duration, but the sense of

¹⁸ Note that this is related to a terminological difficulty that is implicit in the Indian debate, as well as in Thompson's reconstruction of it. As noted earlier, both sides in the Indian debate assumed the self to persist throughout sleep; they merely disagreed whether the self is necessarily conscious. My proposal that we redescribe dreamless sleep experience in terms of pure subjective temporality captures this idea that the self persists in a thin sense even when awareness of any intentional contents is lost. At the same time, recall that dreamless sleep experience is thought to be characterized by a collapse of subject-object duality and by an absence of any intentional objects of awareness. In this state, nothing, including the self, is thought to be known or cognized. There is no longer an individual, consciously experienced first-person perspective. It is this thicker and more substantial notion of a self experienced as distinct from other objects or persons that I propose is lost in dreamless sleep experience; the persistence of such a self would mean that there would still be an intentional object of awareness, and thus would indicate a more complex state than that characterized in the Indian debate as dreamless sleep experience.

¹⁹ This could, of course, turn out to be false. Even if the underlying neural representations are temporally extended, the same may not be true of conscious states themselves; these may still be conceived of as elementary and momentary events lacking spatial or temporal structure. For a recent defense of such a view, inspired by the Abhidharma doctrine of momentariness, see [Chadha \(forthcoming\)](#). Yet, even if the experience of continuity and persistence over time turned out to be an illusion, this would still be an interesting structural feature of phenomenal experience. For present purposes, the basic phenomenological claim, according to which the phenomenal *now* is temporally stretched rather than momentary and discrete, is enough.

succession, of there being a chain of present moments, has been lost.

Importantly, this way of thinking about subjective temporality and the experienced *now* is one which Thompson (2015) endorses. He explicitly appeals to the Husserlian conception of time experience in his defense of retrospective reports of dreamless sleep experience. Here, he suggests that memories of dreamless sleep experience may be grounded by retentional awareness, “the holding onto the just-past as an intentional content belonging to our consciousness of the passage of time, including our mental lives as flowing in time” (p. 9). Because temporal experience has the retention of the immediate past and protention, or the anticipation of the next moment, written into it, the moment after awakening still carries with it the traces of dreamless sleep experience: “Immediately, the ego sense appropriates the lingering impression or retention of not-knowing and associates this retention with itself, thereby generating the retrospective thought, ‘I did not know anything’” (p. 10).

In *Mind in Life*, Thompson (2010) endorses a version of Husserl’s conception of time-consciousness according to which the streaming, flowing character of subjective experience is both the “condition of possibility for every other kind of consciousness, but is not itself made possible by some other, still deeper level of consciousness” (p. 324). This absolute flow of consciousness is self-constituting (p. 324); it is also prior to and essential for phenomenal selfhood. As Thompson (2010) puts it,

to be aware of phenomena across time, consciousness must be retentionally and protentionally aware of itself across time. Therefore, time-consciousness entails prereflective self-awareness. In other words, our being conscious of external temporal phenomena entails that our temporally enduring experiences of those phenomena are self-aware. Inner time-consciousness is thus nothing other than prereflective self-awareness. (p. 328)

This prereflective awareness that consciousness has of itself (its self-luminousness, reflexivity, or

self-acquaintance²⁰) is not yet the same as being or having a phenomenal self in the sense used here. Rather, this minimal form of phenomenal experience is the condition for the emergence of minimal phenomenal selfhood.

My suggestion, then, is that we can enrich our theoretical conception of dreamless sleep experience by applying Thompson’s account of how we *remember* dreamless sleep experience (namely with the help of retentional awareness) to the description of dreamless sleep experience itself. Dreamless sleep experience involves pure subjective temporality that is not yet structured around intentional objects, including a phenomenal self. As Thompson (2015) puts it, “although deep sleep creates a gap or a rupture in our consciousness, we often feel the gap immediately upon awakening. [...] We are aware of the gap from within our consciousness” (p. 4). Just as upon awakening, I am directly aware that it was I who was asleep and unknowing, I am typically aware that a certain (though perhaps indefinite) amount of time has passed. Following Proust’s more poetic formulation in the passage quoted by Thompson,

a sleeping man holds in a circle around him the sequence of the hours, the order of the years and world. He consults them instinctively as he wakes and reads in them in a second the point on the earth he occupies, the time that has elapsed up to his

²⁰ Again, there are subtle terminological differences. For instance, Williford (2015a, pp. 10–11; see also Williford 2015b) writes that reflexivity or self-acquaintance is “an essential structural feature of all consciousness; and I take it to be a phenomenological datum. All streams of consciousness are immediately aware of themselves, and that is the foundation of all other forms of self-representation, autobiographical cognition, and so on. This reflexivity is subjective character (for-me-ness), but it is a mistake to turn this structural feature into a kind of entity or homunculus.”

My account is compatible with much of what Williford says here; I agree that we are considering a basic and essential feature of conscious experience, and one that should not lead us to posit an independent entity that is identified as the self. Yet, I think there is room for phenomenal selfhood as a structural feature of experience over and above the reflexivity of even the simplest kinds of phenomenal states. Even readers who disagree with my description of this as a form of phenomenal selfhood might still agree that the target property of spatiotemporal self-location is distinct from the more basic reflexivity of consciousness. Adopting the conceptual convention of describing this as a form of self-experience does not, I take it, require us to reify the self or to slip into a homuncular view, but simply offers a conceptual tool for describing the way we experience ourselves as being or having a self.

waking; but their ranks can be mixed up, broken. (p. 3)²¹

We might even say that metaphorically speaking, subjective temporality provides a reference frame that is still empty, but poised to integrate and lend temporal structure to intentional contents such as thoughts, objects and events, but also the self, as they arise—for instance by imposing sequential order on them and representing some of them as simultaneous, and others as successive. Yet, this form of temporality is more basic than the events it later integrates; it predates them and provides a space in which they can appear.

Incidentally, this idea fits in nicely with the Vedantan view that, “deep sleep is a kind of ‘ground state’ of consciousness, a lowest-energy state from which the ‘excited states’ of dreaming and waking arise” (Thompson 2014, pp. 260-261). Again, deep sleep is the baseline, the causal source from which other conscious states arise; it is also called “seed sleep”, because it is thought to contain the seeds of both dreaming and waking consciousness. Perhaps we can begin to make sense of this idea by saying that dreamless sleep experience, understood as pure subjective temporality, is a candidate for minimal phenomenal experience.²²

²¹ A prediction that seems implicit in Proust’s observation that if we are suddenly overcome by sleep, we no longer know what time it is upon awakening, is that dreamless sleep experience may bear an interesting relation to the ability to estimate how long one has slept. Perhaps, intermittent periods of dreamless sleep experience even ground our awareness that some time has passed or are responsible for the ability, which may be more pronounced in certain subjects, to awaken just before the alarm clock goes off (thanks to Valdas Noreika for pointing this out). By contrast, if we awaken from a state lacking any form of phenomenal experience whatsoever—as in some forms of anesthesia—there may be no sense of a preceding temporal gap and a more profound sense of temporal disorientation. At present, this is, of course, entirely speculative, but it might be a question worth asking.

²² The temporally dynamic nature of experience is also of central importance for understanding the neural correlates of conscious experience. As Melloni (2015) points out, while the mechanisms for updating the contents of consciousness have been investigated by numerous studies, the mechanisms underlying the maintenance or the flow of conscious experience fall outside the scope of most existing paradigms. She also proposes that the temporal flow of consciousness is a fundamental property of experience and an important target—perhaps the most important target—for future research on the neural correlates of consciousness. Similarly, Noreika (2015) suggests that focusing on the analysis of individual contents of consciousness, as is standardly done in mainstream research on the neural correlates of consciousness, misses the temporality of consciousness; instead, to make progress toward understanding this more fundamental property, he proposes contrasting conscious and nonconsciousness states.

How can we make progress on identifying real-world cases of dreamless sleep experience? Importantly, if the account of dreamless sleep experience defended here is even remotely correct, we should not expect dreamless sleep experience to be restricted to experienced meditators. Instead, dreamless sleep experience might be fairly prevalent even in people without any formal training in contemplative traditions. This approach requires disambiguating between at least two variants of the target phenomenon. Note that within the Indian conception of dreamless sleep, we can distinguish between an insight component and a more basic experiential component. The insight component refers to the ability to become aware, during sleep, of the nature of this state. This is not necessarily a conceptually mediated form of knowing *that* you are currently sleeping dreamlessly, but rather consists “in being able to witness the state of dreamless sleep and recall its phenomenal clarity upon awakening” (Thompson 2015, p. 15). Still, even this nonconceptual form of witnessing is not epistemically neutral, but can lead (or fail to lead) to veridical retrospective reports. To be sure, this form of insight or awareness itself can have a particular phenomenal feel—it bears the phenomenal signature of knowing (Metzinger & Windt 2014, 2015), the feeling of just having become aware of the nature of one’s ongoing state—but importantly, this type of phenomenal experience carries with it epistemic commitments. My feeling of knowing can be true or false. It also seems plausible, as suggested by Thompson, that meditation facilitates this type of lucid dreamless state, or perhaps could even be a way of inducing it systematically.

But the model of dreamless sleep experience as pure subjective temporality also points to a more basic experiential component that as such bears no obvious connection to an epistemic state of knowing or of being aware of the nature of the state one is currently experiencing. Dreamless sleep experience in this primary phenomenological reading refers to a kind of experience during sleep; but this does not require the ability to conceptualize this *as* a form of sleep experience. In principle, you can have dreamless sleep experience without realizing

that you are asleep: dreamless sleep experience is a form of experience occurring *in* sleep, but it is not necessarily an experience of sleep *as* a state of sleep. It might enable us to estimate how long we have slept, but it can also be misleading, maybe even leading us to misjudge whether we have slept at all. This is particularly obvious if dreamless sleep experience is construed as an answer to the question of how we know, upon awakening, that we slept peacefully (Thompson 2015, p. 4). Thompson's reconstruction of the Indian debate, taken together with my analysis, suggests that because this state is characterized only by its temporal character, we have the sense of there being a gap between two periods of wakefulness; and because this gap is devoid of intentional objects, we describe it as peaceful. Yet, this does not seem to require that we were aware of (or took ourselves to be aware of) the nature of this state while it was occurring, namely during sleep. If any sophisticated epistemological reading of insight were indeed crucial to dreamless sleep experience, the experience of having slept peacefully would have to be reserved for special subject groups, such as experienced meditators—and it would be quite mysterious why clearly, it is not.

Perhaps we can model the relationship between the epistemic and the phenomenological components of dreamless sleep experience on the relationship between lucid and nonlucid dreaming. Thompson (2015, p. 15) himself explicitly contrasts lucid dreaming, or knowing that you are dreaming while you are dreaming, with lucid dreamless sleep. Given this suggestion, a good place to begin the project of broadening the investigation of dreamless sleep experience beyond expert meditators is to consider reports from experienced lucid dreamers.

5 Candidates for pure subjective temporality during sleep

5.1 From lucid dreaming to lucid dreamless sleep?

Lucidity is commonly defined as awareness that one is dreaming while one is dreaming (for ex-

cellent reviews, see Voss & Hobson 2015; Dresler et al. *in press*). Often, this is associated with an ability to control not just one's own actions in the dream, but also the course of the dream, the actions of non-self dream characters, etc. In particular, lucid dreamers can signal that they have now become lucid by making prearranged patterns of eye movements, such as looking right – left – right – left within their dream. These gaze shifts correspond to the movements of their physical eyes and can be identified on the electrooculogram. This technique of signal-verified lucid dreaming enables researchers to identify the precise period of sleep during which certain actions were performed during a lucid dream and potentially to identify their electrophysiological and neural correlates (Dresler et al. 2011, 2012). Lucidity can occur spontaneously, but a number of methods for inducing lucidity are discussed in the literature (Stumbrys et al. 2012). There have even been suggestions and attempts to experimentally induce dream lucidity through electrical stimulation (Noreika et al. 2010a; Voss et al. 2014; Voss & Hobson 2015). While still in its early stages, this work clearly shows that lucidity is a robust phenomenon; and combined with the ability to control the dream as it unfolds, it makes laboratory studies of lucid dreaming compelling.

One reason for being interested in lucid dreams within the present context are reports of lucid dreams describing a loss of phenomenal embodiment, or even a dissolution of the self (see Windt 2015, chap.s 7, 11 for discussion). Some of these appear to fulfill the requirements for minimal phenomenal selfhood described earlier: in so-called imageless lucid dreams (Magallón 1991; Bogzaran 2003; Hurd 2008), self-identification may be relative to a disembodied point in space and can arise independently of bodily sensations and even of visual imagery (see also LaBerge & DeGracia 2000). While most of these reports, so far, are anecdotal, it is tempting to think that lucid dreams could be used to systematically investigate the transition from minimal phenomenal selfhood to more complex forms of self-experience involving the experience of being a thinking self and em-

bodied agent. Importantly, according to some of these reports, even this basic sense of self-identification and location within a larger spatial expanse can be lost. I would like to suggest that such cases may involve a shift from a simple form of lucid dreaming involving minimal phenomenal selfhood to lucid dreamless sleep experience. Here is a single example:

I am suspended in space—dream space, I think. There is nothing here, just millions of greyish dots and I am one of the dots, there's no dream-body anymore, I'm just a dot [of] pure consciousness suspended. A feeling of great peace comes over me and a sense of gentle, infinite expansion. It's as if everything and nothing are the same thing and there is a sense of effortless belonging. As the sense of expansion increases I am no longer a single dot of consciousness; all the dots are me and I am them. There's no "I" or "them." We are one. There's just a blissful sense of timelessness and oneness and a merging with the light. After an indefinable length of time, I start to feel the weight of my body in bed, and settle back into it, tingling all over. (Clare Johnson, unpublished dream report, March 19, 1995)

If we take the report at face value, it describes a gradual transition from minimal phenomenal selfhood, characterized by phenomenally disembodied spatiotemporal self-location, to selfless experience. This transition is accompanied by a sense of spatial expansion, in the course of which the sense of the self as distinct from the environment is lost. To the extent that there still is a sense of spatial self-location, this no longer involves the experience of being located relative to something else. There is also a change in the temporal structure of experience, almost as if the experiential present, the phenomenal *now*, had been stretched indefinitely. The period following the dissolution of the self is still experienced as having duration, but this duration is indefinable and no longer structured around any events.²³ Following Metzinger

(2013), we might want to describe this as involving a transition from a minimal unit of identification, in which an unextended point in space is described as the locus of the self, to a maximal unit of identification. In such cases of "pure consciousness", he suggests, the unit of identification is

the most general phenomenal property available for identification at all: Philosophers might call it the global "unity of consciousness", or phenomenality per se, or awareness as such, namely the singular, integrated, all-pervading quality of consciousness characterizing the current totality of experiential contents, as it is given in every single moment of experience. (Metzinger 2013, p. 5)

I would like to suggest that we can now be more precise. The moment at which self-location dissolves—or at which minimal phenomenal selfhood is replaced with the maximum unit of identification—involves a transition to the type of pure subjective temporality that earlier, I suggested might be the phenomenal mark of dreamless sleep experience. As lucid dreaming gives way to lucid dreamless sleep experience, minimal phenomenal selfhood shades into pure phenomenality, in which phenomenal experience is characterized only by its temporal structure. I find it telling that according to Johnson's report, this latter part of the episode appears to strain the limits of reportability, and also that despite its indefiniteness, the experience is described as blissful; again, this is exactly what the Indian focus on the experience of having slept peacefully would lead us to expect.

Clearly, this single dream report presents anecdotal evidence at best; still, I would like to suggest that a first step towards extending the investigation of dreamless sleep experience beyond experienced meditators might be to investigate imageless lucid dreams in experienced lucid dreamers. What makes me cautiously optimistic is that lucidity is often described as a very unstable phenomenon, as involving a balancing act

²³ A similar link between the dissolution of the self and the experience of timelessness, or of an indefinite duration, may exist in deep medit-

ative states (Berkovich-Ohana et al. 2013), but also, for instance, in drug-induced altered states of consciousness (Wittmann in press).

between maintaining lucid insight (rather than slipping back into a nonlucid dream or awakening) and remaining engaged enough in the ongoing dream to prevent it from dissolving completely (Brooks & Vogel song 2000). Lucid dreamers often describe that imagery can take on a faded, washed out quality, or that lucidity is followed by a period of darkness or, alternatively, of light; indeed, this may be why such reports often slip into mystical language to describe such experiences. Here, I want only to suggest that in such cases, the unwanted fading of lucid dream imagery may actually be an opportunity for experimentally investigating the transition to dreamless sleep experience.²⁴

Before moving on, I want to suggest that the comparison between lucid dreaming and lucid dreamless sleep is also interesting for another reason. This is that as is the case for nonlucid dreams, there continue to be a number of conceptual uncertainties about how to define lucid dreaming and whether to describe it as a genuine sleep phenomenon or as a hybrid state between REM sleep and wakefulness (Voss et al. 2009; for a discussion of lucidity and insight from a philosophical perspective, see Kühle 2015; see Voss 2015 for a critical reply). Also, while some authors consider any dream involving insight into the fact that one is now dreaming as lucid, others reserve the term lucidity for cases in which there is a marked increase in the overall vividness of multimodal imagery as well as a shift towards wake-like cognitive activity, including the ability to engage in rational thought, full recall of waking life, and insight into the fact that none of the events occurring within the dream have any real-world consequences (for a first attempt to test these different conceptions of lucidity experimentally, see Voss et al. 2013).

On the conception that I favor, lucidity is not necessarily accompanied by an all-pervading change in the phenomenal character of the dream; rather, lucid dreams are gradually distinguished from nonlucid ones along a number

of dimensions (Windt & Metzinger 2007; Nor-eika et al. 2010a; Voss et al. 2013). While laboratory studies, because of their reliance on signal-verified lucid dreams, necessarily focus on lucid dreams involving at least some form of control, the conceptually mediated insight into the fact that one is now dreaming is orthogonal to the other experiential qualities of dreaming. Insight is also necessary to score a given report as describing a lucid dream—but aside from this methodological fact, the ability to conceptualize one’s ongoing experience as a dream—to have the thought “I am now dreaming”—can coexist alongside the types of vivid, often bizarre and emotionally charged imagery and erratic reasoning that characterize a majority of nonlucid dreams as well. Lucidity can be the outcome of a conscious inference (of the type “this cannot be happening, so I must be dreaming”), but often appears to be driven by a sudden feeling, sometimes described by saying that the dream suddenly took on a dreamlike feel or a hyperreal character (see Windt 2015, chap. 9 for details and further references). Perhaps, this precursor to full, conceptually mediated lucidity is similar to the type of nonconceptual awareness that is thought to accompany lucid dreamless sleep experience as well. This suggests two further questions. The first is whether nonlucid forms of dreamless sleep experience exist as well. The second is whether in dreamless sleep experience, anything analogous to prelucid dreams exists. I discuss these in turn.

5.2 From white dreams to nonlucid dreamless sleep experience?

Again, we can approach the project of identifying candidates for nonlucid dreamless sleep experience by asking whether instances of minimal phenomenal selfhood exist in nonlucid dreams. If so, we could once more expect these to occur in the vicinity of minimal phenomenal experience during dreamless sleep.

A possible candidate for such a state are so-called white dream reports, in which subjects describe the impression of having experienced a dream but are unable to describe it in any detail. It seems plausible that a subgroup of white

²⁴ Similarly, in the tradition of dream and sleep yoga, dream lucidity is sometimes described as a preliminary stage of becoming aware of sleep; again, realizing that one is dreaming precedes the dissolution of dream imagery while maintaining awareness of dreamless sleep. See for instance Wangyal & Dahlby (1998).

dream reports can be explained by forgetting. Especially where the subject describes the distinct feeling of having had a complex dream but being unable to remember it in any detail, this would seem to be the most plausible interpretation. There is some reason for thinking, however, that this may not be the case for all reports of white dreaming. In at least some cases, the impression of having had some kind of experience prior to awakening, coupled with an inability to describe any particular aspects of the experience, such as any specific forms of imagery or narrative contents, might not be an artifact of forgetting, but might reflect the structure of the experience itself. At least a subset of white dreams might involve a sense of spatiotemporal self-location, or minimal phenomenal selfhood, arising in an otherwise imageless nonlucid dream. And if this were supported by future studies, then it might even make sense to ask whether perhaps, a further subgroup of white dreams could more properly be described as involving nonlucid dreamless sleep experience. In the current framework, these latter types of white dreams would not count as proper dreams at all: they would be instances of pure subjective temporality arising independently of the spatial aspects of self-location and self-identification. They would involve a form of minimal phenomenal experience that could no longer be described as minimal phenomenal selfhood, and thus as a dream. Perhaps, we occasionally really do retain some awareness, after awakening, of phenomenal experience having persisted during sleep. And perhaps, unable to remember any specific details, we then assimilate them to more familiar types of experiences, labeling them as white dreams.

Again, all of this is still extremely speculative and everything I have said so far about white dreams should be read, at best, as a careful prediction of what we might say in light of future findings. In particular, I do not mean to suggest that white dream reports, or a subgroup thereof, can already be regarded as examples of dreamless sleep experience: I only mean to propose that they are an initially promising target for future research on dreamless sleep experience. Still, these considerations fit in nicely with

the finding that white dreams are particularly frequent during slow-wave sleep. According to one study, awakenings from stages 2 and 3 NREM sleep were followed by roughly equal rates of dream reports, white dream reports, and reports of nondreaming (Noreika et al. 2009). Their occurrence in the vicinity of reports of dreaming and of nondreaming might indicate that white dream reports describe a transitional state between the two. Moreover, even dream reports obtained following awakenings from these sleep stages were often static, describing experiences lacking narrative progression as well as movement sensations (Noreika et al. 2009, 2010b). Participants sometimes described the sense of being present in a static scene, as in quietly sitting on a bench, with nothing else happening (Valdas Noreika, personal communication; see also Noreika 2014, p. 52). Even in the absence of narrative progression, there was still a sense of duration, and according to subjective estimates, these simple dreams lasted between thirty seconds and one minute.

An interesting possibility could be to investigate the wording of white dream reports in more detail. To my knowledge, this has not yet been done. Maybe there are indeed subtle differences in the wording of such reports, and perhaps these would enable researchers to distinguish cases in which there is the impression of having forgotten a complex dream from ones describing imageless and perhaps even selfless and objectless episodes of phenomenal experience. Again, it might be possible to increase the expressive granularity of reports with the help of training or specific questionnaires, thus rendering subtle phenomenological differences visible that would be otherwise overlooked. A possible finding could be that some of these experiences involve a continued sense of presence and self-location in an abstract, amodally experienced spatial expanse, whereas in others, even this basic sense of self is lost and only the feeling of duration, or of an indefinite temporal expanse, is present.

A particularly promising way to do this would be to use a serial awakenings paradigm, in which participants are awakened multiple

times throughout the night at intervals of 15-30 minutes, thus maximizing the number of reports that can be collected throughout the night (Noreika et al. 2009; Siclari et al. 2014; Siclari et al. 2013). Questions focusing on the temporal aspects of experience could then be used to identify those periods, if any, in which dreamless sleep experience is most likely to occur. For instance, Siclari et al. (2013) asked their participants to estimate how long they had been having continuous experiences before being awakened, but also how long their most recent experience had lasted, how far back in time they could recall any narrative events, and how rich and complex the experience was. They found that during stages N2 and N3, estimates for duration, recall back in time and richness were low. Still, these results could be influenced, in part, by the fact that the interview questions focused on the objects of consciousness and on narrative events. If the questions were reworded in such a way as to cover dreamless sleep experience, the patterns of responses might change. Even so, it is interesting to note that during sleep onset, there was a dissociation between these measures, with participants estimating a long duration of the last conscious experience, but a low richness and ability to recall back in time. At least, this suggests that the estimated duration of conscious sleep states does not always map cleanly onto the ability to recall specific contents. For now, I want only to suggest that a similar strategy could interestingly be applied to the investigation of dreamless sleep experience as well.

This is also attractive in view of the goals of this line of research. Note that Siclari et al. (2014) explicitly use the serial awakenings paradigm to contrast the presence and absence of conscious experience independently of task performance and within the same sleep stage (for a similar suggestion, see Noreika et al. 2009; Noreika 2015), the ultimate aim being to identify the task- and state-independent neural correlates of conscious experience. For this project, dreamless sleep experience, as a candidate for minimal phenomenal experience during sleep, is clearly a relevant target phenomenon.

5.3 From subjective insomnia to unwitting expertise of dreamless sleep experience?

The final example that I wish to discuss is sleep misperception in subjective (or paradoxical, as it is also sometimes called) insomnia. The term objective insomnia, reserved for patients suffering from actual sleep loss as conventionally measured, is sometimes contrasted with subjective insomnia, which refers to subjects who systematically underestimate the time they actually spend asleep (Harvey & Tang 2012; Perlis et al. 1997). This mismatch between subjective sleep perception and objective measures of sleep sometimes leads to a trivialization of subjective insomnia—and the suggestion that their diagnosis as insomniacs is somehow not “real” can be experienced as infuriating by those afflicted by it (Greene 2008). Subjective insomnia is clearly not an imaginary problem, but a cause of real suffering. In fact, patients with subjective insomnia may experience more severe impairments in cognitive functioning than insomnia patients who do not underestimate the amount of sleep they are getting. Furthermore, worrying about getting enough asleep may precede actual sleep loss, and patients who underestimate the time they spend asleep may still be suffering from a real sleep deficit as well (Harvey 2002; Harvey & Tang 2012). The distinction between subjective and objective insomnia has also been questioned, as sleep-state misperception may be prevalent in different subtypes of insomnia. As Harvey & Tang (2012) put it, “many patients with insomnia perceive sleep as wake, systematically overestimate the time they take to get to sleep (SOL) and underestimate the time they sleep in total (TST).” This further highlights the urgency of sleep-state misperception existing alongside actual sleep loss in insomnia.

In the context of the present discussion, the example of sleep-state misperception in subjective insomnia may seem to be a counterexample to, rather than a candidate for, dreamless sleep experience. Thompson (2015, p. 5) considers sleep-state misperception as a possible objection to his view: sleep-state misperception

of the type seen in insomnia challenges the reliability of subjective reports of sleep, thus providing a counterexample to his claim that at other times, reports of dreamless sleep experience and of having slept peacefully are veridical memory reports. He then argues that the mere possibility of there being veridical reports of dreamless sleep experience is enough to disprove the default view. He also proposes that in experienced meditators, “we should observe a stronger correlation between subjective reports of phenomenal qualities of sleep and various objective measures of brain activity” (p. 16). The fact that at other times, subjective evaluations of sleep can go wrong does not contradict this view, but merely shows that the investigation of dreamless sleep experience is best restricted to certain subject groups.

Here, I want to suggest that an alternative interpretation of sleep-state misperception is possible. In this alternative view, patients with subjective insomnia are in fact unwitting experts of various kinds of sleep experience. It is merely in conceptualizing their sleep states as occurring in wakefulness that they go wrong. Yet, this is compatible with saying that during sleep, they maintain prereflective awareness of their ongoing sleep state; in fact, it might be their continued perception of sleep that leads them to mischaracterize it as a state of wakefulness, rather than as sleep. Their expertise, consequently, is of a somewhat paradoxical nature: they have a high-degree of familiarity with their sleep, they observe and perhaps even compulsively attend to it—but they don’t recognize or conceptualize it *as* sleep.

Note that this description fits in well with the distinction, introduced at the end of section 5.1, between different readings of the term lucidity. There, I argued that prereflective awareness of the fact that one is now dreaming often precedes the conceptually mediated insight that characterizes full-blown lucidity. Importantly, these two factors may even be dissociable: a fleeting awareness of the dreamlike nature of one’s current state can be misinterpreted, on the level of conscious, conceptually mediated thought, as indicating that one is awake. In such prelucid dreams, the erroneous conclusion

that one is certainly awake may be prompted by the same type of change in experiential character that in other cases drives the cognitive realization that this is a dream (see also Windt 2015, chap. 9).²⁵

Similarly, the idea is that sleep-state misperception arises when patients misinterpret mental activity and phenomenal experience that in fact occurs in sleep as occurring in wakefulness. Indeed, Mercer et al. (2002) found that when they were awakened 5 minutes after the onset of stage 2 sleep or REM sleep, insomnia patients were more likely than good sleepers to say they had been awake. One possibility is that these patients generally have a heightened awareness of sleep-related experiences; another is that increased attention to and concern about the amount of sleep they are getting may increase their sensitivity to such sleep-related experiences, as well as the likelihood of misdescribing them as occurring in wakefulness.

Interestingly, it does not seem that subjective insomnia simply results from a general deficit in the ability to estimate time (Tang & Harvey 2005). Instead, subjective insomnia appears to be associated with selective attention to and increased monitoring of external cues (such as the time of day or the alarm clock), but also of thoughts and bodily sensations that are taken, by the subject, to be inconsistent with sleep. As Mercer et al. (2002, p. 565) put it, “insomniacs’ reduced sleep-wake discriminability may be caused by either a greater amount of mentation during sleep, mentation that more

²⁵ This is also why such examples of prelucid dreams or of sleep-state misperception do not threaten the transparency of retrospective reports. In the present framework, reports are transparent with respect to the occurrence and phenomenal character of experience only; but we should not expect them to accurately reflect the sleep state in which the respective experiences occurred (or indeed whether they occurred in sleep at all), just as we should not expect them to accurately identify the underlying changes in neural activation patterns. Perhaps training, as Thompson (2015) suggests, can indeed improve the match between subjective experience reports and objective measures of sleep states or of brain activation; but this is in no way guaranteed. Or perhaps, objective measures of sleep should be informed by the conditions under which different subject groups experience themselves as being asleep. A mismatch between subjective and objective measures need not indicate a flaw in subjective reports; it might also indicate that objective sleep measures are poorly suited to capture what normal, healthy subjects mean when they say they have been asleep. Indeed, this latter suggestion is in keeping with Thompson’s proposal of a phenomenologically enriched taxonomy of sleep states.

closely resembles awake mentation, or a misattribution of normal nocturnal mentation as wakeful cognitive activity.” Enhanced memory processing may also play a role (Perlis et al. 1997), as might enhanced physiological and cortical arousal. Intriguingly, insomnia patients show heightened beta and gamma EEG activity during sleep onset, but also during NREM sleep; and in one study, this activity was negatively associated with their ability to correctly perceive that they had been asleep (Perlis et al. 2001). Again, this could be an indication of continued awareness during sleep. Subjective insomniacs may be witnessing sleep whilst failing, unlike the expert meditators described by Thompson (2015, see especially p. 16), to realize what it is they are witnessing.

As is the case for white dreams, I am not suggesting that sleep-state misperception in insomnia be equated with dreamless experience, or indeed that any simple explanation is available. Clearly, a wide range of conscious mental activity occurring in sleep might be perceived as occurring in wakefulness, and much of this might be quite different from the specific type of dreamless sleep experience I am interested in here. And equally clearly, sleep-state misperception in insomnia is a far cry from the peaceful type of sleep experience describe in the Indian debate. In her book-length treatment of insomnia, in which she synthesizes research findings with her own personal experience of insomnia, Gayle Greene (2008) describes her reaction to being told, after a sleepless night in the sleep laboratory, that she has in fact been asleep:

So that’s why nobody had come in with a sleeping pill—the EEG said I was asleep. But I was not asleep. I was truly awake. What in the world was it recording? I may have been in a state of deep relaxation, semi-meditative, I usually am when I lie there, and I may have dropped off, but I was aware of all those thoughts, the feel and look of the room, the long drawn-out boredom of lying there without a book to listen to—it felt like consciousness to me. How could I be aware of all that if I hadn’t been awake? (Greene 2008, p. 254)

When asked, however, if she had been aware of the technician coming into her room, she was not (Greene 2008, p. 253).

Here, I want only to make room for the idea that a subgroup of instances of sleep-state misperception might be more properly described as resulting from an awareness of what is in fact sleep, but then is erroneously categorized as belonging to wakefulness. And at least a portion of this awareness of sleep might consist of dreamless sleep experience, or the persistence of temporal experience devoid of further intentional content or any specific objects of awareness during sleep. Moreover, this may well be the dreamless-sleep analogue of prelucid dreaming, where heightened awareness of one’s ongoing state leads to its erroneous characterization as wakeful activity on the level of conceptually mediated thought.

Finally, sleep-state misperception of this type may not be unique to insomnia, but may be prevalent in the general population. In a paper aptly titled “The perceptual uncertainty of having sleep”, Sewitch (1984) describes the outcome of an experiment investigating the ability of healthy subjects to correctly say whether they have been asleep, as determined by objective markers such as EEG measures. She found that out of 210 awakenings from Stage 2 sleep, 116 were judged to be periods of wakefulness; for REM sleep awakenings, the number was lower, with 45 out of 165 awakenings being judged to have been preceded by a period of wakefulness. The surprising conclusion is that even ordinary sleepers quite dramatically underestimate the amount of time they have been asleep (see also Webb 1975). Other studies point in a different direction. There is some evidence that whereas insomnia patients underestimate their total sleep time, healthy subjects overestimate how long they have been asleep (Means et al. 2003; Pinto Jr. et al. 2009). Clearly, more research is needed. But either way, it would seem that our confidence in our ability to tell whether and how long we have been asleep or awake is overrated. And perhaps, at least part of this confusion stems from the fact that the default view is deeply engrained not just in cognitive neuroscience, but also in

folk-psychology: We expect sleep to be a state of unconsciousness, and so when we recall mental activity that is distinct from dreaming, we mistakenly think we must have been awake.

There is, however, an even deeper conceptual point. The mismatch between subjective and objective (behavioral or polysomnographic) markers of sleep should alert us to the fact that conventional definitions of sleep, and attempts to operationalize them scientifically, for instance in the form of sleep-stage scoring systems, may be oversimplified. The borders between sleep and wakefulness themselves may be fluid. This brings us back to Thompson's proposal that a more fine-grained and phenomenologically informed taxonomy of sleep states is needed. This is emphatically illustrated by the following quotation from one of the participants in Sewitch's study. This participant had subjective insomnia and claimed to have been awake following 22 out of 23 Stage 2 NREM sleep awakenings.

Also, there is for me a state which may be technically sleep to you, but is wakefulness to me and, uhh—it's an intermediate state—it's very hard to define, uhh—but I definitely felt that it's there—and uhh—uhh none of the questions precisely examined this situation. (Sewitch 1984, p. 257)

As Thompson suggests, dismantling the default view may be as simple as asking the right kinds of questions.

5.4 Conclusions

I began this commentary by formulating a number of related challenges to Thompson's analysis of dreamless sleep experience. The first two of these centered on the status of reports of dreamless sleep experience. In order to place the scientific investigation of dreamless sleep experience on solid methodological grounding, it is not enough to establish the logical possibility of veridical reports of dreamless sleep experience; rather, some rationale for distinguishing veridical reports from nonveridical ones is needed. Also, in order for such reports to be in-

dicative not just of the occurrence of dreamless sleep experience, but also of its distribution and quantity across sleep, one will have to assume such experiences to be reportable. This means that positive experience reports and reports of an absence of experience, when gathered under the same reporting conditions and unless there is any empirical evidence of disturbing factors, will have to be considered as equally trustworthy. I responded to these dual challenges by pointing out that the methodological background assumptions upon which scientific dream research has long relied, at least implicitly, directly speak to both issues: Dream reports, at least when gathered under (sufficiently) ideal reporting conditions, are indeed assumed to be trustworthy sources of evidence with respect to the occurrence and phenomenal character of experience during sleep (I called this the transparency assumption), and dreams are also assumed to be assumed to be reportable experiences (I called this the reportability assumption). Elsewhere (Windt 2013, 2015), I have argued that both assumptions are theoretically justified because they best explain dream reporting behavior. Here, I only defended the more limited claim that scientific dream research already offers the methodological resources to turn the study of dreamless sleep experience into a scientific research program. This shifts the burden of proof: in order to meaningfully challenge the report-based investigation of dreamless sleep experience, the methodological background assumptions of scientific dream research will have to be challenged as well.

An important upshot was that the default view is inconsistent with scientific dream research. Due to its methodological background assumptions, scientific dream research is committed to the view that if experiences fitting the profile of dreamless sleep experience are, at least occasionally and under sufficiently ideal conditions (for instance immediately after awakening), reported to occur in sleep, then dreamless sleep experience exists. The default view, understood as an *a priori* and conceptually motivated rejection of dreamless sleep experience, is flawed. I then argued that by taking the analogy between contemporary philosoph-

ical and scientific work on dream reports and the Indian debate seriously, valuable lessons can be learned in the other direction as well. In particular, Thompson's reconstruction and critique of the Nyāya syllogism suggests that certain skeptical objections to the trustworthiness of dream reports run into the same problems, resulting either in circularity or an infinite regress.

The second and third parts of my commentary were dedicated to the third challenge to Thompson's view. This was that even if dreamless sleep experience exists, and even if reports of dreamless sleep experience are taken to reflect this fact, its occurrence in experienced meditators is too remote to warrant the large-scale revision of sleep-state taxonomy proposed by Thompson. I attempted to meet this challenge, first, by first sketching the outlines of a conceptual framework for describing dreamless sleep experience. In this framework, dreamless sleep experience is characterized by pure subjective temporality, or the experience of duration and of an extended presence (a stretched phenomenal *now*) arising independently of any further intentional contents, objects of awareness, or modality-specific imagery. This model extends existing work on dreams, where I argue that the simplest forms of dreaming are examples of minimal phenomenal selfhood, or self-location in a spatiotemporal reference frame (Windt 2013, 2015). In dreamless sleep experience, even this minimal form of self-experience is lost; pure subjective temporality during dreamless sleep experience is a candidate for minimal phenomenal experience, or the simplest form of phenomenal consciousness.

In the final part of the commentary, I discussed what I take to be the most plausible candidates for dreamless sleep experience in this sense: these are lucid dreamless sleep, white dreams, and sleep-state misperception as most prominently seen in subjective insomnia. I also proposed that these states can be meaningfully compared to the transition from nonlucid to pre-lucid and fully lucid dreams. Here, my aim was to show that dreamless sleep experience is not a remote possibility, but might plausibly turn out to be a common characteristic of sleep.²⁶

Importantly, I am not claiming that the proposed conceptual model is the final word on dreamless sleep experience; it is only a very first attempt to delineate the borders of the target phenomenon. The model is clearly open to further conceptual refinement, and I would like it understood mainly as an invitation to do so. What I would hope, however, is that the model might facilitate this process by guiding and informing future research. Similarly, the empirical candidates for dreamless sleep experience that I propose should not be taken to be exhaustive, and their plausibility will depend on future research findings. For now, I hope, however, that they lend further support and urgency to Thompson's case for dreamless sleep experience.

Acknowledgments

less sleep experience, and the addition of dreamless sleep experience to the conceptual tool kit used for the description of sleep and wakefulness, may prove to be no more than a first step in this direction. And while the reconstruction of the Indian debate and its contrast with contemporary views of sleep is a rich and valuable project, important but easily forgotten lessons might be found closer to home as well. The monophasic sleep pattern currently investigated in Western sleep laboratories and taken to be the biological norm may be only a few generations old (cf. Greene 2008, pp. 238-240) and is likely an artifact of a profound change in sleep behavior brought on, to a considerable extent, by electrical lighting. In preindustrial times, sleep was biphasic—two periods of sleep, called the first and the second sleep, were structured around a period of wakefulness that was made up of quiet rest, perhaps even resembling certain meditative states and often involving the contemplation of dreams (Ekirch 2001; Ekirch 2006). Research suggests that under appropriate conditions—in an environment without artificial, electrical lighting and without various nighttime activities that become possible in such an environment, that compete for our attention and increase the pressure for and attraction of staying awake rather than going to bed—we naturally return to this biphasic sleep pattern (Wehr 1992). It does not seem unreasonable to think that the transition to a monophasic sleep pattern, alongside factors such as increased electrical lighting, traffic noise, and time constraints—will have changed not just the structure of sleep, but our experience of sleep as well. With less and less time allotted to sleep, the temptation to simply black out during sleep (or to view sleep as involving such a blackout) may have increased; yet, current sleep behavior in rich, Western societies may be a highly artificial and learned behavior. If we want a taxonomy of sleep states to reflect universal features of sleep, rather than our culturally specific, contemporary sleep habits, we would do well to remember this.

²⁶ Clearly, this is just the very beginning of the conversation on how to refine sleep-state taxonomy. Ultimately, the investigation of dream-

Steps Toward a Neurophenomenology of Conscious Sleep

A Reply to Jennifer M. Windt

Evan Thompson

Windt's groundbreaking commentary expands and enriches my target article by presenting new considerations against the default neuroscience view that "consciousness is that which disappears in dreamless sleep," by proposing a refined conceptual and phenomenological analysis of dreamless sleep experience, and by offering a refined taxonomy of dreamless sleep experiences. These contributions provide new conceptual and methodological tools for the neurophenomenology of sleep and consciousness.

1 Introduction

I would like to begin by thanking Jennifer Windt for her outstanding, constructive commentary ([Windt 2015b](#), this collection) on my target article ([Thompson 2015a](#), this collection), and by expressing my great admiration for her rich discussion, which goes well beyond being a commentary and instead amounts to an original and substantive article in its own right. It is especially gratifying to see the ideas and arguments that I presented be refined and advanced in such a creative and precise way. Indeed, given the wealth of new material that she presents,

her paper calls not so much for a reply as for a commentary of its own. Such a task, however, is beyond the scope of this short reply. Instead, I wish to highlight the advances that Windt makes, so that new experimental research can begin in this area.

The main aims of my target article were (i) to use debates about sleep from classical Indian philosophy to call into question the "default view" in cognitive neuroscience that "consciousness is that which disappears in dreamless sleep," (ii) to suggest instead that there may be

states or phases of dreamless sleep in which consciousness is present, (iii) to argue that sleep science accordingly needs a more refined neurophenomenological taxonomy of sleep states, and (iv) to demonstrate how contemplative methods of mind training provide important resources for the neurophenomenology of sleep and consciousness.

Windt's commentary advances each of these four aims in substantive ways, as I will describe in the following sections.

2 Indian philosophy and sleep science

After answering several possible challenges to my arguments against the default view (see Section 1 of her commentary), Windt shows that the Indian philosophical debate (in which the Yoga and Vedānta schools argue that consciousness persists throughout dreamless sleep, whereas the Nyāya school denies this claim) parallels in certain key respects the Western philosophical and scientific debates about the trustworthiness of dream reports. Given that sleep science must assume as a methodological criterion of dream research that retrospective reports of dreaming and nondreaming are trustworthy (given ideal reporting conditions), we must similarly assume that retrospective reports of the presence or the absence of experience in dreamless sleep are also trustworthy (again, given ideal reporting conditions). This requirement in turn implies that we must refine the conceptual typology of retrospective reports upon awakening from sleep. In Windt's (2015b, p. 11) words, "reports of nondreaming should be further qualified: reporting the absence of experience is not the same as reporting dreamless sleep experience. The former is an instance of reporting an absence of experience, the latter is an instance of reporting a form of experience characterized by the absence of intentional objects; but it is still an experience report." I will not review the steps of her analysis of the methodological requirements of sleep and dream science in detail (see Section 2 of her commentary), but the upshot is that the default view turns out to be inconsistent with the methodological background assumptions of scientific

sleep and dream research. This conclusion strengthens the case against the default view, for whereas I argue that this view is likely to be empirically false, Windt shows that it is inconsistent with the methodological requirements for scientifically investigating the presence and absence of consciousness in sleep.

3 The phenomenology of dreamless sleep experience

Windt's second contribution is to propose a conceptual and phenomenological model of dreamless sleep experience (see Section 3 of her commentary). Starting from my presentation of the Indian conception of dreamless sleep experience as characterized by a feeling of peacefulness and the dissolution of the subject-object duality, as well as my comparison of this conception with Husserl's conception of pre-reflective and pre-egological retentional time consciousness (see Thompson 2007), Windt proposes that dreamless sleep experience is a candidate for minimal phenomenal experience, one characterized only by the phenomenal "now" and a sense of duration, but having no further intentional content. So described, dreamless sleep experience would qualify as the simplest form in which a state can be phenomenally conscious, namely, as minimal phenomenal temporality.

I find this analysis very promising, though two issues require further analysis. The first concerns whether such a minimal phenomenal experience counts as "selfless." Windt proposes that it does, because minimal phenomenal selfhood requires some sense of spatial self-location, whereas dreamless sleep experience consists only in a minimal sense of temporal self-location—not, of course, in the sense of mental time travel (retrospection and prospection), but rather in the sense of a bare feeling of existing "now," with a minimal feeling of flow or duration. Nevertheless, both Advaita Vedānta and Husserl would take issue with this conception of a phenomenal state as "selfless." As I describe in my target article, Advaita Vedānta describes dreamless sleep experience as a state in which the true nature of the self as non-intentional, re-

flexive consciousness is more apparent than in the ordinary waking and dreaming states. For his part, Husserl also describes the pre-egological retentional time consciousness as a minimal structure of self-experience (see [Zahavi 2005](#); [Thompson 2007](#)). It may be that this issue is in part terminological, but there are also likely to be deeper conceptual disagreements about how to analyze the notion of self—whether this notion can be applied to the reflexivity of passive retention (Husserl) or the reflexivity of pure awareness (Vedānta), or whether such states do not meet the criteria for minimal phenomenal selfhood.

Second, and relatedly, I proposed in my target article that, from a Western phenomenological and cognitive scientific perspective, dreamless sleep experience might be describable as a minimal mode of sentience consisting in the feeling of being alive. My point in describing the experience this way was to call attention to the possibly minimal sense of embodiment present in the state. Windt's proposal raises the question of whether even this minimal sense of embodiment may drop away in dreamless sleep, leaving only a bare phenomenal sense of "now." One way to address this question would be to determine whether there can be such a minimal phenomenal temporality in sleep with no affective character, given that one might take the presence of an affective phenomenal character to imply some felt sense of embodiment (assuming that there is a constitutive relation between affect and felt embodiment).

4 The neurophenomenology of sleep states

Windt usefully enlarges the concept of dreamless sleep experience to include a variety of different dreamless sleep states (see Section 4 of her commentary). These states include lucid dreamless sleep (especially the experiential transition from lucid dreaming to lucid dreamless sleep), a possible subclass of white dreams (in which individuals describe the impression of having dreamed but are unable to describe the dream in any detail), subjective insomnia (in which some individuals may maintain pre-re-

flective awareness of their ongoing sleep state while mistakenly conceptualizing their state as wakefulness), in addition to the contemplative practices of lucid dreamless sleep that I describe. Windt's taxonomy is groundbreaking and opens many new avenues for the experimental neurophenomenology of sleep. This is exactly the kind of work I envisioned when I suggested that we need a more fine-grained and phenomenologically informed taxonomy of sleep states.

5 Contemplative sleep states

In my target article, I called attention to the importance of meditative practices of dream yoga and lucid dreamless sleep, because they are closely connected to the Advaita Vedānta, Yoga, and Indian Buddhist conceptions of dreamless sleep, and have begun to be investigated by cognitive neuroscientists (see [Thompson 2015b](#) for further discussion). I agree with Windt that these practices may be too remote from other kinds of sleep experiences in order to justify a wholesale revision of the standard taxonomy of sleep states. For this reason, it is important to place these meditative sleep states within a wider taxonomy that includes other kinds of sleep states, specifically the dreamless sleep states that Windt details. In this way, the meditative practices and their effects on sleep can be integrated into the rest of sleep science. Windt's article provides an excellent framework to this end.

6 Conclusion

Windt's commentary goes far beyond mere commentary in offering new arguments against the default neuroscience view that consciousness is that which disappears in dreamless sleep, by providing a refined conceptual proposal about the phenomenal structure of dreamless sleep experience, and by presenting a new taxonomy of dreamless sleep states and experiences. Thanks to her commentary, sleep science and the neuroscience of consciousness have new conceptual and methodological tools for refining the investigation of consciousness during sleep (see also [Windt 2015a](#)).

What is the State-of-the-Art on Lucid Dreaming?

Recent Advances and Questions for Future Research

Ursula Voss & Allan Hobson

Lucid dreaming may be defined as the conscious awareness that one is dreaming while dreaming. Instead of incorrectly assuming that one is awake, the dreamer gains insight about her or his real state of consciousness. Lucid dreaming is rare and evanescent, which probably accounts for lingering doubts about its veracity and for its marginalization in science. The purpose of this paper is to review the evidence that lucid dreaming is a real phenomenon, including evidence for its occurrence, underlying mechanisms, and scientific value. Based on admittedly still limited but fast-growing empirical evidence, we will introduce four hypotheses centred around lucid dreaming that are deduced from empirical work and that will hopefully have a bearing on future consciousness research. The Brain Maturation Hypothesis (1) relates steps in ontogenetic brain development to the frequency of naturally occurring lucid dreams in children and adults, suggesting that in the immature brain, spontaneous and involuntary lucid dreaming results from accidental and untypical activation of the frontal cortex during REM sleep. The Hybrid State Hypothesis (2) and the Space of Consciousness Model (SoC) (3) build on the electrophysiological peculiarities observed in REM-sleep-induced lucid dreams, showing a wake-like EEG pattern in frontal parts of the brain and an REM sleep-like EEG in posterior areas. The Gamma Band Hypothesis (4) proposes that the same kind of oscillatory activity known to accompany conscious awareness in the awake brain promotes conscious awareness in REM sleep dreams. Finally, we present first experimental evidence that lower gamma band activity is indeed a necessary condition for the elicitation of conscious awareness in dreams.

1 Background

Given its robust and revealing features, it is surprising that dream lucidity was not recognized by philosophers of mind until recently ([Metzinger 2003, 1993](#); [Noreika et al. 2010](#); [Revonsuo 2006](#); [Windt in press](#); [Windt & Metzinger 2007](#)). Although it was described by [Aristotle](#) (without using the term, in 350 BC), lucid

dreaming first appears in the *experimental* literature of the late nineteenth century ([Maury 1861](#); [Saint-Denis & Marquis 1982](#)). It was described as a vehicle for self-experimentation ([Arnold-Forster 1921](#)) in the early 20th century and reported on subjectively ([van Eeden 1969](#)). The modern laboratory study of lucid dreaming

1. While dreaming, I was aware of the fact that the things I was experiencing in the dream were not real.	0	1	2	3	4	5
2. While dreaming, I was able to remember my intention to do certain things in the dream.	0	1	2	3	4	5
3. While dreaming, I was aware that the self I experienced in my dream wasn't the same as my waking self.	0	1	2	3	4	5
4. In my dream, I was able to manipulate or control other dream characters in a way that would be impossible in waking.	0	1	2	3	4	5
5. While dreaming, I thought about other dream characters.	0	1	2	3	4	5
6. While dreaming I was able to successfully perform supernatural actions (like flying or passing through walls).	0	1	2	3	4	5
7. The emotions I experienced in my dream were exactly the same as those I would experience in such a situation during wakefulness.	0	1	2	3	4	5
8. While dreaming, I was aware of the fact that the body I experienced in the dream did not correspond to my real sleeping body.	0	1	2	3	4	5
9. I was very certain that the things I was experiencing in my dream wouldn't have any consequences on the real world.	0	1	2	3	4	5
10. While dreaming I was able to successfully control or change the dream environment in a way that would be impossible during wakefulness).	0	1	2	3	4	5
11. While dreaming, I saw myself from outside.	0	1	2	3	4	5
12. While dreaming, I thought about my own actions.	0	1	2	3	4	5
13. While dreaming, I had the feeling that I had forgotten something important.	0	1	2	3	4	5
14. While dreaming, I was able to change or move objects (not persons) in a way that would be impossible in waking.	0	1	2	3	4	5
15. While dreaming I was not myself but a completely different person.	0	1	2	3	4	5
16. While dreaming, I often asked myself whether I was dreaming.	0	1	2	3	4	5
17. The thoughts I had in my dream were exactly the same as I would have in a similar situation during wakefulness.	0	1	2	3	4	5
18. While dreaming, I had the feeling that I could remember my waking life.	0	1	2	3	4	5
19. While dreaming, I was aware of the fact that other dream characters in my dream were not real.	0	1	2	3	4	5
20. Most things that happened in my dream could have also happened during wakefulness.	0	1	2	3	4	5
21. I watched the dream from the outside, as if on a screen.	0	1	2	3	4	5
22. While dreaming, I often thought about the things I was experiencing.	0	1	2	3	4	5
23. I was able to influence the story line of my dreams at will/at libitum.	0	1	2	3	4	5
24. While dreaming, I was able to remember certain plans for the future.	0	1	2	3	4	5
25. While dreaming, I felt euphoric/upbeat.	0	1	2	3	4	5
26. While dreaming, I had strong negative feelings.	0	1	2	3	4	5
27. While dreaming, I had strong positive feelings..	0	1	2	3	4	5
28. While dreaming, I felt very anxious.	0	1	2	3	4	5

Figure 1: Lucidity in Dreams (LuCiD) scale (adopted from [Voss et al. 2013](#)).

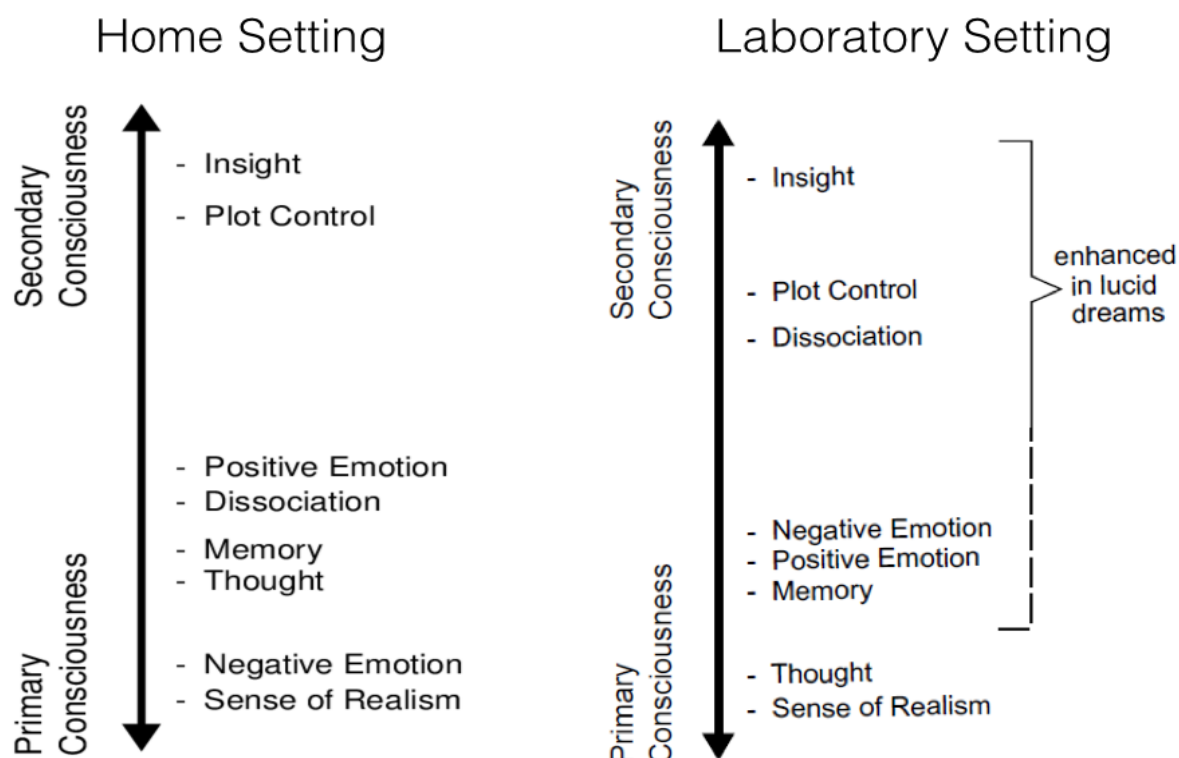

Figure 2: (partially adapted from [Voss et al. 2014](#)): Positions on the primary to secondary consciousness axis are based on the logarithm of ratios of mean scores in lucid and non-lucid dreams. All factors have been identified as components of dream consciousness.

- a) Rank order of logarithm of mean scores derived from dream reports collected in a home setting. Note that these reports were often recorded in the morning instead of immediately following an awakening from REM sleep. Judging from our admittedly limited experience, these reports are less distorted and more story-like than those following forced awakenings in the laboratory.
- b) Rank order of logarithm of mean scores derived from dream reports following forced awakenings from REM sleep in a laboratory setting. Lucid dreams, which are thought to add elements of secondary consciousness, are characterized by increased ratings in reflective INSIGHT, CONTROL over the dream plot, and DISSOCIATION. To a lesser extent, they are accompanied by access to waking MEMORY, as well as NEGATIVE and POSITIVE EMOTIONS.

was pioneered by [Hearne \(1978\)](#) and [LaBerge](#), beginning in 1980 ([1980](#)).

In this paper, we will summarize our five years of scientific research on lucid dreaming, provide a systematic overview of our work, and present new hypotheses about the *why* (because of fluctuations in brain networking) and the *how* (through local changes in lower gamma band activity) of lucid dreaming. Regarding the *why*, our “Brain Maturation Hypothesis” pro-

poses that the probability of lucid dreaming occurring spontaneously is strongly enhanced during the time of cerebral diversification and, most importantly, integration of the frontal lobes into the cortico-cortical and cortico-thalamic networks ([Fuster 1989](#); [Goldman-Rakic 1987](#); [Zilles et al. 1988](#)).

As to the *how* of lucid dreaming, we will outline our experimental findings, focusing on the increase in lower gamma band activity in

fronto-temporal brain areas (Gamma Band Hypothesis). We will then move from our first attempts to provide a brain-based explanation of empirical findings (Hybrid State Hypothesis, see [Hobson & Voss 2011](#); [Voss et al. 2013](#)) to a three-dimensional model of consciousness, allowing for a more structured classification of various states of consciousness, ranging from near-death to highly vigilant wakefulness (“Space of Consciousness”, SoC, compare [Voss & Voss 2014](#)).

The presentation of our empirical contributions will begin with a quantitative analysis of lucid dream subjectivity. This study demonstrates that the most robust difference between lucid and non-lucid dreaming is the increase in insight into the nature of one’s current conscious state that accompanies lucidity. Based on admittedly few recordings (unpublished) of false awakenings, we are currently inclined to assume that there is no notable difference between, for example, the apparent but non-veridical insight accompanying a false awakening and actual (lucid) insight into the fact that one is dreaming. In both falsely and correctly perceived insight into the current state of arousal, the brain apparently operates in a dissociative mode, allowing for a state-related form of meta-awareness similar to the awareness of mind-wandering described for the wake state ([Schooler et al. 2011](#); [Metzinger 2013](#)). However, as our experimentally deduced hypotheses are based on those instances in which the dreamer *correctly* achieved insight into the fact that she was dreaming while the dream continued, we will restrict our discussion of dream lucidity to these instances.

In discussing these results, we will go so far as to suggest that lucidity, as the name implies, *is* insight. We then turn to sleep laboratory studies revealing that the principal brain correlate of lucid dreaming is 40 Hz activation of the frontal cortex. When we electrically stimulated the frontal brain via the scalp, we were able to induce both an increase in 40 Hz brain activation and the subjective experience of lucidity. In our discussion of these results we suggest that the experimental study of lucid dreaming is a powerful paradigm for understanding the brain basis of conscious experience.

2 Quantification of dream lucidity as subjective experience

Perhaps the most problematic aspect of conducting research into lucid dreaming is the difficulty of obtaining both qualified and quantified evidence of the secondary consciousness in dreams. By secondary consciousness we mean the subjective awareness of our state in dreaming, and particularly meta-awareness, meaning an instance of actively acquired self-knowledge or a sudden insight, regardless whether it is accurate or counterfactual (see [Metzinger 2013](#)). Meta-awareness is most clearly manifest in waking consciousness. Dream consciousness, by contrast, is called primary (following [Edelman 1992](#)) because while it is both richly perceptual and powerfully emotional, it is weakly cognitive with conspicuous defects in insight (the main focus of this paper) orientation, and memory, though this does not mean that all thinking is missing ([Hobson et al. 2011](#); [Kahan & Sullivan 2012](#); [Kahn & Hobson 2005](#)). See [Hobson & Voss](#) for detailed discussion of this phenomenology ([2010](#)).

Regarding qualification, [Hearne \(1978\)](#) and [LaBerge \(1980, 1985\)](#) took advantage of the fact that humans can be trained to voluntarily move their eyes in Rapid Eye Movement (REM) sleep and thereby to signal conscious awareness while dreaming. Although care must be taken to minimize the rate of false positive responses, LaBerge’s method has proven quite useful in our own attempts to reliably identify lucid dreaming objectively ([Voss et al. 2009](#)).

With respect to quantification, it is important to note that until recently, lucid dreaming was not quantitatively defined. While some authors described lucid dreams in a narrow sense as dreams in which one knows that one is currently dreaming ([LaBerge 1985](#); [LaBerge & Gackenbach 2000](#)), others subscribed to a broader definition of lucidity as an all-pervading experiential phenomenon, which is purportedly characterized not only by reflective insight into the fact that one is currently dreaming, but also by full intellectual clarity including: the availability of autobiographic memory sources, the ability to actively control the dream, as well as

an overall increase in the intensity of multimodal hallucinatory imagery. This state is often described as taking on a hyper-real quality (Tart 1988; Metzinger 2003; Windt & Metzinger 2007). While sharing an interest in the broader definition, we restrict our attention here to the narrower one in which insight into the fact that one is currently dreaming represents the core criterion for lucidity.

In an attempt to be better able to assess the major and minor determinants of dream lucidity, we developed a Lucidity and Consciousness in Dreams Scale (LuCiD) which was based on hypotheses derived from theory and which we analysed and validated using factor-analysis (Voss et al. 2013). The LuCiD scale presents an important step towards shedding light on the relationship between lucid dreams and other types of dreaming, as well as on the evaluation of cognition in the dream state and its relationship to other aspects of dreaming, such as the intensity of hallucinatory imagery and dream control.

The scale items were constructed by an interdisciplinary team of philosophers, psychiatrists, and psychologists. Our results are based on reports of more than 300 non-lucid and lucid dreams, and verified by reports following forced REM sleep awakenings in the laboratory. Our analysis identified eight factors involved in dream consciousness. Although it is of course possible that our initial item pool did not exhaust all theoretically possible elements, we consider these results a first step in the search for an empirical definition of dream consciousness. According to the factor analysis that we performed, lucid dream consciousness can best be described by the factors (1) INSIGHT into the fact that what one is currently experiencing is not real, but is only a dream; (2) a sense of REALISM, pertaining to the similarity between emotions, thoughts and events with wakefulness as judged after awakening from the dream; (3) CONTROL over the dream plot; (4) access to waking MEMORY; (5) THOUGHT about other dream characters; (6) POSITIVE EMOTION; (7) NEGATIVE EMOTION; and (8) DISSOCIATION akin to taking on a third-person perspective (for a copy of the LuCiD scale see Figure 1).

The factor analysis results support both the restricted definition of lucidity that we have adopted and the broader definition utilised by others. The strength of the factor INSIGHT favors the simple definition, while the wide range of other factors (see Figure 2) favors the more complex definition. While both types of definition certainly have their merits, this difficulty in defining lucid dreams brings some important questions to the fore. What, for instance, is the exact relationship between metacognitive insight into the dream state and the hallucinatory quality of the dream (for the relationship between thinking and hallucinations across the sleep-wake cycle, see Fosse et al. 2001)? And how do these aspects of dream lucidity, in turn, influence the ability to engage in deliberate dream control, which fluctuates considerably?

3 Lucid vs. non-lucid dreams

3.1 Non-lucid dreams

According to our analysis, non-lucid or “normal” dreams are characterized by low absolute values in all factors except REALISM. Non-lucid dreams seem almost to completely lack INSIGHT, CONTROL, and DISSOCIATION. Although mean scores for THOUGHT are higher than those for MEMORY, both are low if we are considering absolute values. Results also show relatively low mean values for NEGATIVE EMOTION. However, as most of our data were collected in a laboratory setting, known to increase positive emotionality in dream imagery (e.g., Hartmann et al. 2001), some caution is advised regarding the interpretation of results with respect to both negative and positive emotion.

3.2 Lucid dreams

Lucid dreams differ from non-lucid dreams in six of the eight factors identified in the LuCiD scale. The leading factor in lucid dreams is INSIGHT. Regarding the relevance of the other factors, we observed different rank orders for dream reports following sleep in a home setting (Figure 2a) and those from forced awakenings in

the laboratory (Figure 2b). The data of our new laboratory study (Voss et al. 2014) confirm the findings depicted in Figure 2b, suggesting that the leading factors in dream lucidity are INSIGHT, CONTROL, and DISSOCIATION. Although, as pointed out by Windt (2013), dream reports in general must be considered trustworthy sources of evidence about subjective experience during sleep, the degree to which these reports can be used to draw scientifically sound conclusions about the dream state strongly depend on the quality of the experimental protocol. Such a protocol is more easily established in a laboratory setting, rendering immediate recalls of the dream experience, which must be considered more reliable with respect to distortions and intermixture with waking thought than those recorded in a home setting (Foulkes 1979; Voss et al., unpublished data), although dreamers might feel less inclined to report on sexual or aggressive content. Furthermore, reports from home settings usually lack information about the particular sleep stage (REM or NREM) in which the dream evolved. Typically, NREM dreams are less bizarre and more story-like (e.g., Dé Waterman & Kenemans 1993).

With regard to the distinction between primary and secondary consciousness in dreams, our findings indicate that INSIGHT is a defining feature of lucidity and that this core aspect of secondary consciousness is related to the emergence of other features of secondary consciousness. Lucid dreamers are able to reflect not only upon the fact that they are currently dreaming, but also upon the unfolding dream events.

The relationship between INSIGHT and CONTROL is clear, as realizing that one is dreaming is an important condition for trying to control not only one's own behavior in the dream, but the dream itself. It must be pointed out, though, that CONTROL is much more infrequent than lucid INSIGHT, and the low covariance of this factor indicates a strongly limited variability of scores, suggestive of a floor effect. In other words, very few participants reported to have experienced some (however small) level of control over the dream plot (see Voss et al. 2013). Despite this limitation, lucid-

ity appears to be characterized not only by lucid insight. INSIGHT also facilitates the emergence of other aspects of secondary consciousness in dreams such as dissociative thought and access to waking MEMORY. Similarly, while our study found non-lucid dreams to almost completely lack INSIGHT, CONTROL, and DISSOCIATION. THOUGHT, e.g., about other dream characters, was not completely absent in non-lucid dreams (Kahn & Hobson 2003).

A surprising finding of our study was that lucid and non-lucid dreams were not distinguished by a difference in the sense of REALISM. Whereas we previously thought that lucidity was characterized by a lack of bizarreness (see Voss et al. 2013), further exploration suggests that this factor is associated with the degree to which the dream feels real. Lucid dreams feel as subjectively realistic as non-lucid dreams. This finding was fully replicated in our most recent study (Voss et al. 2014). A question we are currently not able to answer is whether both dream types are equally bizarre (see also Windt 2013).

Our finding of realistic conviction stands in apparent contrast to reports from other authors who found that the onset of lucidity is often accompanied by a change in the overall experiential quality of the dream, noting that lucid dreams are often described as taking on a surreal, dream-like quality (cf. LaBerge 1985; Brooks & Vogelsson 2000; Tholey & Utecht 2000). At present, we are inclined to think that perhaps the different perceptions may be related to the already-mentioned confounding of wake- and sleep-induced lucid experiences. To our knowledge, lucid dreams entered through the wake state (e.g., Wake-Induced Lucid Dreaming, WILD, see Stumbrys et al. 2012) and those arising out of REM sleep have not been systematically compared with regard to phenomenology or Electroencephalography (EEG). Nonetheless, we think it plausible to assume that the WILD technique will result in more wake-like experiences, simply because they arise out of the wake state or the transition from waking to sleep, usually at the beginning of the night or after morning awakenings. A return to the wake state is in most cases easily ac-

complished. By contrast, dreamers who achieve lucidity out of REM sleep remain in REM sleep, not always being able to wake up voluntarily (Voss et al. 2009, 2014; Voss & Voss 2014). Regarding REALISM, lucid dreams arising out of REM sleep are apparently not accompanied by a change in the subjectively experienced realism of the dream.

3.3 Natural frequency of lucid dreams: The brain maturation hypothesis (1)

REM-sleep-induced lucid dreaming is unique because it represents an exceptional state in which the brain is in two states at the same time: awake and asleep. However, while many have experienced the phenomenon, few experience it on a regular basis. Why? So far, predisposing psychological variables have not been clearly identified (Schredl & Erlacher 2004). We have long speculated (Hobson 2009), and Schredl & Erlacher (2011) have confirmed, that lucid dreaming is negatively correlated with age. Why? And when does lucid dreaming actually set in? These questions need to be addressed in order to provide at least some clues about a very important question: Why does lucid dreaming occur at all?

To investigate the natural frequency of lucid dreaming in children and young adults, we interviewed almost 800 students aged 6–19. Students were recruited from local schools in and around Bonn, Germany, thanks to the enthusiastic cooperation of teachers and parents. Each student was interviewed alone, during school hours, and asked to provide a dream report and to answer questions about dreaming, lucid and non-lucid. In addition, to account for social desirability, students were tested for suggestibility (see Voss et al. 2013), which led to the exclusion of almost 100 data sets.

The main findings of our survey were a surprisingly high incidence of reported lucidity in the young and more frequent lucidity in those who are intellectually more capable. In total, 52% of participating students reported to have recalled at least one lucid episode in their life. The highest incidence rate of recent lucid dreams was observed in the young. Frequency

rates seem to remain at steady levels until age 16, after which they drop dramatically.

In our study, only one third of lucid dreamers claimed to be able to change the dream plot, showing that plot control is not automatically activated in lucid dreaming. As in previous reports (e.g., Wolpin et al. 1992), plot control was significantly associated with frequency of lucid dreaming, suggesting that it is susceptible to training. Plot control was also found to vary with age. It remained at relatively high rates (up to 50% of lucid dreams) from 6 to 14 years and started to decrease from that age on. Lucid dreaming incidence or frequency was not related to sleep duration or napping.

Based on previous research into lucid dreaming, we are inclined to interpret these results as evidence that lucid dreaming is an exceptional mental state occurring naturally in the course of brain maturation. It is noteworthy that the peak in spontaneous occurrence of lucid dreaming coincides with the final stages of frontal lobe myelination and a time of synapse expansion and dendritic growth. These neurobiological changes provide the prerequisites for the integration of the frontal lobes (which are REM sleep-atypically activated in lucid dreaming) into the cortico-cortical and cortico-thalamic networks (Fuster 1989; Goldman-Rakic 1987; Zilles et al. 1988).

Lucid dreaming may thus occur naturally during the final stages of frontal lobe integration, a process similar to an upgrade of computer hardware. It seems to us most likely that the peak in spontaneous dream lucidity in childhood and puberty (Stumbrys et al. 2014; Voss et al. 2013) is nothing but an accidental confounding of conscious states during a time of high cerebral diversification. In an adult, mature brain system, relatively firm covariates for states of arousal have been established. For example, the frontal lobe activity during waking is usually enhanced, whereas it is down-regulated during REM sleep. Our Brain Maturation Hypothesis speculates that during childhood and puberty, frontal lobe activity is sometimes decoupled from the arousal state so that frontal lobes can become active in a state for which this type of activity is untypical. An intriguing

finding is that not only lucid insight but also dissociative phenomena like derealization and depersonalization can easily be trained in the laboratory during this same period in ontogenetic development (Leonard et al. 1999). DISSOCIATION is a key factor that discriminates between lucid and non-lucid dreams (Figure 2, see also van Eeden 1969; Voss et al. 2013, 2014). In lucid dreams, dissociation is often described as taking on a visual third-person perspective, documenting a split between dreamer and dream observer (Gabel 1989; Rossi 1972) (“I see myself from the outside”), whereas non-lucid dreams are typically experienced from the first-person perspective, at least in adults (Foulkes et al. 1990; Gackenbach 2009; Snyder 1970; Voss et al. 2013). At this point, it may be important to note that we do not categorically differentiate between observer dreams and lucid dreams. Based on the results from our LuCiD scale study and in agreement with Gabel (1989), who speaks of “reflections of a dissociated self-monitoring system” (p. 560), we make a quantitative distinction between dreams experienced as first- or third-person, since DISSOCIATION is, next to INSIGHT and plot CONTROL, a key factor that discriminates lucid from non-lucid dreams (see Figure 2).

The fact that lucid dreaming is more readily experienced by those who are more advanced in abstract thinking and charged with reflective insight implies that lucid dreaming is indeed related to brain maturation. Support for this interpretation comes from a study by Lapina et al. (1998). Although details of method and sample characteristics have not been reported, the authors claim a higher level of lucidity in advanced learners. If this is true, however, then why does lucid dreaming decrease in early adulthood, considering that, surely, older students have acquired a higher level of abstraction than younger ones? At this point, we can only speculate about possible and probable causes. One explanation that should be further investigated is that lucid dreaming occurs naturally in the immature but developing brain.

Lucidity could thus be a transient dissociative state during brain maturation that is nor-

mally lost in adulthood but still accessible through training.

3.4 The hybrid state hypothesis (2) of lucid dreaming

The quantification of subjective experience in dream lucidity led us to assume that when the brain-mind shifts from non-lucid to lucid dreaming, it becomes a hybrid state with elements of both waking and dream consciousness. In lucid dreaming, thinking is only partially ruled by primary consciousness. To some extent, the dreamer has—however limited—access to secondary consciousness, enabling her to reflect on her present state. Aside from knowing that the on-going dream is not real, the dream is often experienced as if it were seen from the outside, almost as if the dream were an on-going theatrical production or motion picture (Voss et al. 2014).¹ In other words, lucid dreams can be considered dissociated states of consciousness in which the dream self separates from the on-going flow of mental imagery. The dream is still a dream, but the dreamer is able to distance him or herself from the on-going imagery and may even be successful in gaining (at least partial) control over the dream plot. This phenomenological dissociation is physiologically accompanied by highly selective increases in gamma band activity around 40 Hz in fronto-temporal areas of the brain (Dresler et al. 2012; Voss et al. 2009, 2014), while occipito-parietal regions retain a typical REM-sleep profile. For lucid dreams arising out of REM sleep, we have been able to document the maintenance of sleep throughout the lucid dream, suggesting that lucid dreaming alters REM sleep without surpassing it: REM sleep atonia is unchanged, rapid eye movement bursts (REMs) continue as in REM sleep. However, the EEG frequency spec-

1 We realize that focusing on DISSOCIATION appears to neglect other important aspects of lucid dreaming like agency and knowledge about the ability to exert control, which often seem to occur simultaneously. As a matter of fact, we have observed a significant effect on control, however, during stimulation with 25 Hz but not with 40 Hz, suggesting that oscillatory activity is indeed related to specific brain function. As this is an intriguing but also surprising finding, it is in need of thorough further testing. Please keep in mind that the study of lucid dreaming is still in its fledgling stages and that we have only just begun to explore its possibilities.

trum is significantly altered (Voss et al. 2009). Normally, REM sleep dreams are accompanied by strongly attenuated activation and synchronicity in the gamma frequency band (Castro et al. 2013; Gandal et al. 2012; Voss et al. 2009), especially in frontal parts of the brain (Castro et al. 2013; Voss et al. 2009) suggestive of reduced conscious awareness and executive ego functions (Desmedt & Tomberg 1994). By contrast, gamma band activity in lucid dreaming is significantly increased, while all lower frequencies remain unchanged. This finding strongly suggests that sleep and even REM sleep is indeed maintained. Based on reports of our subjects on their lucid experiences we must assume, however, that lucid dreams push the arousal system towards waking while remaining within the region occupied by REM sleep and thus representing a substate located at the inner boundaries of the REM sleep area within the SoC. Lucid dreaming is, thus, a fragile, destabilized hybrid state. Several participants in our studies have stated that it takes effort to dream lucidly and that such dreams are easily interrupted by noise or state of mind.

Report of a lucid dreamer, f, 30 years old: “To me, being lucid is always a very exciting incident [...] In this state it feels like a struggle in my brain between keeping the dream-scenery and waking. In these short periods of lucidity the awareness of the acting dream body and the real body in bed exist simultaneously and it costs a lot of concentration to keep the balance between both” (for further examples, see Voss & Voss 2014).

We also suggest that lucid dreaming is not just a hybrid state but actually the realization of two normally distinct global functions that usually don't occur simultaneously. This fits in well with the common description of lucid dreams as (partial) awakening in our dreams and involving a split between dreamer and dream-observer, who coexist and change relative dominance of the mind at will (Occhionero et al. 2005). The implications of this line of reasoning have profound impact on the theory of mind. There are two selves, suggesting that the self is a construct elaborated by the brain (Metzinger 2003, 2009, 2013). The two selves of the

lucid dreamer are mediated by distinct brain regions: dreaming is ponto-occipital while lucidity is fronto-cortical. Normally these two brain regions play a winner-takes-all game and dreaming is non-lucid. We come back to this point when we present our physiological model below.

We are attracted by the idea that a key cognitive component of waking, namely insight, can be admixed or even actively injected into REM sleep. Determining the degree to which this enhancement of lucidity is voluntary necessitates a better understanding of altered states of waking conscious awareness, such as hypnosis or mind wandering. We need to know more about conscious state control and to bring that understanding into conjunction with our attempt to understand and influence consciousness.

3.5 Space of Consciousness Model (3)

To speak of lucid dreaming as a hybrid state implies, of course, that states in general have boundaries and intermediates (so-called hybrids). We have, in a recent publication (Voss & Voss 2014) taken this thought further and proposed a model based on the assumption that consciousness is a dynamical process unfolding in a phenomenal state-space continuum occupied by states of arousal such as waking, sleep, and coma. Normally, waking and dreaming constitute two distinct partitions in this state-space. In our new model, what we have called the *hybrid of lucid dreaming* is depicted as a region within the state of REM sleep that stretches REM state variability to the point of destabilizing it, bordering on waking without inducing a complete change of the global configuration.

In our SoC model, we define consciousness as a three-dimensional *space* occupied by *states* that vary as a function of sensing, judging, and motor control. “Sensing” refers to the ability to experience physical and mental fluctuations. “Judging” is meant to describe varying degrees of higher-order cognitive capacities such as reflective awareness, including the ability to dissociate, to think about the past and contemplate the future, and make decisions. The “motor con-

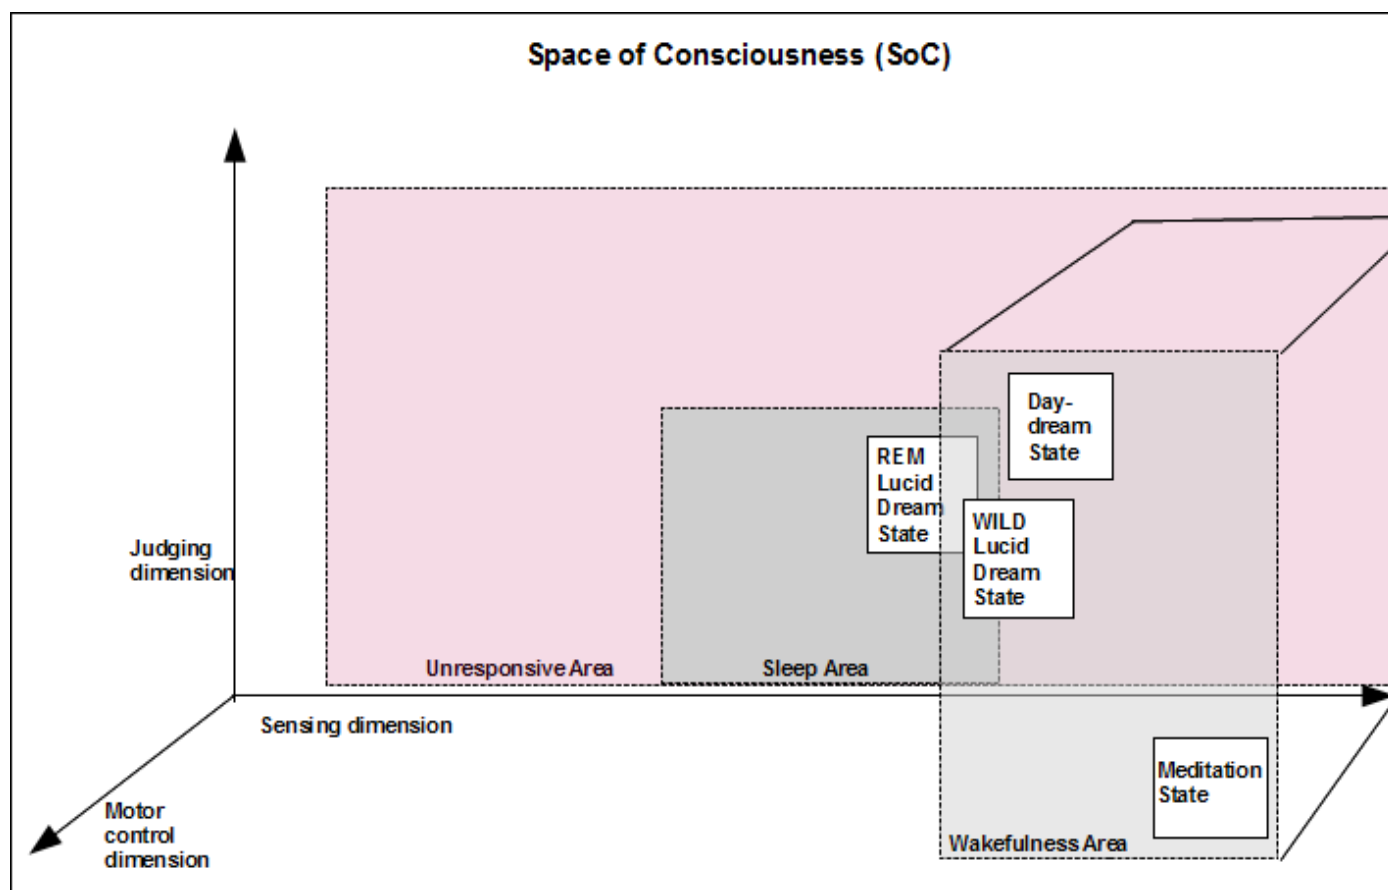

Figure 3: 3-dimensional Space of Consciousness Model (adapted from Voss & Voss 2014, p. 32).

control” dimension was introduced to allow enough space to position different types of unresponsive states such as coma (low motor control, low sensing, and low judging) and, for example, locked-in syndrome, which would be low in motor control but high in sensing and high in judging. Our model is even broad enough to include artificial intelligence (e.g., high judging and low sensing) and to span all forms of animal life as well (see Tononi 2004). Importantly, we do not differentiate between internal and external sources of information or state-dependent neurochemical modulations, as laid out in the AIM model (Hobson et al. 2000; for an early version see Hobson & McCarley 1977). Our space-state model is exclusively phenomenological. The main questions it addresses center around state boundaries and within-state variability.

The *space* is divided into subspaces, corresponding to *states* of arousal, such as waking, sleep, or coma. These *States* largely determine the ability to interact with the external world. We may think of this total space as originating

at the near-death state, spanning over several stages of sleep and wakefulness to some ultimate wake-state of focused attention (see Figure 3). However, it should be kept in mind that the near-death state may not at all be one of minimal expressions of judging and/or sensing (Borjigin et al. 2013; Nelson 2014) so that another altered state may more accurately define the true origin of the SoC.

Lucid dreaming briefly creates a trajectory that dynamically *integrates* the region normally occupied by waking experiences with that of dreaming.

Each state, occupying some area within the SoC, can also be described by a finite number of attributes, and each state possesses a limited degree of variability. Within the partition characterizing wakefulness, for example, we find mind wandering, meditation, and hypnosis, as well as focused attention. Regarding lucid dreams, we assume that wake-induced lucid dreams can be represented by trajectories leading the system very close to the borders, but

which still remain within the overall region inhabited by wake states, whereas REM-sleep-induced lucid dreams initially belong to the sleep state and then evolve towards a brief and unstable integration of the phenomenological substates of waking and dreaming.

Some new questions that derive directly from the model concern (1) the exact number of separable states; (2) specification of the sufficient and causally enabling (perhaps even necessary) conditions allowing for transition from one state into another; and (3) the volume and the dimensionality (the “depth”) of a given region in state-space characterizing each individual state, some perhaps extending over such a broad spectrum of conscious experiences that substates can be defined within the total of SoC and some occupying only a diminutive space such as coma. An example of a high-volume region in phenomenal state-space is wakefulness, covering a wide range of substates including WILD, mind-wandering, focused attention, and hyper-arousal. Another region is sleep, providing a smaller and more dimensionally limited, but nonetheless also considerable range of substates such as light sleep, slow wave sleep, REM sleep (both phasic and tonic), and lucid dreaming.

The SoC model is only an approximation, but we hope that it will prove useful in the generation and testing of specific hypotheses. With regard to lucid dreaming, we hope that this model will contribute to understanding and categorizing the many different aspects and conditions of insightful dreams such as those arising out of the wake state (WILD) versus those arising out of REM sleep. We would expect wake-induced lucid dreams to be accompanied by a much greater motor control, for example, than lucid dreams arising out of REM sleep, simply because WILD are located near the borders of the wake state whereas REM lucid dreams occur in sleep.

3.6 EEG changes associated with lucid dreaming

Our first quantitative EEG study on lucid dreaming aimed to identify changes in brain activity, provided they turned out to be measurable. For this purpose, we trained a relatively

large group of students ($N = 20$) at Bonn University in lucid dreaming. Following several months of preparation, we took those who had achieved lucidity at home 2–3 times per week into the sleep laboratory at the Neurological Clinic of Frankfurt University Hospital.

Although our subjects were highly motivated, our hopes of being able to trace a multitude of lucid dreams soon had to be abandoned, since our enduring attempts yielded EEG recordings of only three spontaneous lucid dreams! Results of this meagre yield were published (Voss et al. 2009), showing that lucid dreaming occurs when activity in the lower gamma band around 40 Hz increases, particularly in frontal parts of the brain. In other words, the results suggested that normal dreaming is cognitively impaired because of frontal lobe deactivation and lucidity only occurs when that deactivation is suspended, either spontaneously or by design.

This finding is depicted in Figure 4, showing single subject 40 Hz EEG power (36–44 Hz) during waking with eyes closed (top), lucid dreaming (middle), and normal non-lucid REM sleep (bottom).

Another finding concerns EEG coherence, or synchronicity (see Figure 5). Whereas the coherence between different brain areas is high in waking (top), it is very low in non-lucid REM sleep (bottom). In lucid dreaming, however, it is significantly increased in comparison to non-lucid dreaming, especially between anterior and posterior parts of the brain (middle).

In this first study, we encountered several methodological difficulties.

1. For the subjects, achieving lucidity in a laboratory setting was difficult. In all three instances, lucid dreaming occurred in the late morning hours, i.e., after 8am. Our study was conducted in the sleep laboratory of the Neurological Clinic at the Frankfurt University Hospital. This implied a noisy early morning routine in which patients were frequently moved for examination purposes, breakfast was served, and floors were cleaned with heavy machinery. It is our opinion now that lucid dreaming arising out of REM sleep

is a fragile state that can be easily disrupted by ambient noise.

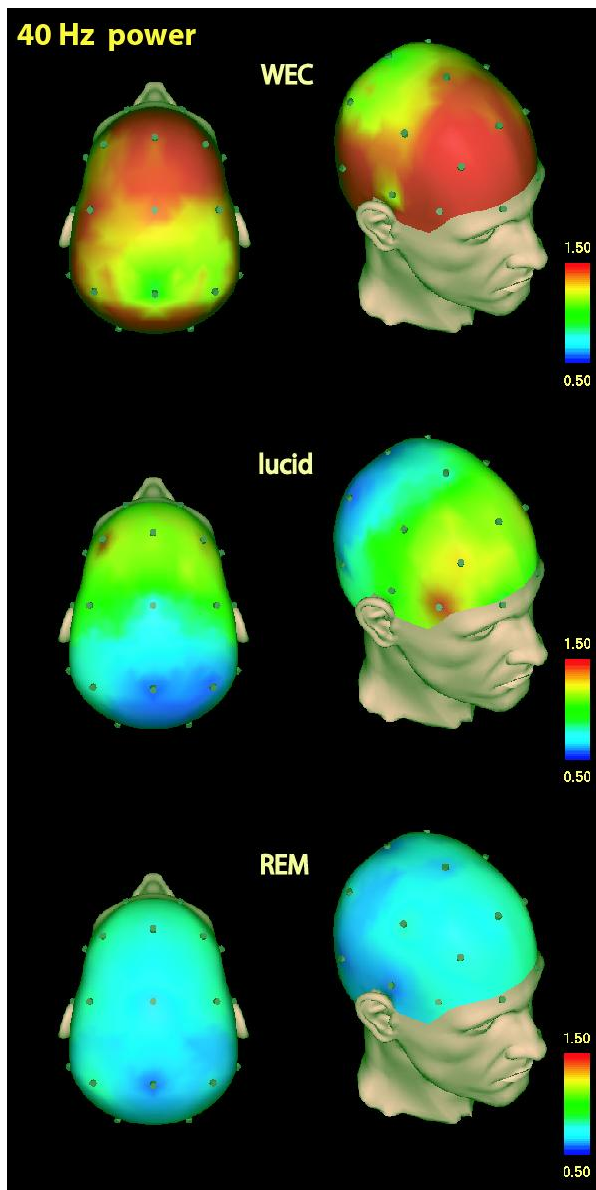

Figure 4: (adapted from Voss et al. 2009). Single subject 40-Hz standardized CSD power during Waking with Eyes Closed (WEC) (top), lucid dreaming (middle), and REM sleep (bottom). Topographic images are based on movement-free EEG episodes and are corrected for ocular artifacts.

2. Several authors have cautioned that some of the variance in gamma activity might be caused by microsaccadic eye movements (Trujillo et al. 2005; Yuval-Greenberg et al. 2008; Weinstein et al. 1991) and by scalp EMG activity (Whitham et al. 2008; Whitham et al. 2007). Although it is not

known, at this point, whether microsaccades are present in steady-states, especially sleep, we have, for publication purposes, conducted a very conservative signal analysis using current source densities (Current Source Densities, CSD). By using this method, we may have overcorrected our EEG scalp potentials, which means that the actual increase in lower gamma band activity is probably even greater than reported.

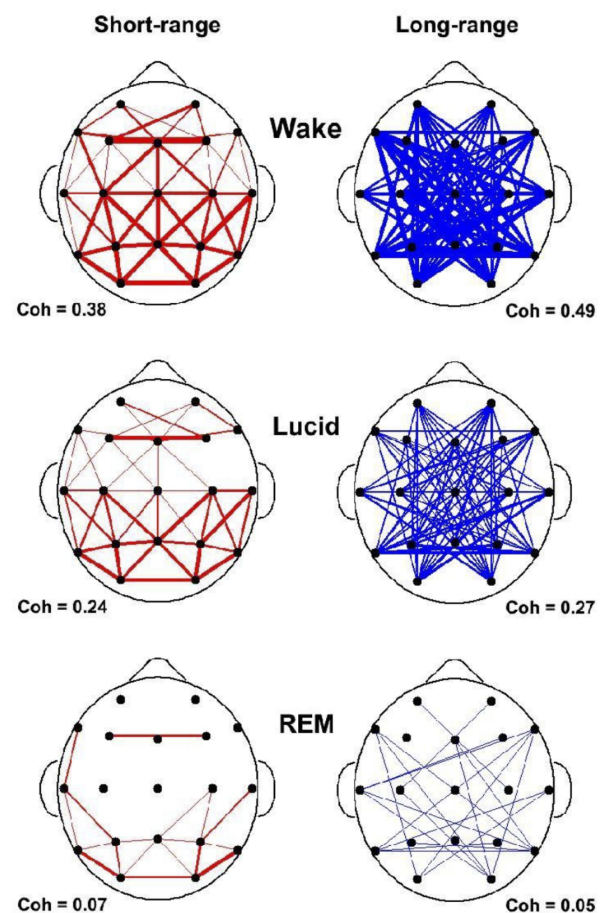

Figure 5: State-dependent short and long range coherences in the 40 Hz frequency band during Waking with Eyes Closed (WEC) (top), lucid dreaming (middle), and non-lucid REM sleep dreaming (bottom). Coherences are indications of interscalp networking and synchronization. Short-range ($N = 55$ pairs) was defined as less than 10cm and long-range (65 pairs) as larger than 15cm inter-electrode distance. Coherences are lowest in REM sleep and strongly enhanced in lucid dreaming.

3. Our subjects reported themselves to be less lucid in the laboratory than at home. When

asked to specify this subjective rating, we found that the subjects' responses were vague and mostly concerned with the amount of plot control achieved in the dream.

The findings of our 2009 study indicate that when subjects became lucid, they shift their EEG power, especially in the 40Hz range and especially in frontal regions of the brain. This shift is, in part, a consequence of pre-sleep auto-suggestion, indicating that REM dream consciousness, which is largely automatic (i.e., spontaneous, involuntary, and intrinsic), is partially subject to volitional force. This observation and its interpretation have an obvious relationship to the question of free will, an implication we will discuss later. Our speculative hypothesis is that dream lucidity arises when wake-like frontal lobe activation is associated with REM-like activity in posterior structures.

3.7 The gamma band hypothesis (4)

In our study of EEG tracings during lucid dreaming, the most striking finding was that lucidity was accompanied by an increased activation of the frontal lobes of the brain. This applies both to synchronicity and to consciousness-related frequencies (around 40 Hz). This observation has led us to propose a “gamma band hypothesis” (Voss et al. 2012; Hobson & Voss 2011), suggesting that brain activation in the 40 Hz frequency range is related to secondary consciousness. We have, in a recent study (Voss et al. 2014), investigated this hypothesis by fronto-temporal application of weak electrical currents in various frequencies. The study was aimed at testing for causality. If activity centered around 40 Hz was causally related to secondary consciousness as expressed in lucid dreaming, then the application of 40 Hz should induce lucid dreaming, provided that it is possible to change brain function in a frequency-specific way through mild electrical stimulation.

3.8 Induction of lucidity via electrical stimulation

In our latest study, we set out to test the hypothesis that lower gamma activity in the

frontal and temporal parts of the brain causally enables lucidity during dreaming. If the observed gamma activity during naturally-occurring lucid dreaming plays a causal role in lucidity, we predicted that facilitation of that frequency band with 40 Hz transcranial alternating current stimulation (tACS) over fronto-temporal areas would increase the probability of lucid dreaming. On the other hand, tACS with a lower or higher frequency should have no effect or even suppress lucid dreaming. The current strength was kept below arousal threshold (250 μ A) in order not to awaken the subjects. Participants were inexperienced lucid dreamers without psychopathology or sleep problems. They were not asked to try to have a lucid dream. Instead, they were told that the study goal was to investigate the effects of mild electrical stimulation in different frequencies on dream content and sleep parameters. While we were doubtful whether it was at all possible to enforce a specific rhythm on the brain (“driving fields”), results suggest that it is indeed possible to change brain activation in a frequency-specific way (see Figure 6). However, we only observed such an effect for frequencies within the lower gamma frequency band. Stimulation with higher or lower frequencies did not result in a measurable change in the respective frequency band, i.e., stimulation with 2 Hz did not lead to an increase in delta frequency band power.

Regarding lower gamma band stimulation, the induced change in lower gamma band brain activity was obviously potent enough to alter conscious awareness in the dream with increased LuCiD ratings especially for INSIGHT and DIS-SOCIATION. Again, this was not observed following stimulation with either higher or lower frequencies.

In this experiment, we tested twenty-seven healthy subjects, during up to four non-consecutive nights. Testing was conducted in a neuro-physiologic sleep laboratory at Goettingen University Hospital. We tested during the summer break of the laboratory and on weekends, which provided a quiet environment and which allowed subjects to continue sleep beyond normal hospital wake-up hours. Participants were allowed

to sleep uninterrupted during the first half of the night until at least 3am.

Starting at 3am, stimulation (30s long) was conducted during REM phases, and subjects were awakened shortly after this stimulation. At this time, they were asked to provide a dream report and ratings to all items of the Lu-CiD scale. The study was performed double blind, so that neither the subject nor the interviewer knew the stimulation frequency applied. In a repeated measures design, all participants were exposed to all stimulation conditions, i.e., sham (no current applied), 2 Hz, 6 Hz, 12 Hz, 25 Hz, 40 Hz, 70 Hz, and 100 Hz (details of methods, see [Voss et al. 2014](#)).

Note that we only applied tACS during REM phases, as lucid dreams arising out of REM sleep were our main research interest. Repetitive stimulation during other sleep stages would have exhausted the experimental protocol and would have led to many undesired side effects such as sleep-deprivation from repetitive early awakenings, changes in sleep architecture, carry-over effects from stimulation in other sleep stages, time-of-night effects, etc.

As shown in Figure 6, only stimulation in the lower gamma band, i.e., stimulation with 25 and 40 Hz, led to an increase in activity in this particular frequency band.

At present, we can only speculate why the other frequencies were not as easily adopted by the brain. Lower frequencies might not have been readily entrained because of state-dependency, as proposed by several authors ([Buzsáki & Draguhn 2004](#); [Vyazovskiy et al. 2009](#); [Tononi et al. 2010](#); [Brown et al. 2012](#); [Suh et al. 2010](#)). It is possible that if we had tried to induce a frequency typically enhanced in slow wave sleep (SWS), for example, such stimulation might have disturbed physiological sleep-dependent oscillations, which would prevent the brain from accepting such a driving field. This notion is supported by direct current (DC) studies (equivalent of 0 Hz) of brain stimulation in REM sleep ([Jakobson et al. 2012a](#); [Stumbrys et al. 2013](#)). Both group of researchers were unable to alter on-going mental activity at 0 Hz, just as we were unable to

induce lucidity at 2, 6, or 12 Hz. Interestingly, dream reports were less frequent in these stimulation conditions ([Voss et al. 2014](#)). However, this does not explain why stimulation with higher frequencies, i.e., 70 and 100 Hz, did not lead to an increase in these frequency bands. It also does not explain why a DC stimulation during stage 2 sleep reportedly effected an increase in visual dream reports although, in this case, the effect was apparently small and, according to the authors, possibly due to arousals and short awakenings ([Jakobson et al. 2012b](#)). At this point, we speculate that lower gamma band frequencies lead to a visible effect because they are linked to the unfolding of secondary consciousness in dreams.

The most striking finding was that subjects reported the ability to “see myself from the outside” and to “watch the dream from the outside as if it was displayed on a screen”. These items belong to the factor DISSOCIATION. Apparently, our subjects took on a third-person perspective following lower gamma band stimulation but not stimulation in any other frequency (2 Hz, 6 Hz, 12 Hz, 70 Hz, 100 Hz) or sham (no current applied).

However, although we were able to induce secondary consciousness in dreams through stimulation with 40 Hz, a similar though smaller effect was observed for stimulation with 25 Hz. Surprisingly, 25 Hz stimulation was associated with CONTROL over the dream plot, whereas stimulation with 40 Hz was not. This finding suggests that specific brain rhythms may be directly linked to cognitive functions and that we have just begun to discover their potential.

Surprisingly, we found no evidence of theta-gamma coupling, as would be expected from NREM sleep studies ([Marshall et al. 2011](#)). At present, we think this may be related to the fact that NREM sleep is highly synchronized, perhaps facilitating such coupling, whereas NREM sleep is desynchronized. As is often the case in science, answering one question generates several others. We will continue to search for answers and also look forward to the extension of our studies by other laboratories.

Effect of tACS on EEG gamma power

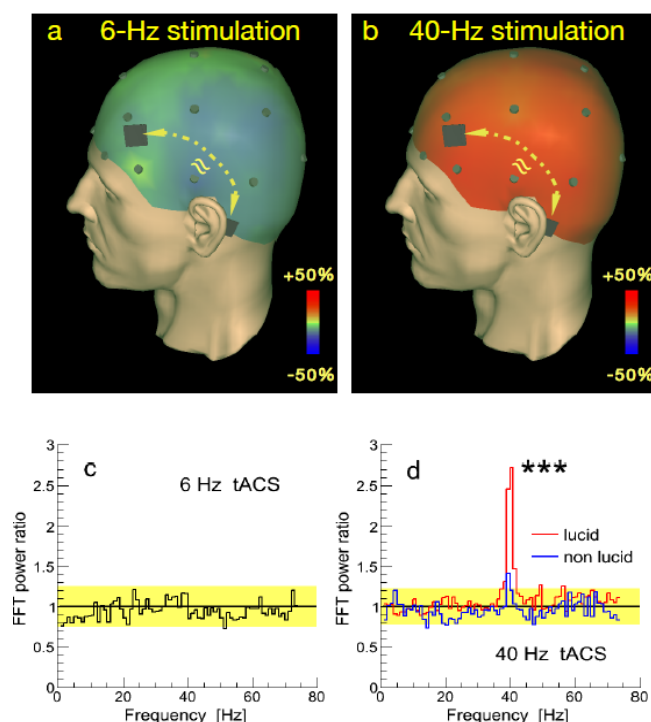

Figure 6: Effect of transcranial alternating current stimulation (tACS) on EEG gamma power. tACS electrodes were placed bilaterally at frontal and temporal positions (black rectangles) and current flowed back and forth between these electrodes. EEG electrode placements are indicated as dark dots.

- Stimulation with 6 Hz resulted in no change in lower gamma activity around 40 Hz (37–43 Hz).
- Stimulation with 40 Hz led to a strong increase in lower gamma activity around 40 Hz.
- Grand average Fast Fourier Transform (Fast Fourier Transform, FFT) power ratios of activity during vs. activity prior to stimulation for the 6 Hz stimulation condition. Yellow shading represents mean values ± 2 standard errors (s.e.). Any excursions outside of this range would be considered significant at least at the $p < .05$ level. However, with 6 Hz, we see no significant stimulation-induced increase in 6 Hz activity.
- Grand average FFT power ratios of activity during vs. activity prior to stimulation for the 40 Hz stimulation condition. Yellow shading represents mean values ± 2 standard errors (s.e.). Note that lucid dreams (red line) are accompanied by a significantly larger increase in the 40 Hz frequency band than non-lucid dreams (blue line) (independent two-sided t tests between lucid and non-lucid dreams during stimulation with 40 Hz: $t_{40\text{Hz}} = 5.01$, $df = 35$, $p < 0.001$).

3.9 Brain Correlates of Lucidity and a Neuropsychological Model.

Our findings of frontal cortical EEG activation to a level intermediate between non-lucid dreaming and waking is compatible with the hybrid state formulation derived from subjective data. More specifically, we attribute the findings to sufficient activation of executive ego functions in the frontal lobes (Baddeley 1992; Goleman & Davidson 1979), but not so intense an activation as to disable the REM sleep generator in the pons and posterior thalamocortical brain that is the physical substrate of dreaming. This formulation is resonant with the oft-repeated complaint that dream lucidity is difficult both to attain and maintain. The hybrid state of waking and dreaming is thus both rare and fragile, suggesting that it is not an adaptive condition for survival and has been eliminated, or reduced to a very low level, by evolution.

It is not difficult to imagine why it would be maladaptive to program waking and dream consciousness at the same time. We will come back to this consideration when we discuss clinical implications below, but at this point we wish to stress the winner-takes-all model that we have sketched as the protoconsciousness hypothesis (Hobson 2009). According to that model, both waking and dreaming are states of consciousness engendered by specifiable brain mechanisms. Waking is governed by aminergic dominance, and dreaming by cholinergic dominance, but both states depend on suppression but not total obliteration of the other. Waking and dreaming are competitive and cooperative brain-mind states.

Of course there is more to the neurophysiology of the differential brain mediation of waking and dreaming. In addition to the chemical neuromodulation mentioned above, we know that REM sleep dreaming is mediated by the active inhibition of both sensory and motor input and output. The data from our studies of lucidity now further suggest that the two states are also differentiated by regional activation of

the cortex. Waking and lucid dreaming are both favored by strong 40 Hz power in the frontal EEG, indicating that frontal lobe activation is a critical mediator of both waking and lucid dream consciousness. Because this sort of activation has been found to correlate with lucidity, we hypothesize that it mediates the wake state component of lucidity. This supposition is also supported by the finding of frontal lobe inactivation in REM sleep, which is correlated with non-lucid dreaming (Braun et al. 1997; Dang-Vu et al. 2007; Desseilles et al. 2011; Nofzinger et al. 1997).

An additional nicety of the theory is that the voluntary eye movements by which lucid dreamers indicate their awareness of their conscious state to third-party observers (Hearne 1978; LaBerge 1980) is evidence of frontal eye field activation in lucid dreamers. This volitional override of the brain stem saccadic eye movement generator is further evidence of the change in the balance of brain-power in several states of consciousness. In lucid dreaming, the wake state control of gaze is returned via frontal lobe activation. According to Metzinger (2013), this is tantamount to the activation of an “epistemic agent model” (EAM), a representation of the self as knowing. This would seem to clinch the argument that conscious states are electrophysiologically differentiated and explained by neurophysiology. This is not surprising, but its specification has been greatly advanced by the scientific investigation of lucid dreaming. A speculative hypothesis that we believe must be tested is that waking entails not only frontal lobe dominance in mediating thought and top-down eye movement control, but that the brain stem itself is primarily harnessed to the analysis of external data with relative suppression of its internal program (see also Activation-Input Gating-Modulation, AIM model, Hobson 1992).

Unfortunately we have no animal model for dream lucidity because we have every reason to suppose that reflective insight such as observed in lucid dreaming necessitates sufficient language capacities assumed essential in the formation of abstract thought (Einstein 1941) or reporting of such. For this reason, we assume that infra-human mammals, which lack significant

language capability, cannot become lucid or report their non-verbal dreams. Whatever one thinks about animal dreams (and we suppose that primary consciousness does accompany their very elaborate REM sleep), no one believes that they are capable of verbally reporting their subjective experience. Dogs and cats do, however, whimper, twitch, and run in their sleep (Lucretius 1995), lending credence to the hypothesis of primary dream-consciousness in animals other than human beings. Animals may dream, and they may become lucid in their dreams, but we doubt the latter and can never offer scientific judgment about either possibility.

The exploration of the physiology of primary consciousness is in its infancy and can be expected to flourish in the future even if we have only rats for subjects (Datta & Hobson 2000; Datta & MacLean 2007). But if we want to learn more about secondary consciousness, we will have to put up with rather severe limitations (Dresler et al. 2012). We trust that advances in brain imaging technology may help this situation. Meanwhile, we hold that the study of lucid dreaming, however difficult, conveys insights about the brain basis of consciousness that is obtainable in no other way.

4 Summary and outlook

What we have learned so far is that the occurrence of lucid dreaming seems to be facilitated by brain maturational processes, in particular the integration of the frontal lobes into the cortico-cortical and cortico-thalamic networks, as outlined in thesis no. 1. Moreover, in lucid dreaming arising out of REM sleep, the apparent spatial dissociation between two states of arousal, waking (rostral) and sleep (caudal) is accompanied by the phenomenological dissociation expressed in an altered conscious awareness, for example, by changing from a first-person to a third-person perspective. This observation has led us to propose that lucid dreaming is to be regarded as a hybrid state (thesis No. 2) within a state-space continuum (thesis No. 3). Another observation concerns changes in frequency-specific oscillatory activity, with significant increases in lower gamma band activity in

lucid dreams, suggesting that lower gamma band activity plays an important role in achieving and/or maintaining a lucid dream. By electrically stimulating the dreaming brain in this frequency band we have been successful in trying to elicit lucid dreams, suggesting a causal role for the gamma frequency band, perhaps not only in lucid dreaming but in higher-order consciousness per se (thesis No. 4).

In spite of this basic scientific progress, our conclusions are only speculative and in need of experimental testing. One future line of research might be the spatial networking involved in consciousness. In our research, we have only stimulated the brain through bilateral fronto-temporal stimulation. We found only lower gamma band activity to be successful in inducing lucid dreaming. What happens, however, when we use different frequencies in rostral and caudal areas? Another question in need of attention is that of applicability. Will wake-training in gamma band activity through Neurofeedback and/or tACS increase the rate of lucid dreaming? What about effects on higher cognitive functions? Finally, we hope that our findings might some day be implemented in clinical settings. This concerns, for example, comatose or locked-in patients who are, through their trauma, confined to a particular state and who may benefit from the possibility of maximally utilizing state capacities.

We have now reviewed and discussed the current state of the art with respect to lucid dreaming. Having been *very* skeptical at first about whether such research could be conducted at all using a rigorous scientific protocol, we have grown increasingly optimistic—if not enthusiastic—about the prospects for the study of lucid dreaming, allowing us to monitor the brain as the mind changes conscious states. In that spirit, lucid dream science may be likened to a moon landing: yes it was hard to achieve, but we did it, and returned to *tell the tale*.

Insight: What Is It, Exactly?

A Commentary on Ursula Voss & Allan Hobson

Lana Kühle

In “What is the state-of-the-art on lucid dreaming? Recent advances and questions for future research”, Ursula Voss and Allan Hobson provide a detailed view of the features characterizing lucid dreaming and put forward four innovative hypotheses to explain why and how lucid dreaming occurs, as well as how lucid dream states are related to other states of consciousness. Their aim is to show that not only is there benefit to studying lucid dreaming in itself, as this would give us a deeper understanding of dream consciousness, but also that it is an important endeavor because of the kind of conscious state lucid dreaming is. To be sure, Voss and Hobson make important in-roads into the empirical study of lucid dreaming that ought to sprout new and exciting research in the area. As I will show, however, there remains much conceptual work to be done. In this commentary I tease out three aspects of Voss and Hobson’s view that would greatly benefit from philosophical consideration. First, I highlight the lingering confusion with what exactly insight is, and I point to how one might go about clarifying this notion. Second, I argue that our understanding of insight and meta-awareness in lucid dreaming could be greatly increased by looking at how these concepts are used and understood in relation to meditative states. Last, I explore the role of the body in lucid dreaming and argue that one’s bodily awareness in lucid dreams is far more multi-faceted than at it might at first seem.

1 Introduction

In “What is the state-of-the-art on lucid dreaming?—Recent advances and questions for future research”, [Ursula Voss & Allan Hobson \(this collection\)](#) aim to defend the veracity of, and value in empirically studying lucid dreaming. They provide a detailed view of the features characterizing lucid dreaming as well as hypotheses for why and how lucid dreaming occurs. As they claim, not only is there benefit to studying lucid dreaming in itself, as this would give us a deeper

understanding of dream consciousness, it is also an important endeavor because of the kind of conscious state lucid dreaming is. The authors argue that the study of lucid dreaming will also deepen our understanding of the structure of consciousness more broadly—the nature of meta-awareness, the notion of a self, and its relation to our ability to be meta-aware, etc.

To be sure, I think that Voss and Hobson make important in-roads in defending the vera-

city of lucid dreaming and putting forward hypotheses that ought to sprout new and exciting research in the area, as I will elaborate in section 2. However, I think there remains a need for caution in how we describe and define lucid dreaming, a great need for further clarification of what lucidity involves, and potentially fruitful connections to be drawn between lucid dreaming states and meditative states. In what follows, my goal is to elaborate on each of the following three points with a view to generating future discussion and discovery not only in the area of lucid dreaming research, but also in areas of meditation research and embodied awareness research.

The first point on which I focus—in section 3—is the concept of “insight”. To be sure, Voss and Hobson do offer us a definition of insight—an awareness of being in a dream, knowing that what one is currently experiencing is not real, etc.¹ However, their definition conflates and confuses whether the insight involved in lucid dreaming is a state or an ability, and whether it is an epistemic or phenomenal state/ability. In other words, does it involve knowledge of something, is it simply experiential, or is it an ability to do or know something, etc.? In this section, then, I delve deeper into what the authors mean by “insight” and explore these questions, as well as inquire whether insight is best understood using epistemological or phenomenological frameworks. Moreover, I consider what the consequences of an underdeveloped understanding of the concept of insight might be for the current state of research on lucid dreaming.

The second point on which I focus—in section 4—is the authors’ suggestion that we look at other states of waking consciousness with a view to determining how exactly insight comes to co-occur with REM sleep. I consider the potential similarities between lucid dreaming and meditation, and suggest that there are fruitful connections to be drawn between the meta-awareness associated with insight in lucid

dreaming and the meta-awareness involved in certain meditative practices.

The third point I consider—in section 5—is the experience of the body in lucid dreaming. In particular, I argue that if we accept one of the authors’ hypotheses—the Hybrid State Hypothesis—then we can enrich our understanding of the bodily awareness involved in lucid dreaming by looking at certain accounts of bodily awareness in waking consciousness. More specifically, I offer one interpretation for why the dual experience of the dream body and the real body in lucid dreaming is said to demand a lot of concentration by appealing to my recent work on bodily awareness in waking experiential consciousness. Before I begin exploring each of these three points, however, let me first summarize Voss and Hobson’s important contributions.

2 Voss & Hobson—A summary

In their piece, Voss and Hobson consider the latest empirical evidence on lucid dreaming and set forth four hypotheses that, they suggest, would begin to explain the whys and the hows of lucid dreaming. The four hypotheses proposed—the BMH (Brain Maturation Hypothesis), the GBH (Gamma Band Hypothesis), the HSH (Hybrid State Hypothesis), and the SCH (Space of Consciousness Hypothesis)—are based on five years of scientific research on lucid dreaming and, together, are meant to provide a multi-faceted picture of what lucid dreaming is, how it arises, why it arises, and how it relates to other states of consciousness.

The first hypothesis they propose is the BMH (Brain Maturation Hypothesis), which serves as a potential explanation for *why* there is lucid dreaming. Evidence shows that lucid dreaming occurs naturally and most often during certain periods of brain development and maturation in children and young adults.² The empirical evidence also suggests that lucid dreams are peculiar mental states that occur during the final stages on frontal lobe integration and, as such, are “nothing but an

¹ See Voss and Hobson’s target article in this collection, and their development of the LuCiD (Lucidity in Dreams) scale in Voss et al. (2013).

² See Schredl & Erlacher (2011), as well as the Voss & Hobson target article (this collection).

accidental confounding of conscious states during a time of high cerebral diversification” (Voss & Hobson [this collection](#), p. 8). For these reasons, Voss & Hobson hypothesize that “during childhood and puberty, frontal lobe activity is sometimes decoupled from the arousal state so that frontal lobes can become active in a state for which this type of activity is untypical”—the BMH ([this collection](#), p. 8). This, they propose, explains *why* lucid dreaming occurs.

Voss and Hobson then offer three other hypotheses—GBH, HSH, and SCH—as explanations of *how* lucid dreaming occurs. The GBH (Gamma Band Hypothesis) provides an account of how lucid dreaming arises by appealing to specific changes in brain activity associated with the onset of a lucid dream during ongoing REM sleep. Specifically, this hypothesis holds that the principle brain correlate of lucid dreaming is 40Hz activation of the frontal cortex—activation at this frequency brings about the meta-awareness associated with secondary consciousness. The HSH (Hybrid State Hypothesis) & SCH (Space of Consciousness Hypothesis) shift away from particular brain activity and, rather, provide a brain-based explanation and classification, respectively, of what lucid dreaming is in relation to other mental states. The HSH suggests that lucid dreaming involves elements of both waking and dreaming consciousness, and is, indeed, a destabilized hybrid state involving both frontal cortex activation, as suggested by the GBH, and REM sleep cortical activation. The HSH explains the *how* of lucid dreaming by offering a way to reconcile the subjective reports of lucid dreamers with the empirical data of cortical activation. The SCH lays out a three-dimensional model with which to categorize various states of consciousness and to see how the spectrum of mental states relate to one another along certain variables. This model allows us to situate lucid dreaming within a state space of consciousness and ascertain the similarities it might hold with other waking states of consciousness. These four hypotheses work together to consolidate the quantitative and qualitative data on lucid dreaming and provide a picture of why and how lucid dream-

ing occurs. For my purposes here, I will set aside the BMH and the GBH and will instead return to the HSH and the SCH in sections 4 and 5.

Importantly, the authors specify that their interest lies in considering REM-sleep lucid dreaming. In other words, the focus of their paper is to consider cases where the dreamer correctly achieves insight into the fact that he or she is dreaming while the dream continues (see Voss & Hobson [this collection](#), p. 4). The authors appeal to the Lucidity and Consciousness in Dreams Scale (LuCiD) they developed to assess the various features of a lucid dream state, and with this they describe eight features of lucid dream consciousness: insight, realism, control, memory, thought, positive emotion, negative emotion, and dissociation.³ Of these eight factors, three are highlighted as particularly important to the study of lucid dreaming—insight, control, and dissociation—as they do not typically appear in non-lucid dreams.⁴ The core criterion of lucid dreaming, however, appears to be insight. This feature, once it appears, then causally enables the possibility of control and dissociation. One of the issues that I will explore further in the next section is whether insight should be thought of as an epistemic or a phenomenal state, and what either of these interpretations might mean for understanding the role of insight in lucid dreaming.

Most of Voss and Hobson’s article discusses the features of insight and dissociation in relation to recent empirical evidence, and although there is indeed very illuminating discussion of these features, I nonetheless think there is still much conceptual confusion and semantic vagueness with regard to what exactly they are and how they relate to our non-dreaming conscious states. As I show in the next section, this is where philosophical considerations can help clarify the conceptual landscape and help move the empirical project forward.

³ Voss and Hobson don’t discuss the possibility of there being varying degrees of lucidity, and thus how these features might relate to such varying degrees. For a discussion of this, see Noreika et al. (2010).

⁴ There are rare cases where some of these aspects do occur in non-lucid dreaming states. See Voss et al. (2013) and Voss et al. (2014).

3 Understanding insight

The first element of Voss and Hobson's piece on which I want to focus my attention is the concept on insight. More specifically, I want to explore what the notions of lucidity and insight involve and how they relate to dream consciousness. As the authors clearly state throughout their paper, lucidity involves insight, and insight seems to be the key feature of lucid dreaming as it serves the basis of dream lucidity and enables the other elements of dream lucidity to arise, e.g., dissociation, control, etc. Without insight, it appears, one could not have lucid dreaming. Or, at the very least, it seems conceptually essential to have insight in order to be in a state of lucid dreaming.⁵ Given the importance of insight, it is key that we obtain a clear view of precisely what it is.

In the first place, I think it is necessary to distinguish between the *state* of insight and what one has insight about—let us refer to this as the *content* of insight. With regards to the state of insight, it is not so clear what this precisely is, and the authors do not adequately clarify it. For example, if it is an epistemic state, then it would have an intentional object. The questions then become: what are the intentional objects of the state of insight? What kind of knowledge does the state of insight involve? It is in the second section of their paper, "Quantification of Dream Lucidity as Subjective Experience", that Voss and Hobson attempt to describe and define what the state of insight is. There, they liken insight to a subjective awareness of our mental state. This subjective awareness, they go on to claim, is a form of secondary awareness, or meta-awareness that arises in lucid dreaming. They define meta-awareness, following Metzinger (2013), as "an instance of actively acquired self-knowledge or a sudden insight, regardless whether it is accurate or counterfactual" (Voss & Hobson this collection, p. 4). In short, insight appears to be a form of awareness that arises out of a more primary

awareness, and it allows the subject to attend to, or "see" what is occurring in primary awareness.

Now, a number of questions and issues arise from this definition of the state of insight. First, it seems quite problematic to define insight as a form of meta-awareness, and then to define meta-awareness as an instance of sudden insight. Perhaps, however, we might want to rely on the first half of the disjunct in the definition quoted above and understand insight as a form of actively-acquired self-knowledge. Given that the authors refer to insight as a form of reflection (Voss & Hobson this collection, p. 6) and as a form of knowing (ibid. p. 8) elsewhere in the text, I will assume that this is the more accurate reading of the definition. However, this still raises questions. In what way are we to understand "actively acquire" in the case of lucid dreaming? What does the dreamer *do* in a non-lucid dream state to acquire insight and thus bring about lucid dreaming? Is lucid dreaming an ability?⁶ If so, then perhaps it is trainable. Trainability might, in turn, provide us with an answer to the first two questions: namely, what might be involved in actively acquiring insight and what exactly the dreamer does. If it is an ability, perhaps the ability in question is one of moving into a state of meta-awareness. Moreover, if the ability to shift into a state of meta-awareness is an element of what the subject "does" to actively acquire insight while dreaming, then looking to other mental states that involve meta-awareness and that are also "trainable" could be beneficial.

One such set of mental states that involve an aspect of trainability are meditative states. Meditation is a practice, and with practice one is able to achieve and sustain certain forms of awareness—focused attention, open awareness, etc.⁷ If we take the element of practice in meditation as being akin to a form of trainability, and the forms of awareness in meditation to be

⁶ For a review of the ways in which lucid dreaming is trainable see Stumbrys et al. (2012).

⁷ Focused attention meditation involves developing one's ability to concentrate on an object for an unlimited amount of time. Open presence/awareness meditation involves opening one's awareness to all experiential aspects of the moment, e.g., mental states, bodily sensations, environmental stimuli, etc., and not attending to anything in particular.

⁵ We might not, however, be warranted to make a similar empirical claim, i.e., that insight is empirically essential *and* sufficient for lucid dreaming. Indeed, there is controversy over whether insight is empirically sufficient for lucid dreaming. See Voss et al. (2013) and Windt & Metzinger (2007) for further discussion of this issue.

akin to meta-awareness, then looking at the practice of meditation—what one does, how one improves, and so on—might be informative in ascertaining whether actively acquiring insight in lucid dreaming is something that is trainable.⁸ As I will detail in the next section, I believe there are also other reasons to consider meditation in relation to lucid dreaming.

Another line of questioning that arises from Voss and Hobson's definition of the state of insight relates to the concept of self-knowledge that, they claim, is an element of insight. How are we to understand the concept of "self-knowledge" as it applies to the insight gained in lucid dreaming? What is the "self" involved? And how strict a use are we making of the concept of knowledge—do we mean a justified true belief? The state of insight seems to involve very different characteristics. Voss and Hobson hold that insight involves knowledge, or the realization that one is dreaming, and they also describe insight as an experiential phenomenon, and one that involves reflection. The issue here is that "knowledge", "realization", "experiential phenomenon", and "reflection" are not interchangeable concepts. It remains quite unclear from the descriptions of insight provided whether we should view the state of insight as an epistemic or phenomenal state of consciousness. Based on the information Voss and Hobson provide in their piece, I am inclined to move away from an epistemological view of the state of insight as I think the concept of self-knowledge is too complex for the phenomenon that Voss and Hobson describe. What I mean here is simply that with the concept of self-knowledge come notions of identification, veridicality, the self, and so on, and I do not think that such a complex concept is necessary to account for the *experience* of insight in lucid dreaming. As Voss & Hobson explain, insight is "[t]o some extent, the dreamer [having]"—"however limited"—"access to secondary consciousness, enabling her to reflect on her present state" (this collection, p. 8), and "[b]y secondary consciousness we mean the subjective

awareness of our state in dreaming" (*ibid.*, p. 4). Instead, I would suggest using the concept of self-awareness to capture what is involved in insight, and by self-awareness I mean here simply the awareness of being in a certain experiential moment.⁹ So, in the case of insight, one becomes aware of dreaming—a self-awareness—rather than acquiring the self-knowledge that one is dreaming. Perhaps, however, there is reason to separate the concept of insight from that of lucidity, and with this distinction we might want to describe lucidity as a phenomenal state and insight as an epistemic state. I think there might be good reason to take this route, and I explore this in the next section by considering the potential relation between insight in lucid dreaming and insight in meditative states.

Now, these are issues that arise when considering what is meant by the "state" of insight. As I distinguished earlier, however, there is also the "content" of insight. With regards to the content of insight, in cases of lucid dreaming things are relatively clear: one gains insight on the nature of one's current dream state, i.e., that one is currently dreaming. In other words, insight involves coming to realize *that* one is dreaming. This way of describing what occurs in insight, however, could be seen as problematic in that it takes insight to involve a particular kind of knowledge, namely, knowledge-THAT. If indeed insight involves knowledge-THAT, then this opens the door to theory-contamination; that is, the content of insight is contaminated by what one already believes about dreams, consciousness, etc.¹⁰ Although I grant that this issue shows that there is a need to clarify what exactly the content of insight is, I am uncertain that it is as problematic as it might at first seem to hold that insight involves knowledge-THAT. How else would one be able to "realize" that one was dreaming if one was not able to identify, to some degree, that the state one is in is a dream state? Moreover, it certainly seems that to perform such an identification one

⁸ The Tibetan Buddhist practice of dream yoga is a particularly interesting area worthy of exploration in relation to this issue. See LaBerge (2003) for a discussion of dream yoga in relation to lucid dreaming research.

⁹ The "self" in self-awareness here does not refer to an ego or any robust notion of a self. Moreover, the kind of awareness I'm suggesting is not a categorical awareness, i.e., an awareness of the experiential moment as belonging to a category of consciousness (see Metzinger 2009). Rather, it is meant simply to point to a reflexivity of awareness (see the concept of "pre-reflective self-awareness" in Zahavi 2005).

¹⁰ Thanks to Thomas Metzinger for pointing out this issue.

would rely on theory-contaminated beliefs—certain conceptions of what a dream is like, etc. Perhaps there is no way of avoiding theory-contamination altogether, and thus the issue becomes one of determining how much contamination is allowable in the case of insight.

I certainly grant that given the state of research into lucid dreaming—it is still very much in its infancy, no doubt—it is not unexpected that a clear understanding of a complex concept such as “insight” is still lacking. To be sure, the authors have provided a good starting point for developing a full description of the state of insight. However, given that it is, arguably, the key element of dream lucidity, I worry about how well we can empirically investigate, or interpret our empirical findings of the whys and hows of lucid dreaming if we don’t first ensure that we have a working understanding of insight. To define insight as a form of meta-awareness, or secondary consciousness that involves actively acquired self-knowledge, is not informative enough to allow us an understanding of what insight in dream consciousness is or why it is so special and important.

To be sure, I think it would be entirely inappropriate to hold Voss and Hobson accountable for not teasing out the concept of insight further. They are empirical researchers, and as such have paved the way for future research in this area. However, I think that the lack of conceptual clarity and the semantic vagueness that remains in this area point to the need for philosophical inquiry and the value of integrating philosophical work with empirical work on lucid dreaming. It now lies in the hands of philosophers to ensure that the future progress of this research is based on a strong conceptual foundation. One direction to take in this endeavor is to follow Voss and Hobson’s suggestion and look at other areas of research concerned with meta-awareness, reflection, and insight. In the next section, I propose that one such area is that of meditation.

4 Lucidity, meta-awareness, and meditation

The second point I want to focus on is Voss and Hobson’s desire to consider other states of con-

sciousness to better understand the state of lucid dreaming. In particular, they express an interest in considering altered states such as hypnosis or mind wandering. I suggest that there might also be benefit in considering meditation. Specifically, I think we can fruitfully make use of how the notion of insight in meditative experiences is developed to clarify that of insight in lucid dreaming. We would first have to show that there are enough important similarities between the notion of insight involved in meditation and the notion of insight involved in lucid dreaming, and this will be my aim in what follows.

To be sure, there are many and various meditation styles and practices, each with its own experiential path to higher states of awareness. Broadly speaking, there are three categories of meditative practice, each with variants, and there is overlap in some respects between the categories.¹¹ First, there is focused attention meditation—this involves developing one’s ability to concentrate on an object for an unlimited amount of time. Second, there is open presence meditation—this involves opening one’s awareness to all experiential aspects of the moment, e.g., mental states, bodily sensations, environmental stimuli, etc., and not attending to anything in particular. Third, there is insight meditation—this involves developing mindfulness or meta-awareness over one’s mental states. More specifically, and most interestingly when compared to the concept of insight in lucid dreaming, “[insight meditation] is also one of the earliest and most fundamental forms of meditation. For Buddhist theorists, [insight meditation] is a style of meditation that, in combination with the focus or stability provided by cultivating [focused attention], enables the practitioner to gain insight into one’s habits and assumptions about identity and emotions” (Lutz et al. 2007, p. 504). For my purposes here, I will set the finer variations among these three main styles of meditation aside since I’m merely concerned with drawing out the similarities, in broad strokes, between the sought-after meditative state and the insight it is intended to provide,

¹¹ See Lutz et al. (2007) for a more detailed account of the various styles of meditative practice and their historical roots.

and the lucid dreaming state and the insight required to bring it about. Interestingly, however, the concept of insight applied to the practice of insight meditation is quite similar in many respects to the concept of insight applied to the experience of lucid dreaming.

To be sure, the concept of insight, as it relates to meditation, is very complex, and also not fully defined. There are many levels of insight, and many aspects of mental life, the self, and life more broadly that one achieves insight about, depending on the style of meditation one engages in and the level of mastery one develops in one's meditative practice. For example, in the practice of focused attention meditation, a novice practitioner might be said to have gained insight upon becoming aware of the difficulty involved in maintaining attention on the flow of the breath through the nostrils. The insight here is of a particular aspect of mental life, namely, the fleeting nature of attention. Whereas in the case of an experienced practitioner with hours of meditative experience, the insight gained may involve the nature of the self—for example, that it is characterized by desire and craving, or that it is ultimately an illusion. Nevertheless, I think that we can certainly make use of the way the concept of insight is broadly understood in meditation to clarify its relation to lucid dreaming, if it has any relation.

First, I take it that when we speak of insight gained through meditation, we aren't referring to a particular state that is achieved, but rather to a form of knowledge that is gained within a state of consciousness. The state from within which we might be said to achieve insight is a state of meta-awareness, but being in this state doesn't necessarily imply that insight has been achieved. For example, the novice practitioner may become meta-aware of what it is like to try to maintain focused attention on the breath, but this doesn't necessarily mean that he gains knowledge from this about the nature of attention and consciousness more broadly. Conversely, it seems that in the case of lucid dreaming, at least as described by Voss and Hobson, insight is understood to be synonymous with meta-awareness. This seems a natural understanding given that, as per Voss

and Hobson, when lucidity is achieved there is necessarily insight. That is, one could not, it appears, be meta-aware of their dreaming without having insight into the fact that they are dreaming. However, is this really *insight*? This is where I think we may want to tease apart the notions of lucidity and insight, following our understanding of meta-awareness and insight in cases of meditation.

In the case of lucid dreaming, there certainly is the experience of coming to realize one is in a dream state. This is the phenomenological interpretation of the state of insight I discussed in the previous section—what I also called the self-awareness of dreaming. However, we may want to refer to this aspect of lucid dreaming as lucidity, rather than insight. In other words, when lucidity occurs while dreaming, why should we not be satisfied saying that one has simply become aware of their dreaming? Why should we take this to be insightful? Maybe because lucidity doesn't merely involve a passive awareness of the dream state, but also an understanding by the dreamer of *what* she has become aware of—and this enables dissociation, plot control, etc. The suggestion that there is now an understanding that the dreamer has of being in a dream, however, brings into the picture the epistemological interpretation mentioned earlier. Given this, insight is better viewed as an epistemic state. In fact, maybe there is not only a need to dissociate lucidity from insight in the case of lucid dreaming; we may want to grant that both admit to phenomenological and epistemological degrees.¹² As we see in meditation, there are many levels of insight—many areas of our existence of which we can gain knowledge—and so maybe there is also reason to think that there are further forms of insight to be had in lucid dreaming as well. One particularly interesting point of convergence between the empirical work on lucid dreaming and meditation is in the phenomenon of dream yoga.¹³ As a result, we might not want

¹² This very idea has been explored in Windt & Metzinger (2007), as well as in Noreika et al. (2010).

¹³ In particular, the case of Tibetan dream yoga mentioned earlier, which involves using meditative practice in the dream, might be an instance of exploring just how meditation and lucid dreaming can come together, and could be informative for our understanding of

to define insight as a state of consciousness, or as a meta-awareness. Rather, we may instead see insight as a form of knowledge that accompanies lucidity, and lucidity as a form of meta-awareness.

Another area of similarity between meditation and lucid dreaming that I want to explore lies in the structure of each of these experiences.¹⁴ Both seem to involve some form of dissociation. As [Voss & Hobson \(this collection\)](#) describe, “lucid dreams can be considered dissociated states of consciousness in which the dream Self separates from the ongoing flow of mental imagery. The dream is still a dream but the person is able to distance him/herself from the ongoing imagery and may even be successful in gaining (at least partial) control over the dream plot” (pp. 8–9). The experiential feature of separation of the dreamer from the dream while the dream continues to unfold is akin to the observational stance that one strives to take in meditation, in particular in focused meditation. When meditating, one aims to become aware of one’s stream of consciousness—one tries to separate oneself, as it were, from the stream of thoughts, beliefs, desires, etc., in order to become aware of its transient nature. For example, one becomes aware of, say, the fleeting nature of attention and mental life. Similarly in lucid dreaming, one becomes aware of being in a dreaming state.

However, the concept of “self” that seems to underlie Voss and Hobson’s discussion of lucid dreaming is quite different from how the self is understood in meditation. Voss and Hobson appear to have a very robust sense of self at play, and I’m not quite sure why this is so, or whether we want to bring such a conception of self into the picture. One of the most telling passages in their article, and one that I find most problematic is the following:

both the nature of meditative states and that of lucid dreams. As [LaBerge](#) notes, “for more than a thousand years Tibetan Buddhists have believed that it is possible to maintain the functional equivalence of full waking consciousness during sleep. This belief is not based on anything as tenuous as theoretical grounds but upon firsthand experience with a sophisticated set of lucid dreaming techniques collectively known as the Doctrine of Dreams or dream yoga” (2003, p. 233).

¹⁴ See [Evan Thompson’s](#) entry in [this collection](#), as well as [Thompson \(2014\)](#).

This fits well with the common description of lucid dreams as (partial) awakening in your dreams and of involving a split between dreamer and dream observer who coexist and change relative dominance of the mind at will ([Occhionero et al. 2005](#)). The implications of this line of reasoning have profound impact on the theory of mind. There are two selves suggesting that the self is a construct elaborated by the brain ([Metzinger, 2003, 2009, 2013a](#)). The two selves of the lucid dreamer [...] ([Voss & Hobson this collection](#), p. 9, emphasis added).

Why would we want to describe the result of the dissociation in lucid dreaming as one that involves a split between a dreamer self and a dream-observer self? Furthermore, on the basis of what would there be reason to argue that the self is a construct?

If the experience in lucid dreaming is one of shifting back and forth between being meta-aware of being in dream consciousness and being in the dream itself as the dreamer, why would we not want to speak of this as a change in experiential perspective rather than as an experience of two selves?¹⁵ Moreover, if we look to how similar meditative experiences are described, we don’t speak of there being two selves, the self within the stream of consciousness and the self that observes the stream of consciousness. Rather, we speak of our shifting experiential perspectives wherein we move, as a single subject of experience, from being within the flow of consciousness to observing the flow of consciousness. Furthermore, one of the insights gained from meditative practice is that there is indeed no self.

I grant that it is perhaps in keeping with the subjective reports of lucid dreamers to speak of two selves in the lucid dream state. If the subjective report that [Voss & Hobson](#) quote in their paper ([this collection](#), p. 9) is but one example of the way in which subjects describe their experiences, then it certainly seems nat-

¹⁵ The shift in experiential perspective might even be more complex than this; see [Rosen & Sutton \(2013\)](#) for an interesting discussion of self-representation in dreams.

ural to take on such a view of the self. However, I suspect that the subjective reports may be constructed in a manner that is biased by a certain colloquial manner of speaking about the self,¹⁶ and thus don't rightly capture if and what the self is in relation to the structure of consciousness. Certainly I am not suggesting that we shouldn't take the subjective reports seriously—indeed I think that they provide invaluable information into the phenomenology of lucid dreaming. However, we must be careful to properly interpret these reports, and perhaps this will involve developing ways to discover whether certain biases have come into play in the subject's report of her experience, and how these biases have affected the qualitative data.

5 The hybrid state hypothesis and bodily awareness

The third and last point I want to consider is the place of the body, and bodily awareness, in lucid dreaming. I was particularly struck by two lucid dreamer reports. The first is the one that [Voss & Hobson](#) quote in their paper wherein the lucid dreamer explains that “[i]n these short periods of lucidity the awareness of the acting dream body and the real body in bed exist simultaneously and it costs a lot of concentration to keep the balance between both” ([this collection](#), p. 9). The second comes from Dutch psychiatrist Frederik van Eeden, who coined the phrase “lucid dreaming”:

In January, 1898 [...] I was able to repeat the observation. [...] I dreamt that I was lying in the garden before the windows of my study, and saw the eyes of my dog through the glass pane. I was lying on my chest and observing the dog very keenly. At the same time, however, I knew with perfect certainty that I was dreaming and lying on my back in my bed. And then I resolved to wake up slowly and carefully and observe how my sensation of lying on my chest would change to the sensation of lying on my back. And so I did, slowly and

deliberately, and the transition—which I have since undergone many times—is most wonderful. It is like the feeling of slipping from one body into another, and there is distinctly a double recollection of the two bodies. I remembered what I felt in my dream, lying on my chest; but returning into the day-life, I remembered also that my physical body had been quietly lying on its back all the while. This observation of a double memory I have had many times since. It is so indubitable that it leads almost unavoidably to the conception of a dream-body. ([van Eeden 1913](#))¹⁷

I found the description of there being two bodies rather interesting, and, particularly in the subject report cited by Voss and Hobson, the mention of the cost of concentration to be very intriguing. To be sure, there is but one physical body, namely the one lying in bed. Yet the dreamer experiences both the body in bed and the body with which she is engaged in the dream, and finds it somewhat demanding to maintain an experiential balance between both. In this last section, I put forward an explanation of this experience by relying on the Hybrid State Hypothesis alongside my work on bodily awareness during waking consciousness.

According to the HSH Voss and Hobson put forward, lucid dreaming is a hybrid state with both elements of waking and dream consciousness. This is so because there is a dissociation that occurs between the dream self and the ongoing dream imagery. Physiologically, although brain activity associated with REM sleep continues, in lucid dreaming there arises, in addition, brain activity in parts of the brain associated with conscious awareness and executive ego functions. The hypothesis, then, is that “lucid dreams push the arousal system towards waking yet remaining within the region occupied by REM sleep [...]. Lucid dreaming is, thus, a fragile, destabilized hybrid state” ([Voss & Hobson this collection](#), p. 9). If this hypothesis is correct, then there may be value in looking at how we are aware of our body in a waking con-

¹⁶ This, as Metzinger would point out, would be another instance of theory contamination.

¹⁷ Thanks to Metzinger for pointing out this classical description of a lucid dream experience.

scious state to help better understand the seeming duality of bodily awareness involved in lucid dreams. More specifically, if we take seriously the above-quoted subjective report, then the hybrid state hypothesis in combination with certain hypotheses about bodily awareness in waking conscious states might shed light on how the experience arises.

What I find particularly interesting about the reports are two things:

- a. the simultaneous experience of a dream body and the real body in bed; and
- b. the amount of concentration needed to keep the balance between both.

In regards to the first, I find myself wondering the following: what does the subject mean by simultaneous, here? Does she mean that both bodies are experienced *at the same time*, or rather, that there is a very quick and continuous shift back and forth from the dream body to the real body, such that it *seems* like they are both being experienced simultaneously? I am inclined to think that what is happening is a very quick attentional shift back and forth between the two “bodies”. My reasons for thinking this come from how I account for our bodily awareness in waking life.

I take it that in our everyday experiential lives we are aware of our body both as an object and as a subject. The distinction between awareness of the body as object and as subject stems from the Phenomenological tradition¹⁸ and it is best understood as follows. I can be said to be aware of my body as object when I direct my attention to my body and thereby perceive it as I would any other object in the world. The key characteristic of our awareness of the body as object is that it is attentional. Alternatively, I can be said to be aware of my body as subject when I am aware of my body as that *through* which I experience the world—not as an object onto which I turn my attention, but rather as that which engages with my environment. My awareness of my body as subject is

also referred to as a bodily self-awareness, and it is characterized by an inattentional awareness—a form of awareness that does not involve holding attention to an object.¹⁹

Now, my typical experiential consciousness involves a bodily self-awareness, although it doesn’t always involve an awareness of the body as object. This is because I don’t always attend to my body. Take, for example, my sitting in a chair reading a book. Typically, my attention lies with the book—I focus on the words on the page, say. In attending to the book, I don’t simultaneously attend to my hands holding the book, although they are certainly a part of my overall experience insofar as they don’t disappear from my awareness entirely. I certainly can shift my attention to my hands, and thereby become aware of them as object; however, in doing so, I contend, I am no longer attentively aware of the words I was reading a moment ago. In fact, I take it that if I were to try to be aware of my hands and the words on the page simultaneously, I would find this quite difficult as it would involve a continuous and rapid shift in attention back and forth between the words and my hands. I think a similar account holds in the case of lucid dreaming with regard to the dream body and the real body.

I propose that in the case of one’s bodily awareness in lucid dreaming, the real body is experienced both as subject and as object. It is the subject’s actual body, and therefore one that she is aware of as subject, but in addition her experience of her real body, in the lucid dream, is of her body as an object—she becomes aware of her body as object by her attention shifting to it momentarily. However, her attention does not remain with her real body; instead it quickly shifts back to the dream body as well. In that experiential moment, the dream body becomes an object for her as she attends to it. I think the further clue as to why we should interpret the experience of the body in lucid dreams as one of shifting attention, and even perhaps competing attention between the real and the dream body, comes from the second element of the subject’s report men-

¹⁸ A philosophical tradition most often associated with the work of Husserl, Merleau-Ponty, Sartre, etc.

¹⁹ I develop this distinction further in my thesis, “Embodiment and Subjectivity—the Origins of Bodily Self-Awareness”.

tioned above—the claim that “it costs a lot of concentration to keep the balance between both”.

Why is there a need to keep a balance between the real and the dream body? Perhaps because, as the HSH suggests, there are elements of both waking and dreaming states at play. If we take bodily awareness to be a fundamental element of waking consciousness—or even consciousness tout court, as I do—as well as a key element of dream consciousness, then it makes perfect sense that in a lucid dream the subject finds herself with these two bodies that must be balanced in the same way that the waking and the dream states must be balanced to remain in the lucid dreaming state.²⁰

The question then becomes: why does it cost a lot of concentration to maintain this balance? I think the answer to this question brings us right back to my suggestion above, namely that the simultaneity of the dream and real body experience is one of shifting, or even competing attention. If there is a continuous shift in attention, rather than a joint experience of both bodies, then this would explain the apparent cost of trying to maintain concentration on both bodies in a lucid dream state. It would be like walking a tightrope, trying to avoid leaning too far to the right or too far to the left, and doing so by continuously shifting your body to maintain that balance. It would require an incredible amount of concentration—in a general sense, one experiences everything all at once, but in a more precise sense, one’s attention is continuously shifting between one’s body and one’s environment in order to maintain balance.²¹

One last point of inquiry. As I mentioned above, there is a distinction to be made in accounting for our bodily awareness in waking experiential consciousness between our awareness of the body as object and our awareness of the body as subject, i.e., bodily self-awareness.

²⁰ The place and role of the body, and our bodily awareness in lucid dream states, is far more complex than I can show here—in fact, there are instances of bodiless dreams. Although a complete consideration of these issues is beyond the scope of this commentary, an excellent discussion of this topic can be found in Windt (2010).

²¹ This is also how lucid dreams are commonly described in the literature, i.e., as a balancing act. See LaBerge (1985) and Brooks & Vogel-song (2000).

However, I wonder if a similar distinction might also apply in cases of lucid dreaming given the HSH. In other words, is there a bodily self-awareness—of the real body or even the dream body in a lucid dreaming state? And, if so, how does it relate to the awareness of the dream body and the real body described by subjective reports? To begin answering these questions we would need to explore the subjective reports of lucid dream experience in relation to bodily awareness more specifically. Perhaps we might begin by looking back upon the report by van Eden. Indeed, I certainly take this to be an interesting avenue of exploration given the ever-increasing interest in taking an embodied approach to consciousness.

6 Conclusion

In closing, let me review the three points of inquiry on which I chose to focus here. First, I inquired as to what exactly the concept of insight involves in the case of lucid dreaming and whether we should think of insight as a phenomenal or epistemic state. I suggested that the lack of clarity with regard to the concept of insight shows the need for rigorous philosophical inquiry with a view to laying down a solid conceptual foundation from which to pursue future empirical research. Second, I inquired as to how meditation and lucid dreaming are similar and where research on meditation might provide information to research on lucid dreaming. I highlighted some interesting overlaps in the concepts of insight in meditative practice and lucid dreaming, and explored the feature of dissociation in lucid dreaming in relation to the notion of a self. Third, I looked at how we are aware of our body in lucid dreaming and considered whether our accounts of bodily awareness in waking consciousness can be used to inform our understanding of bodily awareness in lucid dreaming. I also suggested that the distinction between awareness of the body as object and of the body as subject used to describe waking bodily awareness could help us tease out the ways in which the body is experienced in lucid dreams.

As I stated above, the empirical study of lucid dreaming is still very new and, thus, still very much in an exploratory phase. As a result, it is easy to point out various areas for further inquiry and suggest avenues of future investigation. However, it is nonetheless important to acknowledge the work that Voss and Hobson have done to advance our understanding of the phenomenon of lucid dreaming. Not only have they provided a convincing account of why lucid dreaming occurs (BMH), they also put forward an interesting hypothesis for the neural basis of lucid dreaming (GBH). Moreover, their HSH and SCH will serve to further the conceptual analysis of lucid dreaming and its relation to other mental states across the spectrum of sleeping to waking consciousness. In short, I agree with Voss & Hobson that “the experimental study of lucid dreaming is a powerful paradigm for understanding the brain basis of conscious experience” (this collection, p. 4). Moving forward, we must now expand the area of research to allow for important philosophical considerations that will strengthen the conceptual framework underlying this exciting new paradigm.

Reflections on Insight

A Reply to Lana Kühle

Ursula Voss

In this reply to Kühle, I will respond to her comments on the role of insight in lucid dreaming, especially regarding the question of whether it may be knowledge-based or instead express a sensorial experience. My answer rests on experimental findings, acknowledging Kühle's remarks, and taking her methodological challenges into account. I will challenge her proposal that insight might be called a state, opting for a definition of a transient thought atypically embedded within the state of dreaming, which may suffice to retrospectively call a REM dream lucid, but which will not satisfy the assumptions underlying the existence of a state.

1 Introduction

The commentary by Kühle reminds me of a remark made by a distinguished and renowned Swiss sleep researcher who asked me recently, during a lengthy discussion of our work on lucid dreaming, “how can you be sure that what you call a dream really exists”. In other words, he wanted to know how we could prove that dream narratives were memories of REM-sleep mental activity instead of, say, fantasies occurring during the process of awakening or memories of hypnagogic hallucinations, etc. It struck me then that I had neglected to openly postulate the key assumption that our work rested upon, namely that dreams really exist. So I still owe

him a detailed response and Kühle's commentary provides me now with the opportunity to generate an adequate reply. In the following, I will focus on Kühle's main argument, which seems to circle around the definition of “insight” and the question of whether it represents an epistemological statement or a phenomenological experience. I will shortly enter into discussion of whether it is justified to define insight as a state, as this assumption is not to be deduced from our work but certainly points to a need for clarification. While interesting, I will refrain from commenting on her speculations on whether insight may or may not be an ability

except for proclaiming that in my view, insight represents nothing but a result of neurobiological processes we still know far too little about. However, it is a fact that entering the state of lucid dreaming can be trained. Can insight *per se* be trained? I doubt it. Can the ability to generate insight be trained? According to recent studies on gamma-band activity in the developing and mature brain (see references in the main text), it is at least a possibility.

2 The role of insight in lucid dreaming

In her commentary, Kühle claims that the way we use the term “insight” leaves many—mostly philosophical—questions unanswered. While I certainly agree in principle that solving one question often generates many others, I also believe that there is some need for clarification regarding terminology. It seems that the discussion of what insight is and what it isn’t reveals one of the key methodological differences between our disciplines. Whereas philosophy of mind is mainly involved in meta-theory and the conceptualization of psychological theories, the focus of experimental psychology lies on the testing of hypotheses, albeit neither foci apply exclusively. By definition, however, experimental psychology aims at identifying cause-and-effect relationships between observable phenomena by applying experimental methods to induce controlled manipulations of so-called “independent variables”, leading to reproducible changes in “dependent variables”. Although experiments are hypothesis-based, testing specific (confirmatory) or unspecific predictions (exploratory) derived from theory, progress is often made when such an experiment leads to an unpredicted result. Such was the case in the construction of our LuCiD scale.

In the set of lucid and non-lucid dreams investigated and reported on by our group (Voss et al. 2013), we identified a factorial structure in which eight item clusters (which differed from the theoretically predicted ones) showed sufficient common variability to consider the items within each cluster related. These eight factors accounted for a large portion of variance in dream consciousness as

defined a priori, and based on theoretical considerations. The items in the item pool statistically identified as the single factor we referred to as “insight” pertained to the verbal communication that one *knew* one was dreaming while the dream continued. As such, insight would have to be regarded (in an epistemological sense) as understanding that at a particular moment within the dream, the dreamer acquired knowledge about his or her state of consciousness, which would be the hybrid state of lucid dreaming.

As Kühle correctly points out, this may or may not be true, however. It is just as possible that a dreamer who states upon his or her awakening: “I *knew* it was a dream while the dream continued” only thought that he or she knew, while in truth, he or she may have *sensed, felt, or experienced* that the ongoing dream action was not real. This would then pertain to a phenomenological experience similar to what Duncker (1947) refers to as “conscious participation” (p. 505), describing the sensorial experience that one is, at a particular moment, consciously aware of (pp. 508–509). On the other hand, even if we really experienced insight in a phenomenological sense, how can we be sure that this experience was not the result of the epistemological recognition of some sort of incongruence within the dream at some particular point in time? To me, this line of thought resembles that revolving around the question of whether we can be certain that a dream is really a dream and not something else. Philosophically, this is of course fascinating. But to experimental psychologists, such a discussion is unsettling because it is so difficult to translate into testable, i.e., operationalizable, hypotheses. Our admittedly very pragmatic approach is to define underlying assumptions such as “*we assume that dream reports generated from REM sleep awakenings are mentations generated during REM sleep and (fractionally) remembered (at least) until questioning*” or “*we assume that verbal accounts are reliable and valid*”. These assumptions can then again be challenged by separate experimental studies. In the case of doubting the existence of REM sleep dreams, an experiment

could be set up, for example, interrupting different states of arousal such as meditation, daydreaming, NREM sleep, or REM sleep and questioning the subject with respect to immediate recollections of mental activity. A comparison would lead to the conclusion that reports from REM sleep awakenings differ fundamentally from reports gathered from other states of arousal. This has, of course, been successfully achieved and repeated many times. However, the question is still not solved. It is doubtful, for example, whether an arousal from REM sleep enables as accurate a report as an arousal from the meditative state. Similarly, we cannot exclude the possibility that REM sleep alters mnemonic processes in a different way to NREM sleep, so that obvious discrepancies in NREM and REM reports are due to state-dependent retrieval and filtering processes and not at all related to different fantasies generated during the particular state.

In the same way, it certainly is appropriate to wonder about the true nature of what we refer to as “insight”. To psychologists, the explanation that a factor name is really only an attempt to describe a commonality between different but related observations is probably satisfactory. To philosophers, this will of course not be the case. However, with psychological pragmatism in mind, I would like to point to some empirical findings (and their immanent difficulties) regarding the question on how to further explore the nature of insight in lucid dreams: when we constructed the LuCiD scale (Voss et al. 2013), we started out with a set of 50 items that were selected on the basis of theoretical consideration. In a first step, these items were tested on a large sample of dreamers, leading to 158 dream narratives considered valid. These were then analyzed for factorial structure as well as for item reliability. Several items that might have been potentially informative regarding the question of epistemology vs. phenomenology proved either indistinct in differentiating between lucid and non-lucid dreams or they yielded too high statistical item difficulties so that they had to be eliminated from further evaluation. Some examples are:

- While dreaming my sensations were the same as when I imagine something or daydream during wakefulness
- While dreaming I was convinced that I was awake.
- I wasn’t in the dream, I had no self.
- While dreaming I felt that I knew where I was sleeping.
- While dreaming I was more than one person.

This finding of no-difference is of course by no means sufficiently informative to consider the question of insight in dreaming solved or even solvable. The finding of high item difficulty in particular poses some problems: items are considered difficult if they do not yield a reasonable number of affirmative answers (Moosbrugger 2008; Schermelleh-Engel & Werner 2008). Thus, an item that is not often selected as true will be eliminated from analysis although it might contain valuable information, e.g., that the statement is considered false by the majority of participating subjects. Further, in the case of subjects awakened from sleep, they may not affirm an item although it is true, simply because they are not yet able to comprehend its content (sleep inertia). For example, the item “I wasn’t in the dream, I had no self” was not often selected as true. Was this because in most cases, dreamers felt they did have a self or was it because they didn’t understand what was asked of them? I hope that this example highlights some of the problems that arise when we try to subject philosophical theory to experimental testing. Perhaps a different design, opting for a specific comparison of questions addressing epistemology vs. phenomenology during a steady state of wakefulness (such as mind-wandering or meditation) might generate more concrete answers, avoiding sleep inertia effects should they exist. We look forward to such results.

3 Insight as a state of consciousness?

According to Kühle, our results suggest that insight may be considered a state. Moreover, she claims that the LuCiD scale does not allow for the identification of different lucidity

levels. These assumptions are not to be deduced from our research but must stem from a misconception or misunderstanding of the factorial structure of the LuCiD scale. Concerning this matter, we reported that dream consciousness can be described by eight factors, six of which are capable of distinguishing between lucid and non-lucid dreams: insight, control, dissociation, positive emotion, negative emotion, and memory. A person can have a range of scores in each factor, for example in insight, such that scores are graded and allow for varying degrees of lucidity. Furthermore, the factors identified are correlated, i.e., not independent (see [Voss et al. 2013](#)), which means that one factor alone may not be sufficient to define a lucid dream. Our results also suggest that a dream might be considered lucid even with low scores of insight! So the assumption that the state of lucid dreaming is equivalent to the proposed state of insight cannot be inferred from our data. Kühle's proposal reveals another problem, however, that we tried to address with our Space of Consciousness model (SoC), which is the definition of "state". What is the relationship between a state of arousal and a state of consciousness? In the case of insight, the recognition "I am dreaming" may be only a fleeting thought. But this thought is embedded in relatively enduring neurophysiological patterns such as regional changes in blood oxygen levels (see [Dresler et al. 2012](#)) and enhanced gamma activity in frontal regions ([Voss et al. 2009](#); [Voss et al. 2014](#)). Our suggestion to situate lucid dreaming within the SoC attempts to incorporate these observations. In my view, a state is comparable to background activity enabling or disabling certain transients such as thoughts or memories. It is courageous to consider a fleeting thought a state, and I think such definition would need more detailed specifications. Of course, one may ask whether a dream would be considered lucid even in the absence or perhaps following the thought "this is a dream". According to our model, this assumption would have to be affirmed. If the state of lucid dreaming is considered a neurophysiological state of sleep bor-

dering wakefulness, enabling the mind to produce a transient thought (insightful thought), this thought may or may not be repeated several times within the state of lucid dreaming. The important factor is, as Kühle proposes, capability. During the state of lucid dreaming, the mind is able to be insightful. It is not the other way around, such that the mind is able to enter a lucid dream during the thought of insight. The importance of insightful thought thus does not lie in its being a state but in it being measurable! We cannot expect a subject to provide a truthful answer to the question "were your frontal lobes producing gamma band activity?" We can, though, ask about the quality of their thoughts and sensations. Finally, if, in spite of my objections, we define insight as a state of consciousness, how would this state be defined in terms of arousal (see the SoC model), or in terms of other determinants such as, for example, judging, sensing, or moving? Supposed insight were defined as a point in the SoC. Where would it be located? Within mindwandering, meditation, lucid dreaming, focused attention—or all of these?

4 Conclusion

While Kühle's comments are greatly appreciated, they show how important dialogue between the different disciplines involved in studying consciousness really is. Neuroscience, psychology, and philosophy are all connected in their quest for a better understanding of the true nature of consciousness and its underlying physiology. They depend on each other to formulate predictions based on theory, and to test and reappraise these on the grounds of cause-and-effect relationships established through experimental testing. Experimental research rests upon certain assumptions that may not or may only fractionally apply to philosophy. The most important assumptions of dream science are to consider it true that there exists a real world (1), that REM sleep dreams exist (2), that healthy awake humans are able to make valid statements about knowing and feeling (3), and that restrictions to this ability (e.g., sleep inertia) can be reliably identified (4).

Representationalisms, Subjective Character, and Self-Acquaintance

Kenneth Williford

In this study I argue for the following claims: First, it's best to think of subjective character as the self-acquaintance of each instance of consciousness—its acquaintance with itself. Second, this entails that all instances of consciousness have some intrinsic property in virtue of which they, and not other things, bear this acquaintance relation to themselves. And, third, this is still compatible with physicalism as long as we accept something like *in re* structural universals; consciousness is a real, multiply instantiable, natural universal or form, but it likely has a highly complex, articulated structure, and “lives” only in its instances. In order to make these cases, I give a characterization of subjective character that accounts for the intuition that phenomenal consciousness is relational in some sense (or involves a subject-object polarity), as well as the competing and Humean intuition that one of the supposed relata, the subject-relatum, is not phenomenologically accessible. By identifying the subject with the episode or stream of consciousness itself and maintaining that consciousness is immediately self-aware (“reflexively” aware), these competing intuitions can be reconciled. I also argue that it is a serious confusion to identify subjective character with one's individuality or particularity.

I argue that deeper reflection on the fact that consciousness has only incomplete self-knowledge will allow us to see that certain problems afflicting acquaintance theories, like the one I defend, are not the threats to certain forms of physicalism that they might seem to be. In particular, I briefly consider the Grain Problem and the apparent primitive simplicity of the acquaintance relation itself in this light.

1 Introduction

In this study, I argue for the following claims: First, it's best to think of subjective character as the self-acquaintance of each instance of consciousness—its acquaintance with itself.¹

¹ As will become clear shortly, contrary to ordinary ways of speaking, I do not hold that persons must be the “subject relata” of acquaintance relations. Rather, I hold that episodes of consciousness are, fundamentally, the subject relata.

Second, this does indeed entail that all instances of consciousness have some internal relational property (or intrinsic property) in virtue of which they, and not other things, bear this acquaintance relation to themselves. And, third, this is still compatible with physicalism as long as we accept something like *in re* structural universals. There is always a price, but in this case

it's arguably no more than the price we pay to be scientific realists.²

To make these cases, I must consider some important preliminaries. I give a characterization of subjective character that accounts for the intuition that phenomenal consciousness is relational in some sense (or involves a subject-object polarity), as well as the competing Humean intuition that one of the supposed relata, the subject-relatum, is not phenomenologically accessible. If the latter is true, it is hard to explain how we could have immediate evidence (as opposed to some sort of inferential knowledge) of the existence of this relational structure—evidence we do seem to have. If we identify the subject with the episode or stream of consciousness itself (however we individuate or ontologize these)³ and maintain that consciousness is immediately self-aware (“reflexively” aware⁴), then the intuition of relationality and the Humean intuition of the missing subject can be reconciled.

I also argue that it is a serious confusion to identify subjective character with one's individuality or particularity. This will be considered first from a phenomenological point of view, in relation to our tendency to describe subjective character in terms of ownership or “mineness”, and then from an ontological point of view, in relation to the metaphysical individuation conditions of distinct streams of consciousness.

Further, I argue that deeper reflection on the fact that consciousness has only incomplete self-knowledge will allow us to see that certain problems afflicting acquaintance theories, like the one I defend, are not the threats to certain forms of physicalism that they might seem to

be. In particular, I briefly consider the Grain Problem⁵ and the apparent primitive simplicity of the acquaintance relation itself in this light.

Preliminary to all this, we must first briefly consider the inadequacies of representationalism, and at least adumbrate some of the motivations for the recently renewed interest in the idea of acquaintance (see e.g., Chalmers 2003; Tye 2011, pp. 96–102; Gertler 2011, pp. 87–128, 2012; Balog 2012; Howell 2013, chs. 3 & 4; Goff forthcoming). I argue that, indeed, we need to lose our fear of moving beyond reductive naturalistic representationalisms, especially in regard to subjective character. My conclusions, and in many cases arguments, are not entirely new, but I attempt to cast the material in a new light, in a spirit of synthesis.

The dialectical structure of this study is somewhat circuitous. In section 2, I argue that the most plausible representationalist theory of consciousness is a self-representationalist one (or “Same-Order” representationalism) because it captures subjective character, which I view as essential to consciousness, with the smallest theoretical cost. However, I argue, all forms of representationalism about consciousness are ultimately implausible. This leads to a focused discussion of the notion of subjective character in section 3, the notion that motivates higher-order and same-order representationalisms. In that section, I argue that subjective character should be identified with the self-manifestation or self-appearance of consciousness. Consciousness, the claim goes, appears to *itself* no matter what else appears to it. This in turn allows us to make sense of the competing relationality and Humean “no-self” intuitions mentioned above. Combining these elements from sections 2 and 3, I argue in section 4 that we should understand self-manifestation in terms of self-acquaintance rather than self-representation. In section 5, I clear up what I regard to be the not uncommon confusion of subjective character with individuation. And in section 6, I argue

² This is not to imply that scientific realism entails physicalism, of course.

³ This is a difficult issue I will not enter into. See e.g., Dainton (2000, 2008); Strawson (2009).

⁴ I will occasionally use the terms “reflexivity” and “reflexive awareness” to denote just this characteristic of consciousness (i.e., that of its always being aware of itself). It is not to be confused with “reflection” in the sense of introspection. It is more like the logical usage of “reflexive” (as in “reflexive relation”). The acquaintance relation is reflexive on the domain of conscious states, according to the view accepted here (as well as being anti-symmetric). But not everything that stands in this relation is self-acquainted—episodes of consciousness are, but they are also acquainted with sensory qualities, and these latter are not acquainted with anything.

⁵ The Grain Problem, customarily attributed to Wilfred Sellars, is a problem for any identity theory according to which sensory qualities are really brain properties of some sort. Roughly put, the problem is that brain properties are complex and structured while sensory qualities seem, on the face of it, ultimately simple and unstructured. For good discussions with references to Sellars see Clark (1989) and Lockwood (1993).

that though the view espoused here implies that being conscious is a matter of having certain intrinsic properties, this is compatible with a certain type of physicalistically acceptable hylo-morphism—the view that complex kinds of physical objects, properties, or processes involve the concrete instantiation of real structures and cannot be properly understood in abstraction from such a “marriage” of form and matter.

2 Representationalisms: From first-order to same-order

In the theory of consciousness, the term “representationalism” has, aptly but somewhat confusingly from a historical point of view, come to designate any view according to which being phenomenally conscious is equivalent to representing the right sort of things in the right sort of way. There is, of course, much internecine disagreement over these things and ways, but the main idea is simple and attractive enough. If we could understand consciousness in terms of representation and representation in terms of some naturalistically acceptable relations, then we could “naturalize” consciousness. I’ll call representationalisms that are coupled with naturalistic theories of content *reductive representationalisms*.

Representationalisms are typically divided up into various “orders.” These orders have, in a way, to do with the kind of content (or object) a conscious representational state supposedly must have. For First-Order (F) representationalisms the relevant states are, fundamentally, just directed at worldly objects and properties (typically the sensible properties of tables, chairs, etc., see, e.g., Tye 1995, 2000; Dretske 1995). For Higher-Order (H) representationalisms, the states must be directed at mental states of “lower-order”—possibly but not necessarily first-order (see e.g., Rosenthal 2005; Lycan 1996). For Same-Order (S) representationalisms, the representational state must be directed at itself (or, perhaps, some part of itself, or a whole of which it is a part, or another part of the whole of which it is a part).⁶ I also add Priv-

ileged-Object (P) representationalisms as a distinct category. For these, the state must be directed at some special type of entity—a model of the organism as a representational or embodied homeostatic system, a “proto-self” or, less naturalistically, perhaps an enduring substantial ego entity.⁷

There is, however, no obvious reason why there could not be unconscious representations with any of these contents. And, generally, it seems implausible that something could be conscious in virtue of representing a certain type of object—this is Alvin Goldman’s so-called “Problem of the Rock” (thinking about or seeing rocks does not make them conscious, so why should it make anything else conscious?), which seems to apply to H, S, and P theories—but see below (see e.g., Goldman 1993; Gennaro 2005; Lycan ms).

For F theories, since it is admitted there can be conscious and unconscious states with the same sort of content, another distinguisher between conscious and unconscious mental states will have to be found. For F theorists, this has typically been a functional constraint placed on the representations (e.g., poise, feeding into the mind-reading system, becoming available to the global workspace, see, e.g., Tye 2000 and relatedly Baars 1997; Dehaene & Naccache 2001), sometimes coupled with the necessary condition that the properties represented must be represented in a “non-conceptual” way (whatever that is taken to amount to).⁸ For the H theorists, it has been a somewhat different story.

H theorists are generally motivated by a phenomenological inadequacy they see in F the-

theorist. S theory is also often called self-representationalism.

7 For naturalistic versions, see e.g., Damasio (1999 and 2010), Metzinger (2004), and Sebastian (forthcoming). I am sure that Damasio, Metzinger, and Sebastian would reject this label, but the point of it is that all these theories identify subjective consciousness, in one way or another, with the representation of a “self,” understood in a naturalistically acceptable sense. See e.g., Metzinger (2004), p. 302: “In short, a self-model is a model of the very representational system that is currently activating it within itself” (emphasis original); and Damasio (2010), p. 180: “[T]he brain constructs consciousness by generating a self process within an awake mind. The essence of the self is a focusing of the mind on the material organism that it inhabits.” It should be noted that Metzinger allows that there could be conscious experience that does not involve subjective character (see Metzinger 2004, pp. 559–560). Thus my categorization here applies at most only to his theory of subjective consciousness. Since, for me (as for Damasio), all consciousness necessarily has subjective character, this difference in detail will not loom large in what follows.

8 See the excellent discussion of the “non-conceptual content” literature in Hopp (2011).

6 See e.g., Gennaro (2012); Kriegel (2006, 2009); Weisberg (2008, 2014). Williford (2006) can be taken to express a pure S view—the conscious mental state has itself for its own object, not some portion of itself. We can also classify Carruthers as an S theorist; see Carruthers (2000, 2005). Gennaro would not describe himself as an S

ory. F theorists generally stress the so-called “Transparency Intuition”—the idea, roughly put, that first-order consciousness reveals only properties and objects in the world and nothing directly about consciousness itself, the perceiving mind, the subject, or the vehicles of representation (see e.g., Harman 1990; Tye 2000; Byrne 2001). H theorists, on the other hand, are with varying degrees of explicitness motivated by the equally powerful intuition that consciousness involves some sort of “for-me-ness” or “to-me-ness,” often termed “subjective character” (see e.g., Rosenthal 1986, p. 345 and Gennaro 2006. See also Levine 2001, pp. 104–111). This gets encoded in the H mantra that the conscious states are just those that one is “Aware of Being In”, those that one is aware that one is oneself in (see e.g., the “Introduction” to Kriegel & Williford 2006). The thought is that F theory simply does not capture that intuition. F theorists and their fellow travelers would consider such “essentially indexical” contents or the “sense of self” to be more advanced cognitive products or artifacts of social cognition, certainly not in the very ground floor of consciousness (see e.g., Edelman & Tononi 2000, pp. 103–104 and Macphail 1998, pp. 2–5).

There is here an important bifurcation in intuitions about consciousness. Some significant percentage of us thinks that subjective character (however we ultimately understand it) is essential to consciousness, is in the ground floor. And some significant percentage of us thinks that it is not; that somehow qualitative character (perhaps understood as having the right sort of representational content) is essential but that subjective character is derived, secondary, or tertiary. This bifurcation shows up in neuroscientific and psychological thinking on consciousness as well.⁹ We will briefly return to the significance of this bifurcation point in the next section.

The H theorist has a few options about the exact content of the H representation, the higher-order thought (or perception [or global state]).¹⁰ There are serious and well-known

problems here. If the represented lower-order state (L state) of, say, visual perceptual awareness were different from the representing H state in terms of relevant content (e.g., if the one represents a phenomenally green ball and the other a phenomenally red one), what would we consciously see? “Red. No, green. No, red...” This is the Problem of the Division of Phenomenal Labor, or mirepresentation problem, as I will sometimes call it, and is related to deep and probably insoluble problems about the epistemology of introspection that are pertinent to such models (of both H and S varieties).¹¹ If the L state simply did not exist, would your conscious experience in that case be a sort of Meinongian hallucination? This is the Problem of Targetless H States.¹²

To take up the latter problem just a bit, if one takes literally much of the talk one finds in the literature on H theory, the H thought is supposed to *make* the L state conscious. Being conscious is a kind of extrinsic (external relational) property of the L state, a property it has in virtue of its being represented by the H state. Thus, if there is such an H state, it does confer at least a relational property (the property of “being made conscious by the H state”) on the L state. In the cases in which the L state does not exist but the H state directed at it does, some non-existent object, the L state, is made conscious by an H state. Thus the L state would literally have a relational property; it would stand in a relation, even though it does not exist. This literal interpretation of the view entails some form of Meinongianism (at least about non-existent L states) and that you can seem to yourself to be conscious when you are not. Thus, presumably, it should not be taken so literally.¹³

¹¹ See e.g., Neander (1998); Horgan & Kriegel (2007); Weisberg (2008); Tye (2011, pp. 4–8). See Kidd (ms) for an excellent discussion of these epistemological issues in the (not interestingly different) case of S theory.

¹² See Mandik (2009 and forthcoming) on the “Unicorn problem” and Block (2011). See Rosenthal (2011, 2012); Weisberg (2011a, 2011b); Kiefer (2012); Wilberg (2010), and Berger (2013) for discussions of various strategies for dealing with Higher-Order-Thoughts (HOTs) without Lower-Order-Thoughts (LOTs).

¹³ What I am calling the “non-literal” interpretation is, in effect, the position in Berger (2013). And in Rosenthal (2011, p. 436) he in effect claims that the non-literal position (as I am calling it) has always been his view. See Mandik (forthcoming) on this.

⁹ For example, Tononi & Koch (2008, pp. 240–241) do not seem to think that the “sense of self” is essential (though Tononi (2014) may have recently changed his view); Damasio (1999, 2010) is in the opposing camp; see also Northoff (2013).

¹⁰ I’ll not go into the Higher-Order Thought vs. Higher-Order Perception debate. See e.g., Gennaro (2012).

The non-literal interpretation, however, is inimical to one of the reductive pretensions of the H strategy. It's not inimical to reductive representationalism as such. But it does draw in to question the idea that a reductive theory must construe the property of being conscious as an external-relational property of otherwise unconscious mental states (see [Rosenthal 1997](#)). Thus, it could only be in virtue of the specific content or structure of the H state itself that there is consciousness. One would then be putting forth the presumably phenomenologically motivated *a posteriori* identity hypothesis that the conscious representational states are just the ones with that content. There may be differences over the specific content (e.g., Is it about some of my other mental states, or is it just about the non-mental objects and properties of the world?) and differences over other criteria (e.g., poise); but otherwise, on the non-literal interpretation, H theory is structurally just like F theory. We can of course wed either of these to a reductive theory of representation, but this will only make "being conscious" into an external-relational property to the extent that the theory of representation adopted makes all representation an external-relational matter.

If one is still conscious when the L state does not exist, then the H state would seem to be doing all the work. And that's what we should focus our explanatory efforts on. What could be special about it? Again, putting aside other types of external relations (e.g., being available to the global workspace), it must have a special sort of content. But it is not in virtue of *being represented* that a state could be conscious. Rather, on this non-literal interpretation, it is in virtue of *being a representation of X* (where *X* is a special object of some sort, e.g., oneself being in a state) or *that p* (where *p* is a proposition with a special content) that the state is conscious; and we can, as with any other sort of contentful state, try to figure out how different naturalistic theories of representation would construe states with that content.

Whatever theory of content we adopt, we'll want to know what salient or interesting properties, from an explanatory point of view, such representations have. What is it about you

that you can represent yourself as being in a state or that a conscious state of yours is occurring now? Find that out, the promise goes, and we will understand consciousness. But, I would argue, none of the theories of representation we have to go on tell us anything very significant about such states. The beaver's tail splash, says Millikan, to take one sort of example, can represent the very time at which it occurs (among other things; [Millikan 1995](#), p. 98). This does not make it conscious. This particular example applies directly to Same-Order theories, but surely the beaver's tail splash *could have* represented a previous tail splash and its content or its simultaneous front paw splash, etc., but that would not in itself make anything conscious either, right?

Naturalistic theories of representation will not themselves tell us anything that interestingly distinguishes H states (or S states) from F states (or P states for that matter). In every case (F, H, S, P), it is just a matter of some physical representational vehicles standing in some set of external (or externally mediated) relations to other physical objects (and sometimes to themselves). From this point of view, we see nothing that interestingly distinguishes the theories.

Moved by these problems, H theorists might try to go the "essential indexical" route (cf. [Weisberg 2012](#)). After all, on Rosenthal's original formulation, the conscious states are those one is aware of *oneself* as being in. But here they are faced with a difficult choice. If they presuppose a teleosemantic theory, then they have to face the fact that on this theory there are no literally *essential* indexicals (see e.g., [Millikan 1990](#)). Change the relevant history and other external relations and you change the content—now an indexical, now a proper name, now a substance term, etc. If they abandon teleosemantics, they could go back down some Fregean rabbit hole.¹⁴ That way lies murk or perhaps triviality (see [Cappelen & Dever 2013](#)). But it seems inadequate just to postulate that

¹⁴ I assume here but will not argue that teleosemantics is the most plausible naturalistic theory of content. There may be other naturalistic options that allow one to make good sense of the notion of essential indexicality in a way that could help H theory here, but I doubt it.

the H state contains a definite description that happens to pick oneself out. Thus the H theorist might be led to consider what is in effect a P theory. One then tries to find a suitable entity to play the role of the privileged object (a privileged signified, if you will): the proto-self, the self-model, or what have you.¹⁵

It is hard to see how any of these possible objects would somehow help us to make sense of subjective character. And it is hard to see how representing some special object could be that in virtue of which something is conscious. If “essentially indexical” content is either explicable in terms of something more basic (as seems to be the case to me), or impossible (as on teleosemantics), or metaphysically fraught in an ultimately un-illuminating way, then it seems like the best bet is to adopt a version of S theory.

For one thing, we can reduce the metaphysical load that threatens to plague the notion of essential indexicality and solve the non-existence problem at once.¹⁶ All we need are token mental states representing themselves. As a corollary, we can give a deflationary account of “essentially indexical” content in token-reflexive terms¹⁷ that is potentially compatible with teleosemantics (or whatever non-Fregean account one prefers) and find some other way to capture the grain of truth reflected in the opacity arguments presented by Castañeda, Lewis, and Perry.¹⁸ In my view, anyone committed to the intuition motivating H theory should become an S theorist, if for no other reason than because of the non-existent L state problem. The other possible solutions (e.g., Gennaro’s “WIV”) introduce a kind of theoretical inelegance that renders them less plausible.

H theories are better than F theories, given my intuitions anyway, because they en-

code the essentiality of subjective character to consciousness. If that intuition is good then, of the two classes, H theories are the better ones. But H theories face the non-existent L state problem. To solve it, they must either embrace murk or metaphysical baggage (if they go in the direction of some P theories), or embrace the postulation of certain epicycles, or go some other order. S, in my view, is evidently the best option for the representationalist.

S theory avoids *ad hoc* moves, better reflects the clarified phenomenological intuitions that are the real motivation, can ground a theory of indexicals, and does not commit one to an enduring self-entity of any sort; nor does it seem to attempt to get subjective character out of something’s representation of something else that is structurally similar to itself, as this last move runs afoul of the Fichte-Shoemaker Regress.¹⁹ S theory evidently does not fall prey to the non-existent L state problem, even if it does not avoid the misrepresentation problem. In the end, however, it is itself nothing more than a type of P theory. The Privileged Object is just the token mental state (or episode) itself. Clearly, there is no self-evident reason why something’s representing itself should make it conscious, even if it is in fact true that all conscious episodes do represent themselves.

We surely cannot seriously imagine that consciousness emanates from a special object it needs to look at, even if that object is just the current experiential time-slice itself. Further, something’s representation of itself, naturalistically understood, is no more theoretically inter-

¹⁹ See Henrich (1982); Frank (2002, 2007); Shoemaker (1968). The issue, which is part of the “essential indexical” problematic, is, when put into a “self-model theory” context (which is not to be identified with Metzinger’s views), just that modeling something structurally isomorphic to oneself is not sufficient for knowledge that one is modeling oneself, as opposed to having behavioral control through such an interface (I could be controlling my doppelgänger unwittingly and just as effectively). One would need to know that the thing modeled is oneself (and not something else that happens to be isomorphic to it, like one’s counterpart in a close possible world). One cannot, on pain of regress, derive such knowledge from a set of descriptions of oneself without already knowing that at least one of the descriptions does indeed apply to oneself. So one must have some direct self-knowledge, such as knowledge by acquaintance that one is the relevant so-and-so. An S theory wedded to a teleosemantic theory of representation and externalist theory of justification has the advantage of being able to accommodate direct reference and non-inferential knowledge of oneself, though one will regard this as a mere simulacrum of the phenomenology.

¹⁵ See Sebastian (forthcoming) for a Damasio-inspired turn toward a P theory (at least, that was my interpretation of it).

¹⁶ We can’t eliminate the misrepresentation problem, however. But we bracket that for now. See Kidd (ms) and Weisberg (2008).

¹⁷ A la Higginbotham (2003 and 2010) and before that (implicitly) Smullyan (1984); see Cappelen & Dever (2013, pp. 160-161). The hyperset model in Williford (2006) is the skeleton of such a theory. See also Kapitan (2006).

¹⁸ See Cappelen & Dever (2013, ch. 10). They attempt to capture this grain by appealing to relatively un-puzzling epistemic limitations. I believe they are on the right track, even if I would characterize the specific limitations in question a bit differently (see the discussion below on our ignorance of what fundamentally individuates us).

esting (or even surprising) than its representation of the world or of one's other thoughts and perceptions. Thus, that does not, *a priori*, appear to be the sort of thing that would be more likely to be equivalent to consciousness than something's representation of something else. Perhaps adding functional constraints would help here but no more than it might help H or F theory.

Even if it is true that all conscious states are self-representational, it is, of course, far from clear how that fact should help us *explain* consciousness. The same can be said for H theory and other P theories. Rather, in all these accounts, we are merely trying to isolate what we take the unique content of consciousness to be and then to apply our theory of representation to states with such content. Absent some strong phenomenological intuitions to the contrary, the conscious mental states, it seems, might well have been all and only those states in which dogs are represented. In the end, though, all "normal" physicalists (i.e., those who reject Russellian Monism, Panpsychism, and Pan-proto-psychism) are reduced to *some* such strategy. All "normal" physicalists, representationalist or not, will identify consciousness with something that is not *a priori* known to be equivalent to it. We return briefly to this familiar problematic at the end.

But, perhaps most alarmingly, reductive S theories (and H theories, and everything in between) are either subject to a version of the old Swampman objection or otherwise untenable.²⁰ Since the conscious states are, on the theory, just special representational states, they are subject to the constraints of the underlying theory of representation (in this case, teleosemantics). If they don't have the right history, then they don't have the right content. And if they don't have the right content, they are not conscious. Surely there is something simply absurd about the idea that one might or might not be conscious depending on how one's atoms happened to get into the current arrangement.

²⁰ See e.g., Tye (2000, ch. 6). I will not be able to go into the back and forth over Swampman. Suffice it to say that despite hearing many attempted rejoinders over the years, I still find the objection to be a *reductio* of representationalist theories of consciousness wedded to historico-externalist theories of content.

It is not that one cannot concoct a response to the objection; it is, rather, just the very fact that the view invites such objections in the first place. It demands a rather serious and ugly epicycle; and that counts strongly against it. But if we reject teleosemantics and adopt an internalist theory so as to escape from Swampman, we face equally difficult problems that we cannot, unfortunately, go into here.²¹

The view then is that H theories are better than F theories on phenomenological grounds and that S theories are better than H theories on dialectical *and* phenomenological grounds. But all versions wedded to naturalistic historico-externalist theories of representation are shipwrecked on the Swampman problem, and internalist versions face other equally difficult problems. What then shall we do?

We might consider trying out a non-reductive representationalist version of S theory. This is a possibility we will return to in section 4. But first we need to reflect a bit on what H, S, and P theories are trying to capture in the first place. What is the phenomenological datum designated by this phrase "subjective character," and why is it that F (and related) theorists don't see it as essential to consciousness, while H, S, and some other theorists do?

3 Subjective character

Subjective character is often described as a certain "for-me-ness," "mineness," or even "me-ishness" that is phenomenologically manifest and, presumably, always accompanying, even if in a muted or background form, any consciousness whatsoever (see e.g., Zahavi 2005; Levine 2001; Kriegel 2009 and Block 1995). F and related theorists point out that it also seems that one can become so absorbed in one's actions, at one extreme, and perhaps so dulled at the other that one loses all sense of oneself (see e.g., Tononi & Koch 2008, pp. 240–241). Moreover, they might argue that it does not seem reasonable to suppose that worms and bees have a

²¹ See e.g., Carruthers (2000, 2005) and Gennaro (2012, pp. 45–49). Briefly, the sort of functional role semantics Carruthers embraces derives actual, occurrent content from dispositions, and it is actually subject to variations on the Swampman theme.

sense of self at all, and yet they may be conscious. A common reply from the defenders of subjective character to the first claim is that we are not talking about focusing on oneself or one's current mental state as an object of attention or concern, and that, if they tried harder, F theorists would realize that even in the most dulled or, at the other pole, absorbed state, they are still aware at some level of themselves (or the very experiential state they are in). To the second objection, the typical reply is that the sort of subjective character we are envisaging does not require the sort of conceptual sophistication or reflective capabilities that would make it impossible for dogs (or even bees and worms) to count as conscious beings (see e.g., [Gennaro 2012](#), chs. 7 & 8). Of course, the replies can be replied to, and so on. And we won't enter into these debates here. Suffice it to say that, unsurprisingly, those who think that subjective character is essential to consciousness have ways of answering objections, just as do those who deny its essentiality. As commonly happens, the answers drive us back to questions that are themselves at least as hard to settle as the ones we began with. Moreover, appeals to the neuroscientific and psychological literature in the attempt to decide these issues sometimes get what plausibility they have from interpretations of the experiments and results that are as questionable as the claims they are supposed to support.

My view here is that one should follow the modeling path inspired by one's "phenomenological muse" and give up fighting phenomenological intuition wars. If you find subjective character to be essential, develop models of consciousness that encode that, and see where they lead. If you don't find it essential but find other things to be more important (multimodal information integration or availability in the global workspace or whatever), model those. And let's not forget that we might all be working on different parts of the same elephant, so perhaps we will be able to combine models fruitfully one day. Eventually we may have ways of more or less decisively testing the different models.²²

²² See [Kriegel \(2007\)](#) for an excellent discussion of phenomenological impasses. Thanks to Jennifer Windt for reminding me of this lucid article.

Different intuitions about what is essential to a phenomenon drive different models of the phenomenon. As long as enough people (and don't ask for a number) share one's phenomenological intuitions, one's project won't be, we hope, insane or unmotivated. In regard to the present bifurcation point, many otherwise sane, rigorous, and careful thinkers in many widely distributed traditions and disciplines have had some version of the intuition that consciousness, somehow, involves a sense of self or sense of itself.²³

Now, how should we characterize subjective character at the phenomenological level? It does not add much to say that it is a "sense of self." What sort of a sense of self are we talking about? To say that it is "mineness" or "for-meness" makes it seem as though we are talking about the *ownership* of experiences. But this is probably just a certain analogy based on the ownership of property. Yes, for all that matters here, it may well be the case that, always, if I am in a position to know, without having to observe any behavior, that *there is* a pain in the room, then I am in a position to know that it is my *own* pain in the room. But it does not do much good to say that "me-ishness" or "mine-ness" adheres to my experiences like a property or haecceity. It is not as if I just see that my experiences have Willifordhood instead of Zahavihood or Gallagherhood, and thereby know whose are whose—like distinguishing two otherwise qualitatively identical coats by different name tags on the inner pockets.

Note that looking for a special property of the experience is not that different from seeking out its relation to a special object (its owner or The Self) that one may be directly acquainted with. In both cases we are looking for a special something that individuates the experience. There is no interesting difference here between a special unique property that only my experiences have and a special unique self-object to which they all relate.

²³ For just a few examples of the historical pedigree here, see [Caston \(2002\)](#) on Aristotle, [Williams \(2000\)](#) and [Coseru \(2012, ch. 8\)](#) on the Indian and Buddhist debate, [Thiel \(2011\)](#) on the early modern problematic, [Frank \(2004\)](#) on the German Idealist and Romantic discussion, and [Zahavi \(1999 and 2006\)](#) on the Phenomenological movement.

Subjective character should probably not be thought of as a matter of a constant relation to a self-object or as a special property of mine-ness or me-ishness that all experiences come with, all the more is this so if it is possible to misattribute ownership to certain sensations.²⁴ The first-personal dimension (Zahavi), the sense of self in the act of knowing (Damasio), for-me-ness, me-ishness (Block), ipseity, *être-pour-soi* (Sartre), *Selbstvertrautheit*, and so on—these are all suggestive names for the phenomenon in question. But we'd like to know if there is not an at least somewhat less ambiguous way of characterizing it.

One name for it that I do rather like depends on a grammatical analogy that can be fleshed out a bit more. Every experience, we may say, involves the appearance *of* something *to* something (or someone). The former can be called the *genitive of manifestation* (appearance-of), the latter the *dative of manifestation* (appearance-to).²⁵ The genitive of manifestation corresponds to the intentionality of consciousness—its directedness at objects; the dative of manifestation corresponds to subjective character. The identification of subjective character and the dative of manifestation may not at first be so obvious.

The primary intuition here is that there is no such thing as the mere non-relational phenomenal appearance of an object or quality. Objects and qualities don't just phenomenally manifest—full stop. Rather, anything that phenomenally appears, appears to someone or something (cf. Strawson 2011, pp. 41–46). If this were false, phenomenal consciousness would be more like a monadic property of its objects than like a relation between a subject and an object of some sort (see Butchvarov 1979, p. 250). The idea that consciousness could be phenomenally manifest but manifest *to* no one is

either incoherent or, at best, strains credulity. Yet this seems to be exactly what F and related theorists are committed to—aches and pains that can appear (be phenomenally conscious) but appear to no one.

If we accept that there is a dative of manifestation, that objects and qualities appear *to* someone or something, we are closer to but not quite up to subjective character just yet. Subjective character, recall, is supposed to be something phenomenologically detectable. And one might raise the following sort of worry. Suppose phenomenally manifest objects and properties are manifest *to* something or someone. It does not follow from this alone that that *to which* they are manifest is itself manifest or even manifestable. Nor does it follow that the *fact that* they are manifest to something is manifest or even manifestable. In other words, there could indeed be a dative of manifestation and yet no direct phenomenological evidence of this at all. In fact, Hume's famous failure to find his own self and Moore's similar but more tentative musings on this issue can be taken as expressions of the intuition that we do not find a distinct subject relatum in experience.²⁶ And surely it is true that we do not find a little ubiquitous homunculus—the constant and ever-present thing Hume might have been seeking, like the little face at the bottom of old first-person video games like Quake—to which all our experiences relate—nor do we find a self-haecceity forever re-instantiated by our conscious episodes.

There is, however, this strong intuition that phenomenal consciousness is relational, that it involves a subject-object polarity. And the strong intuition that we do not find any entity or special criterial property that could be a self-entity, me-haecceity, me-ish quale, or subject-relatum is in some apparent tension with this intuition of relationality. Moreover, a *hidden* subject-relatum would not account for the phenomenology of subjective character, evidently. There is a real question here. How is it that consciousness seems to have a subject-object relational structure, and yet we do not

²⁴ See e.g., Lane & Liang (2011). (Thanks to an anonymous reviewer for pointing this nice article out to me.) If, as I shall argue, subjective character is not fundamentally a representational matter at all, the issue of *representational* immunity to error through misidentification is orthogonal. To the extent that the attribution of ownership is a representational matter, it may or may not be possible to misattribute ownership, as far as the view defended here is concerned.

²⁵ The terminology apparently derives from Prufer (1975) and is very common in phenomenological quarters. See e.g., Zahavi (1999); Crowell (2011, p. 16).

²⁶ See Moore (1910); Butchvarov (1979, p. 250, 1998, p. 55), and Williford (2004). On Hume in this regard, see Strawson (2011).

seem to be able to find the subject-relatum, one of the relata of the relation? Isn't it the case that if something non-inferentially seems relational, then we are non-inferentially aware of its (at least) apparent relata? Speaking naïvely and barring certain irrelevant counterexamples, if I see that the cup is on the table, don't I see the cup and see the table too? In the case of the subject-object polarity, do we imagine or project this relation? Is it a product of reflection and memory?

It seems to me that the F theorist should say that it is somehow a product of higher cognition that is projected onto normal adult human conscious experience. But if one is really committed to the intuition that subjective character is an essential and hence ubiquitous feature of conscious experience, then one will simply have to abandon self-relatum and self-haecceity accounts as characterizations of the phenomenology (and as explanatory models, for that matter). What we need is an account of how it is that consciousness manifestly and non-inferentially appears to have a relational structure even though one of the relata is, in a certain sense, invisible.

Here the view that consciousness is self-manifesting can save the day. An episode or perhaps stream of consciousness, on this view, appears to itself at every moment while other things appear to it as well. This will require more unpacking, but at present we just want to clarify the putative phenomenological content of the claim as best we can. We leave the notion of *appearing* or of *phenomenally manifesting* undefined. Or, if you prefer, we define it ostensibly by inner ostension and hope that our interlocutors know what we are talking about and have similar conscious minds (cf. Fales 1996, pp. 147–148).

Let's say that phenomenal manifestation is just the appearance to/in consciousness of something. Let's leave it open what that something is (qualities, facts, objects). We all can know what phenomenal manifestation is, in this purely phenomenological sense, if we are conscious and capable of normal reflection, attention, memory, and conceptual cognition. If we have tasted coffee, then the taste of coffee has

been phenomenally manifest to us. If we haven't, then it has not. And think of this generically—it's what experiencing the taste of coffee has in common with seeing the blue sky and with feeling one's own existence.²⁷ Now, the claim is that an episode of consciousness is phenomenally manifest to itself whenever anything else is phenomenally manifest to/in that episode. Whenever anything else appears to consciousness, that act or episode or stream of consciousness appears to itself as well. And it is important to remember that this does not mean that one is reflecting on one's experience or that one has any propositional attitude towards that experience or that one is paying any attention to that experience as such.

Now, let us suppose that this is the case. Can we recover a notion of subjective character from this in a way that accounts for both the Humean intuition that the subject-relatum is, in some sense, invisible and that, nevertheless, consciousness has a subject-object relational structure that is phenomenally manifest and non-inferentially knowable? Yes, we can, and at a relatively low price.

The subject-relatum, on the current proposal, is just the episode of consciousness itself. The episode appears to/in the episode. Other things (qualities, objects, etc.) appear in/to the episode as well. The episode is a unified whole, the differentiated qualities and objects appearing in/to it are like its parts (stressing "like"—it's an analogy).²⁸ We do not find episodes that do not have parts (except perhaps in some very special circumstances), but it is foolhardy to look for some special entity or haecceity that is separable from all the other parts or like a part among the parts. There is no such thing. And that, arguably, is the sort of thing Hume was failing to find. No such subject is given, hence we don't find it. Nonetheless, the true subject-relatum, the episode of consciousness itself, is not invisible. It is manifest.

²⁷ Cf. Moore (1910, p. 57). (This paper of Moore's is not as well known as his "Refutation of Idealism," but it deserves to be.)

²⁸ I will not attempt to offer an account of the (synchronic or diachronic) unity of consciousness in this paper (again, see e.g., Dainton 2000) or of mereological principles governing "parts" of episodes of consciousness and episodes as "wholes." It is enough for my purposes that one recognize that conscious episodes are internally variegated unities of some sort.

The main price to pay here is that we must try to wrap our heads around the idea that an episode of consciousness could be the phenomenological *subject* of consciousness. I say, and say truly, that such and such appears to *me* or that *I* see, feel, hear, or am conscious of such and such. If I am a subject of consciousness and all subjects of consciousness are just so many episodes, then am I just an episode of consciousness?! I've seen the incredulous stares with my own eyes and have been told that the sentence expressing the view that the subject of consciousness is the episode of consciousness has the same status as sentences like, "Pink dreams sleep furiously."

Indeed, this claim seems wildly counterintuitive at first. But once we realize that there is a certain temporal element connoted in our usage of "I," then this can be ameliorated. "I" normally refers not just to the present experience but to a whole history of connected experiences and much else besides. So it would be a mistake to infer from "I've seen the incredulous stares" the claim that "Incredulous stares were seen in/by this current episode of consciousness." Instead, in the spirit of Four Dimensionalism, one should translate thus: There was a past series of conscious episodes suitably connected to each other and to the present one; incredulous stares were seen by/in them for some time; and the episodes are being recalled in/by the present conscious episode, which bears the same relation (transitively conceived), or some suitable analogue thereof, in the case of broken streams, to that sequence of earlier episodes.

Note, however, that fundamentally the use of "I" is anchored in moment-by-moment, self-manifesting conscious experience. Imagine a person with severe anterograde amnesia and retrograde amnesia as well. Such a person might think, from moment to moment, "I am seeing this," "I am feeling that," but beyond a certain perhaps necessary amount of working memory, they may not carry any of that information into their future. We can imagine truly minimal subjects that have only the minimal amount of working memory required for consciousness, supposing that some amount is required. On the view proposed here, such a conscious being's

consciousness would still have subjective character. It would simply fail to be more or less automatically enriched by memory, projection, familiarity with one's body and dispositions, autobiographical idealizations and distortions, etc., that is, by the autobiographical representational grid through which our experience is normally spontaneously filtered. Perhaps such a person could not think "I" in the sense in which we normally think it. They may lack an "autobiographical self" and even "extended consciousness", as Damasio would put it (see [Damasio 1999](#) and [2010](#)). But their experience would be self-manifest and other things ("parts") would be manifest in/to that experience as well.

Still, isn't it a bit too odd to hold that the whole episode is conscious of its "parts"—however we end up construing these? Or that the "parts" are phenomenally manifest to/in the whole they belong to? Doesn't this still seem like a totally bizarre thing to say? We have to remind ourselves that there is no thing in consciousness, no ego entity, no homunculus that these qualities could be manifest *to*. We don't find any such thing; and no *hidden* thing could allow us to account for the phenomenology. However, we agreed (I hope) that consciousness has a relational, subject-object structure and that this structure is itself phenomenally manifest and not inferred.

Another way to put it is to say that there is a kind of contrast present in our experience all the time. Something is before me, and it is not me. Something is present to consciousness, but it is not that consciousness. Given our mereological analogy, this contrast is a bit *like* that between a whole and its proper parts. The whole is not a proper part. Yet, at a suitably generic level, it bears the same relation to itself that it bears to its constituents (everything is a part of itself too, though an improper part).

Assuming that this relational structure is not projected onto the experience in reflection, assuming that is, that this is a genuine "prepredicative" structure of experience, the contrast between the subject-pole and the object-pole is manifest, even if it normally remains unthematized or attended to as such. On the hypothesis that consciousness is always self-manifesting,

there is no problem here. The relevant contrast is *like* the contrast between the parts and their unified whole. The parts are manifest. The whole is manifest (self-manifest). So all the needed elements are present for their relations (of differentiation, unification, and inclusion) to be manifest.

Moreover, the idea that the difference between the parts and the whole is prepredicatively manifest is no more implausible than the idea that the difference between parts and other parts is prepredicatively manifest, something almost no one would deny. If I see a red patch on a black background, I have a differentiated, contrastive visual experience. The same goes for differences between the sensory modalities: we see and hear simultaneously, etc. If those sorts of contrasts can figure into the ground level of experience, why not the contrast between the unified self-manifesting whole and all its manifest “parts”—the totality of simultaneously manifesting qualities (however we understand them exactly) in all modalities (sensory and possibly cognitive, conative, and affective)?

Subjective character then, on this view, is just the self-manifesting character of an episode of consciousness. This view has the nice feature that it allows us to simultaneously account for the Humean-Buddhist “no-substantial-self” intuition and the intuition of relationality, with its attendant minimalist “sense of self”—as subject-pole.²⁹ It does this with less metaphysical cost than self-entity and self-haecceity theories, even supposing that those theories are not entirely phenomenologically implausible and explanatorily bankrupt. Let’s remember, however, that this is meant as a phenomenological claim fundamentally: consciousness is self-manifest just as the unified totality of sensory qualities (etc.) is manifest; and their contrast is manifest too, just as the contrast between such qualities (etc.) is manifest. This phenomenological claim has an ontological significance only if we accept that consciousness is indeed how it seems to be upon reflection. A claim that I accept in this case, but one need not accept it to appreciate

the phenomenological point and the virtues of this way of articulating it.

4 From self-representation to self-acquaintance

I gave up on reductive self-representationalism for quite general reasons, reasons affecting all representationalisms. As such, one might be tempted to suggest adopting some non-reductive form of S theory. For example, if one adopts the phenomenal intentionality³⁰ view, one might hold that whatever phenomenal representation *is*, consciousness represents itself in *that* way. It seems like this view might be just another way of describing the same phenomenological facts belabored in the previous section. If that is so, the phrases “phenomenal intentionality” and “acquaintance” are going to be basically synonymous, and the advocate of the former terminology can just translate. If we build nothing into the notion of representation other than the idea that something (an object, property, episode of consciousness, or whatever) is phenomenally manifest (to someone), then the views are indistinguishable at the phenomenological level and, maybe, the ontological level as well.

If this is not what is intended, however, then it is probably because the phenomenal intentionality theorist wants to mark an important distinction between intentionality (representation) and acquaintance. Perhaps they would prefer not to be committed to acquaintance if possible, and there are several reasons they might want to avoid such a commitment. But I will argue that in a certain sense, to be plausible at all, all forms of representationalism, reductive and non-reductive (including a phenomenal intentionality-based representationalism), ought to embrace a type of acquaintance relation.

Consider, for a moment, fictionalist representationalism about sensory qualities (projectionism about colors, for example). One could embrace a view according to which the sensory qualities are phenomenally manifest, though they in fact are never really instantiated by

²⁹ I defend this view also in Williford (2011a, 2011b) and in Williford et al. (2012); Dreyfus (2011) is an articulation and defense of a similar view from a Buddhist perspective.

³⁰ See e.g., Kriegel (2011) and the papers in Kriegel (ed.) (2013), as well as Kriegel’s excellent introduction to that volume.

anything. In such a case, one would not want to think of sensory phenomenal consciousness as a matter of bearing a real acquaintance relation to such qualities or quality instances. Instead one might prefer an adverbial construal of the situation that avoids any commitment to anything literally having (or perhaps even to there being) the properties phenomenally represented. On this view, one denies that there is a relation that supports existential quantification over these immediate objects (whatever they are), and one cannot conclude from the fact that one is phenomenally conscious of a red patch that there exists a red patch of which one is conscious.

Of course, this failure of existential quantification won't apply in the case of one sort of object, namely the conscious episode itself. But it will not be *because* it is an object of phenomenal intentionality that one can validly, existentially generalize from it; generally that fails, just as in other intentional (and intensional) contexts. Rather, it will be because it is the subject or *bearer* of phenomenal intentionality that one can validly generalize from it. In other words, we take episodes of consciousness to be individuals that have this pseudo-relational property. That is why we can quantify over them, and not because of anything that they pseudo-bear that pseudo-relation to. Such "objects," after all, can be nonexistent. Thomas Reid's "ambulo ergo sum" would be appropriate here, not the Cartesian *Cogito* conceived in a phenomenologically performative way.

This situation is rather paradoxical. If the only mode of awareness of our own consciousness (even supposing ubiquitous self-manifestation) is via phenomenal intentionality so construed, then our evidence for the very existence of our own consciousness is really no better than our evidence for the existence of phenomenal colors. Just as we might be persuaded that there really are no phenomenal colors, perhaps we could become persuaded that there is no such thing as phenomenal consciousness either. I regard this as absurd. It is like saying that perhaps we only think we think, or that perhaps it only appears to us that things appear to us. Consequently, consciousness must bear some evidentially relevant relation to itself and to its own being, other than the phenomenal

intentionality pseudo-relation it pseudo-bears to phenomenal colors.

Thinking of consciousness as "being-appeared-to-existingly" does not help here, since that applies to phenomenal colors and all other perceived pseudo-objects and pseudo-qualities as well. Any theorist committed to self-manifestation should not try to construe this as just a case of phenomenal intentionality as just described. From our self-consciousness we can conclude that we do exist, and this is not just because we know by inference or in some other way that we are the bearer of a property, as in Reid's *Ambulo*. We must be acquainted with our own existence—in the sense that every episode of consciousness, however individuated, is acquainted with its own existence. This applies to the subject-pole. What about the object-pole?

In the context of the theory of perceptual consciousness, I think it is a mistake to maintain that any view according to which one can always legitimately quantify over the "immediate objects of conscious awareness" is committed either to some form of direct realism (or perhaps a disjunctivist version thereof) or to old-fashioned sense-datum theory. Any plausible form of representationalism—fictionalist or realist, externalist or internalist, reductive or non-reductive, is, I'll argue, committed to such quantification, though this must be understood in a particular way. I am not, of course, saying that if we seem to consciously visually perceive a pink rat then we can infer that there exists a pink rat that we see. There is, however, something other than just the conscious state itself (*qua* whole) that we can legitimately, existentially quantify over.

Our conscious perception of differentiation (in unity) entails, even on a representationalist view, that there exists something of which we are aware, namely, at the least, differentiation (or contrast) itself. For example, suppose I hallucinate purple and pinkish smoke clouds arising from stereo speakers as "Fairies Wear Boots" comes on. Evidently I cannot conclude that those purple and pinkish clouds exist. Still, I maintain, we can conclude that there exists some differentiation or contrast of which we are aware. By hypothesis, we cannot say that the difference is that between the pink smoke cloud and the purple one, since they

do not exist. Differences between non-existent objects cannot be appealed to in order to make sense of real differences.³¹ But we are aware of some *real* and phenomenally manifest differentiation here. If we say no to that, we'd have to assume that reflection is simply inaccurate when it comes to such hallucinations; that we seem to have a differentiated experience when in fact there is no phenomenal difference at all. But if that itself is a phenomenal state, say a conscious reflection on an ongoing hallucination, we have the same problem all over again.

If the difference we are aware of is not and is not to be accounted for by a difference in the objects (since they do not exist), it must be a matter of the difference in the representations. Hence, albeit in an indirect manner and, as it were, under the guise of a difference in the pink and purple clouds, we must be aware of some differentiation inherent in the representational states themselves.³² If we reject disjunctivisms, then we ought to maintain that in every case of differentiated phenomenal awareness we are, in fact, acquainted with (and not merely representing) the differences inherent in our episodes of phenomenal consciousness. This is, at any rate, what I think is the most plausible account, even if the considerations just given don't absolutely clinch it. Again, it is not that there cannot be some sort of representationalist response.³³ It is, rather, that I regard the line I take to involve fewer epicycles.

We cannot make good sense of the appearance of a phenomenal difference without direct awareness of differentiation. But, by hypothesis,

in the case of hallucination it cannot be that we are aware of a real difference in the objects of representation. Moreover, it cannot be a difference in something that is *hidden* from conscious awareness—some difference in the externalist conditions determining the content of the representational states, for example—that we are aware of. The most plausible candidate, then, is that we are directly aware of (acquainted with) differentiation or modifications in consciousness itself (and hence the Transparency Intuition (see page 4) is, strictly speaking, false; we are indeed aware of features of consciousness itself even in so-called “first-order” awareness). This applies to both reductive and non-reductive forms of representationalism. If this line of thought is correct, representationalist theories really presuppose some sort of non-representationalist, acquaintance theory.

Implicit in the above discussion is something like this definition of acquaintance:

Acquaintance =_{Def} (1) the relation (R) the subject (s) of consciousness (i.e., the episode or stream itself) bears to the differentiated phenomenal manifold ($D\langle x_1, x_2, \dots, x_n \rangle$), such that (2) if $sR[D\langle x_1, x_2, \dots, x_n \rangle]$, then we may infer truly that $(\exists x)(sRx)$.

Of course, clause (2) can be taken as redundant, given the usual understanding of real relations and that the R of clause (1) is so taken. But in this context it is important to emphasize the point. The first clause is just an inner-ostensive phenomenological characterization that assumes that the relational appearances are indeed the reality; the second is a logico-ontological characterization. Importantly, we can “quantify in” here: If, in any concrete particular case, we stand in that relation to some phenomenally differentiated field, then we can truly infer that *there exists* something differentiated we stand in that relation to. However, it is in general *not* the represented (or intentional) objects that we are thus acquainted with. It is, rather, the common factor of all episodes of phenomenal consciousness, be they hallucinations, dreams, or the “perceptions” of brains in vats. This, again, is often precisely what is denied when one says

³¹ We could possibly hold that even if the property instances are not real, the universals represented are, and try to account for the difference in phenomenology in terms of those real differences. But this sort of view does not allow us to make sense of the concrete but hallucinatory representation of different particular instances of the different properties.

³² I have briefly made similar arguments in Williford (2013).

³³ In particular, a representationalist could say that the represented difference between the pink and purple clouds is just as hallucinatory as the clouds themselves. This is, in a sense, correct. However, representationalists hold (or ought to hold, anyway) that phenomenal differences *always* correlate with differences in the representations themselves (and only normally in the objects of representation). If there are phenomenal differences, there exist some differences inherent in consciousness that are not merely the objects of representation. What I am claiming is that we are acquainted with this differentiation under the guise of differences in objects represented. An adherent of the Transparency Intuition would deny this, of course. And I don't take these considerations to constitute a knock-down argument. (Thanks to an anonymous reviewer for bringing this up.)

that a state is one of representation as opposed to acquaintance. If it is true that *I represent A*, I cannot infer from this that *there is some X such that I represent X*. Adverbialisms and other forms of representationalism were, recall, developed precisely around this insight in order to overcome the problems of sense-datum and other relational theories of perception. Is the theory I am suggesting here a form of old-fashioned sense-datum theory?

Unfortunately I cannot give a short answer to that question and can't give all of the long answer here. This will have to suffice: (1) We can regard sensory qualia (or hyle) as being complex, relational properties of consciousness (and its concrete embodiment in brain processes); in fact, they could be something like irresolvable structural properties that appear simple precisely because they mark a limit of our sensory resolution. (2) In order to flesh this out, we must reject the Revelation Thesis—the thesis that acquaintance yields up all of the properties of sensory qualia. In particular, we can (and should) reject the idea that acquaintance tells us all of the categorial properties of sensory qualities. There is no good reason to believe that it does. Hence, they could fail to seem relational and yet still be relational. This is a solution to the “Grain Problem”—a problem arising from the fact that brain properties are “complex” and relational while sensory qualities (phenomenal colors, tones) do not seem to be. If we infer from the appearances then we cannot consistently hold that they are identical to brain properties. But we have no good reason for making that inference.³⁴ (3) It is not hard to understand why the sensory qualities would be integrated into a spatialized and “intentionally animated” grid that can serve as a “user interface” for us to deal with the external world, yielding a “transparent” manifold in Metzinger’s sense, a manifold we are built to systematically and automatically “see right through”—causing us to suffer from a sort of delusion of direct realism (see Williford et al. 2012; Williford 2013; Metzinger 2004, p. 163, and Revonsuo

2006). Finally, (4) appeals to the “Transparency Intuition” (in Tye’s sense of “transparency”) thus carry no serious weight. All the phenomenological data in question are accounted for by 1–3, and there are good independent lines of reasoning for each of these (that we do not have time to go into here).

I’ve argued that the notion of acquaintance, when interpreted in the rather minimal, phenomenological, and logico-ontological way proposed, is the proper notion for characterizing the relationship between consciousness and the differentiated but unified multimodal experiential manifold. Moreover, on the view proposed here, consciousness bears this same relation, generically understood, to itself.

If the episode of consciousness bears the relation to itself, then evidently there is something to which it bears that relation. But, non-trivially, we could not have the sort of direct evidence of its existence that we do have if consciousness were not self-acquainted—and acquainted with its own existence. And if the episode of consciousness bears the relation to the differentiated manifold that constitutes the surface that serves as its contact with a differentiated reality beyond it—i.e., if it bears it to a differentiated portion of itself—then there is something differentiated of which it is non-representationally aware. One is directly aware of the *difference* or *differentiation* even if one only, strictly speaking, *represents* what the things so differentiated happen to be or interprets them as being such and such (mental, physical, surfaces of objects, internal sense data, quotidian objects, etc.). In other words, I can see that red is not blue even if I do not know what colors are exactly, or if they are in physical space or only in a virtual space in my brain. One does not *merely* represent this difference or differentiation. One is acquainted with oneself and with the differentiation one contains. Of course, one is also acquainted with the apparently intrinsic properties that mark these internal differences, but again, this need not mean that the properties are in fact non-relational and simple. In fine, we are self-acquainted and acquainted with a differentiated manifold and thus, at some level, with real differences in the mind, the

³⁴ I’ve argued this is in a bit more detail in Williford (2013). For relevant background ideas see Williford (2005 and 2007). For a discussion of the Revelation Thesis see e.g., Stoljar (2006, ch. 11) and Goff (forthcoming).

world, or world-mind boundary.³⁵ The acquaintance relation consciousness bears to itself is, generically speaking, identical to the relation it bears to sensory qualia (or hyle)—which are taken here as ultimately just transient modifications in the unfolding embodiment of consciousness. It is important to understand that this does not imply that there is a special type of sensory quality (a “me-ish” quale) peculiar to consciousness. It is as diaphanous as G.E. Moore said. Remember that the acquaintance in an instance of acquaintance with phenomenal red is identical with the acquaintance in an instance of acquaintance with phenomenal C#, even though phenomenal red and C# are utterly heterogeneous.

One might reasonably ask for a more substantive definition or account of acquaintance. The definition given relies on phenomenology and logic and is otherwise quite empty. But this is as it should be, in my view. Any further account of the nature of acquaintance, of what the acquaintance relation *is*, will be the result of empirical inquiry and a well-supported *a posteriori* identification.

5 Self-acquaintance, subjective character, and individuation

Earlier I briefly noted that at the phenomenological level we should probably not construe subjective character fundamentally as a matter of “mineness” or a “sense of self” where the latter is thought of as a sense of oneself as an owner of experiences. It is not that I do not think this description contains a grain of truth; I do. The worry, though, is that if we go this route, we might come to the conclusion that subjective character involves acquaintance with a haecceity—Zahavihood and Gallagherhood once again. Here I want to consider the same issue from a more ontologically oriented point of view.

We are indeed individuated and aware of ourselves (something individuated). And we can be aware of ourselves *as* distinct individuals and owners. But this does not at all entail the doctrine of haecceities immediately present to con-

sciousness—for-me-ness or me-ishness as a special property that no one else can share. Rather, subjective character is a common form that all conscious states have; but having this form does not alone make something the individual it is, evidently. It may be that in virtue of which we can be *aware* of ourselves as individuals, but it is not that in virtue of which we *are* the individuals we are. Yes, there is a determinate individual (somehow construed) that is acquainted with itself. No, this does not necessarily mean that it is acquainted with that *in virtue of which* it is individuated. That could be whatever it is that individuates physical objects. Or, perhaps, nothing is metaphysically individuated *by* anything else. But it ought to be clear that simply in being aware of myself I need not be privy to anything non-trivial about my metaphysical individuation conditions.³⁶

You are aware of your consciousness as something individual. You are a self-aware individual, if you prefer. But this does not mean that your subjectivity consists in being directly aware of *what* individuates you or the very property in virtue of which you are the individual you are. Or, perhaps, one may be aware of this property or set of properties, but only in the guise of being an individual that is thus and so. The “thus and so” part (all your contingent properties, your “facticity”) is radically changeable. You need not have been thus and so. (You could have been a contender! And if only you’d been rich!) You can also be aware that you are a particular instance. So, yes, you can become aware of your particularity. But everybody is aware of their own particularity. And it is, in a way, an empty and non-material (in the “formal vs. material” sense) property. It’s not as if my particularity has a special something that yours lacks and vice versa. Hence, I would not be able to tell, by phenomenological intuition alone (or in any other way for that matter), which of the infinitely many duplicate and near-duplicate worlds I am in (cf. Elga 2004). Am I in the world in which one of Napoleon’s buttons had a bit of his blood on them the morning of the Battle of Jena or in the world in which that was

³⁵ I have considered our acquaintance with a differentiated manifold *qua* mind-world boundary in more detail in Williford (2013).

³⁶ I have briefly argued this before in Williford (2011b). I was pleased to find that a similar line of argument was pursued by the eleventh-century Buddhist philosopher Ratnakīrti; see Ganeri (2012, p. 217).

not the case? I cannot tell by introspection, yet, depending on the correct answer, I am one type of individual (and of course, one token of uncountably many of that type) and not of the other type (which type also contains uncountably many individual counterparts of mine). I am individuated, and I know that; I belong to just one of these worlds. But I do not have complete access to my individuation conditions or the conditions, if there are any, that determine that this individual is in one world as opposed to another. I have uncountably many counterparts who feel exactly the same way because, to speak loosely, they don't know that they are not me; none of us can tell the difference. I cannot locate my Homeworld on the map of worlds that contains my relevant counterparts.

It is a mistake, then, to make subjective character depend on the sense of individuality; this reverses the proper order of explanation. Self-acquaintance and concrete instantiation yield the sense of individuality, and they do it again and again in many places and in the same way. Evidently, the contingent filling that experience and history infuse into the formal shell of conscious subjectivity is not relevant at the level we are concerned with. Hence, it can also be metaphysically, not just phenomenologically, misleading to use terms like “for-me-ness,” “mineness,” “me-ishness,” etc. That is to make something derived seem like something basic. The basic things are self-acquaintance (“reflexivity”) and actual, concrete instantiation or constitution. The sense of individuality comes from these, not the other way around.

Of course, if you are a real, concrete individual, you are individuated. But individuation is evidently not self-acquaintance. The latter is, however, required if one is to get the *sense* of being an individual, to know, feel, and be concerned with oneself *as* an individual. If we generally equated self-acquaintance with something's being the individual it is, then we'd have to hold either that every individuated thing in the cosmos is self-acquainted and conscious, or that conscious things have one type of metaphysical individuation conditions, and non-conscious things another, for very obscure reasons. Moreover, we either must not take subjective character to be a

univocal notion or must resort to some sort of hopeful brute resemblance nominalism about subjective character and maintain that we cannot not really know that, say, I, *qua* subject, am in any meaningful sense like you, *qua* subject. This is not a very good dilemma to be in.³⁷ I think the more plausible view is that self-acquaintance is not the source of the individuation of consciousness but rather something that both concretely depends upon individuation and enables the knowledge of individuality and, consequently, self-location in surrounding spaces.

It is misleading, then, both phenomenologically and ontologically to refer to subjective character principally as “mineness” or “me-ishness” or “for-me-ness,” even though subjective character is one of the bases of the sense of individuality. We should not think of self-acquaintance (and subjective character) as anything more than this relation all episodes of consciousness bear to themselves. It is a perfectly uniform structure and a kind of universal—in that sense, supposing one is some sort of realist about universals, there is indeed some identical thing that unifies all episodes (or subjects) of consciousness, namely the very property of being self-manifesting; but we are all distinct instances. Thus, in a very special and non-Vedantist sense, we could say that there are many instances of consciousness but only one subject, with some instances connected to each other and grouped together in other important ways as well. But there is no substantial self. In this regard, I am with Hume, Sartre, Parfit, Strawson, Metzinger, the Buddhists, and other “non-egological” theorists of consciousness. Note that this does not mean that consciousness is “anonymous” in the sense of “subjectless.” Every stream of consciousness has its transient subject (*viz.*, itself) but that is not a substantial self.

6 Self-acquaintance, intrinsic properties, and physicalism

Should we really regard self-acquaintance as a relational matter? Is it really a matter of some

³⁷ Previous episodes of consciousness normally connected to the present episodes (the ones producing this document) found themselves trying to live with the latter horn of the dilemma in the flawed Williford (2005).

sort of thing standing in a relation to itself? On the one hand, there is no special problem either logically or phenomenologically speaking with the idea of something relating to itself in this way. Appearance is appearance-to. That's relational. There is no *a priori* reason why something could not appear to itself. It does not lead to a regress.³⁸ One should put aside misleading and question-begging spatial analogies—consciousness is not like a knife trying to cut itself. Advocates of self-acquaintance will claim, opposing one analogy with another, that it is more like a candle's flame illuminating itself by emission while it illuminates other things by the reflection of its light; it does not require another candle flame for it to be illumined.³⁹ Moreover, one must remember to exclude from one's mind the sort of objectification and description-based cognition that normally overlays the phenomenal manifold. We are talking about the sphere of immanence, to speak Husserlian, and not about intentional objects or constituted objectivities given via *Abschattungen*. Again, we are talking about immediate self-acquaintance, not the representation of oneself as being such and such. It is indeed more like the emission of light than the reflection of light, if we must pick an analogy.

Nevertheless, even if we accept the relational construal and remember that it is an immediate and direct relation not mediated by concepts or descriptions, we still have a problem. It is not as if conscious episodes just happen to be self-manifesting. The property of being self-manifesting is not something that a thing can have and then not have—like changing coats of paint. It is of the very essence of a conscious episode. This is not an external relation to itself or one mediated by convention or history or anything else. Hence, it must have some set of intrinsic properties in virtue of which it is self-manifesting. Thus, the Heidelberg School, Michel Henry, and Dan Zahavi, I'll

concede, win on this ontological point. Dieter Henrich, Manfred Frank, Henry, and Zahavi have all maintained that self-manifestation could not be a relational matter (e.g., [Henrich 1971, 1982](#); [Frank 2002, 2007](#); [Zahavi 1999](#); [Henry 1973](#)). And they are very close to being right. I think, however, that it is more accurate to say that even if it is a relational matter, it is not an *external* relation we are dealing with. So there must be something about the internal structure of consciousness that grounds the relation. In short, as Henrich and Frank have long said, there must be some intrinsic property in virtue of which episodes of consciousness (out of all other things in the world) are self-manifesting. What could this property be? Are we left with something that cannot be physical, or, even if it is physical, is nevertheless irreducible in some sense?

It may seem now that David Rosenthal is having his revenge.⁴⁰ In effect, I have been arguing against the extrinsicalist view—the view that something's being conscious has to do with external relations the thing stands in—be those external relations to other mental states or external relations to historically distant states of affairs or to other parts of one's cognitive apparatus. Now, to our chagrin, it seems we are left with something explanatorily basic. At this point we are left with two problematic strategies. We could go the panpsychist route ([Strawson 2006](#)): It's no surprise that we're conscious if everything is! Or if, as I do, one thinks (after Locke in a similar context) that “every sleepy nod doth refute” this, we can hold that only certain physical complexes instantiate this particular property (or set of properties). This will mean either some form of property dualism or some form of identity theory (possibly with its “Harder Problem”; see [Block 2002](#)). If one does not want to be a dualist or a panpsychist, what can be said?

Here is the sort of approach that seems most attractive (to me, anyway). We want to hold that consciousness is indeed some sort of physical process. It's not, however, just a matter of the satisfaction of some functional role. I

³⁸ This is demonstrable. First, obviously, there is no logical problem with reflexive relations. Second, it requires special and highly questionable premises to generate another regress here. See [Williford \(2006\)](#). See also [Kriegel \(2009, p. 124\)](#) and [Janzen \(2008, p. 110\)](#).

³⁹ The knife blade and candle flame competing analogies loom large in the Indo-Tibetan debate on this issue. Clearly, the analogies will be found, by opponents and proponents, to be exactly as plausible as the views they encode.

⁴⁰ Though even Rosenthal's own view was pushed into being (or always was) problematic in this regard, as noted above.

think it also has a functional role. But it is not *in virtue of* playing that role that something is consciousness; rather, consciousness is suitable for that role because of its properties.⁴¹ In principle, many different things could play that role (at least if we specify it entirely in behavioral terms). Or, at least, this is an open question. Consciousness has a functional role, but it is not to be identified with just any arrangement of elements that can play that role as causally and behaviorally specified. There is some special, distinctive physical process that is consciousness. It plays its functional role in virtue of its having the properties it does and *not vice versa*. But then does some version of Russellian Monism start to seem attractive (see e.g., [Stoljar 2006](#), ch. 6 and [Pereboom 2011](#), chs. 5 and 6)? Am I saying that the functional role is just being (contingently) satisfied by a (somehow) unified and self-manifesting group of qualia? Or something *wild* like that?

Here we play the same sort of trick we played when dealing with the Grain Problem. Consciousness is self-acquainted, but we are also, as Fumerton and Fales would say, acquainted with acquaintance; we are given givenness ([Fumerton 1985](#), pp. 57–58 and [Fales 1996](#), pp. 147–148). The relation does not seem complex or to involve many layers of relational structures. But we cannot infer from this appearance that it is in fact such a simple relation. Again, its not seeming complex does not, without controversial and implausible completeness assumptions, entail its being simple. Moreover, once we realize that normal consciousness involves a great many intricately related aspects—at least (non-contingently) differentiated unity and temporality, and (contingently) animation functions operating on a differentiated sensory manifold, iterations of these functions, pattern extractions, etc.—we have all the more reason to suppose that there is complicated machinery hidden from our introspective view. In fact, it will be noted in a Sartrean and Moorean vein, that consciousness, both as acquaintance relation and subject-relatum, seems mightily empty. Once we realize that Revelation theses fail, then we no longer need read this ap-

pearance as “consciousness *qua* acquaintance relation appears simple.” Rather, we read it as “consciousness *qua* acquaintance relation *does not appear* complex.” These are, in many cases, phenomenologically indistinguishable, but they are logically different.⁴² The first reading, coupled with an infallibility thesis (or with just a strong presumption in favor of the deliverances of naïve introspection), leads to the view that acquaintance is simple. But the other requires a Revelation (or completeness) thesis to get the same result. Revelation is, again, totally implausible. And even if we were to assume infallibility, we have no a priori reason to favor one interpretation of the phenomenological data over the other—the “seeming non-P” vs. “not seeming P” formulation. We do, however, have plenty of *a posteriori* inductive reasons for preferring the latter: It does not seem complex, but it is (or at least could be for all we can tell phenomenologically).

Since we have an extremely limited resolution when it comes to penetrating into the nature of consciousness by introspective means, we are quite free to adopt another strategy. We can accept an *a posteriori* identity theory. Consciousness is identical to some sort of recurrent physical process unfolding in the brain. Fundamentally, what we get from introspection is a sort of structure and some irresolvables—the sensory qualities—that are like reflections of the materials in which the form or structure is instantiated. Since we have rejected Revelation (completeness) theses, we can accept that sensory qualities (and the acquaintance relation itself) are complex and involve layers of relations even though they do not seem this way (just as the headless woman⁴³ in the famous illusion does not seem to have a head—absence of appearance is transformed into the appearance of an absence; see [Armstrong 1968](#) and [1973](#)).

⁴² They are phenomenologically indistinguishable in the way that the stream of consciousness’s being temporally continuous is, plausibly, phenomenologically indistinguishable from consciousness’s being punctate or discrete, or in the way in which consciousness’s seeming free from causal determination is phenomenologically indistinguishable from its simply not seeming determined (because the causal relations are inaccessible, as Spinoza suggested).

⁴³ See the following links:
<https://www.youtube.com/watch?v=LXOqD5B5Sxc>
<http://www.deceptology.com/2010/10/headless-woman-illusion.html>

⁴¹ Here I am in considerable agreement with [Langsam \(2011, ch. 3\)](#).

We can use what structure we are aware of, however, to build models to guide our search for the neural correlates of consciousness. One thing we see is that the (only apparently simple) acquaintance relation involved is such that whenever xRy , xRx ; while it is not the case that if xRy , then yRy (in the case where y is a sensory quality or manifold thereof). And we have some idea of what the qualities in the manifold could be—e.g., limits of resolution or irresolvables operated on by a spatializing filter. We can also see that spatial projection, integration of multimodal information, temporality, and the modulation of attention are involved (along, of course, with more advanced things like intentional animation, cognitive filtering and reprocessing, and poise for action). We have a self-manifesting totality containing a unified and spatialized but differentiated manifold. Consequently, we do need to look for processes that can do information integration and binding, but that is only necessary, not sufficient. We need to look as well at processes that spatialize the multimodal (and multidimensional) information (see [Williford et al. 2012](#)).

This does not at all mean we are looking for a little room in the brain that has patches of red, yellow, blue, and green mental paint in it. Rather we must look for more abstract correspondences. In the case of the sensory qualities, we are possibly looking for higher-order relations between fairly complex structures, structures that can transiently be pulled into and “rendered” by the core process. Basically, this panoply of contrast-related irresolvables gets generated in a real-time and transient fashion, now occupying this virtual “location”, now occupying that, depending on a whole host of input factors (head orientation, background, conceptualization, etc.). These “locations” map onto (we hope) real physical space at a certain scale, but it is not a matter of finding a “bubble within a bubble.” It is a matter of an abstract correlation of structure. The isomorphisms (or homomorphisms) could be there even if the internal “space” of experience is entirely virtual, a kind of computational “movie in the brain” to use another phrase of Damasio’s. Assuming the principle that the positive and critically evalu-

ated set of phenomenological descriptions gives us not just the way consciousness seems, but the way it in fact is, along with our identity postulate, we can be sure that something in the brain has a structure corresponding to this, no matter how transformed by “layers of abstraction” it may be.

What is more, self-acquaintance will demand that we explore models in which real reflexivity can be encoded. Hofstadter’s model is one of these.⁴⁴ But following D. Rudrauf and further encouraged by D. Bennequin, I have moved in the direction of considering projective geometrical models. There is no space to go into this here, but suffice it to say that there exist mathematical frameworks that allow us to conceptualize and investigate more deeply the self-acquaintance-related features of consciousness by considering the interplay of the space we project and the origin of the projection (see [Williford et al. 2012](#) and [Rudrauf et al. ms](#)).

The goal of such work would be the refinement of mathematical models of the structure of consciousness. Upon the achievement of that end, we would then try to determine how such models could possibly be physically realized in the brain. Once we can say what the physically detectable signatures of such a realization might be, then we could one day meaningfully test such theories. Were we to verify the existence of such a structured process in the brain, explaining consciousness would reduce to explaining how the process is realized—what parts have to be in what order doing what and at what time scale.

It will always seem to be a brute fact, at some level, that consciousness is physical process X , however X gets fleshed out. But we’ll just get used to it, as long as there is some somewhat intelligible bridge (in this case provided by mathematical models) from the lived phenomenon to its brain correlate. We’ll get used to it just as we’ve gotten used to water being H_2O . It could be that there will be multiple ways to implement such a process. Sup-

⁴⁴ While Hofstadter’s Gödel-inspired model might be problematic (both in terms of physical implementation and in terms of the strong mathematical realism it might presuppose), it is certainly in the right class of models we should be considering. See [Hofstadter \(2007\)](#).

pose, just for example, that it has to do with generating certain types of fields and that multiple substrates, not just brains, can generate and support the relevant sorts of fields. Then consciousness will be, to that degree, multiply realizable. Suppose it is a matter of realizing a certain computational organization. Then, in effect, implementing a certain program will be equivalent to being conscious; and if machines made from different substrates or with different architectures can run the program, consciousness will be multiply realizable in the sense of computational functionalism. Your particular consciousness then, as you know and love it, would be just the concrete running of the program in your particular brain.

We might wonder, in such a case, what it is to “run” a program or to “have” a certain structure or to “instantiate” such an arrangement or system of fields or whatever. Of course, this is a quite general metaphysical problem that we should not confuse with any problem specific to consciousness. However, given that we are acquainted with our own individual existence, it seems that somehow its instantiation makes its very instantiation available or manifest in some non-representational way. This is rather peculiar. If we are going to be physicalists who are nonetheless responsible to the phenomenology, however, this is what we have to accept, or so I have argued. Something is conscious if it has a certain internal structure and attendant dynamical profile. Being conscious *is* having that structure and profile. We will never be able to explain *why* that is the case because it is simply a confusion to think that identities like this admit of explanation; they can only be discovered (Papineau 2002, ch. 3). We must, of course, give evidence in favor of the relevant identity claim; uncovering such evidence is the goal of scientific research on consciousness. Our choice is between this sort of view and the view that *there is something else, something non-physical* that just *is* consciousness. Of course, we’d never be able to explain why *that* is the case either. So in the absence of compelling arguments for dualism or panpsychism, Occam’s Razor would lead us, as Smart pointed out so long ago, to embrace an identity theory.

The identity theory only adumbrated here would be neither a crude type-type identity theory nor a causal-role functionalist token-token identity theory where the realizers do not matter at all. Since any concrete consciousness is a marriage of form and matter (and the self-appearance of that marriage), and since there no doubt are physical constraints on what sorts of materials can be put into that form, we want to identify consciousness with neither a specific type of material (or “wonder tissue” in Dennett’s phrase) nor with an abstract, disembodied form that seems trivially realizable by practically any set of elements—since purely abstract isomorphisms may be a dime a dozen.⁴⁵ In other words, we need a non-eliminativist and non-idealist account of what it is to *really* realize a structure, instantiate a form, or, as the case may be, to *really* run a program or compute a function. To my knowledge, no one currently has such an account.

At bottom, this is just the old metaphysical problem of the Methexis—the relation of universals to particulars or of form to matter. When I am feeling optimistic, I imagine that I’ve reduced the problem of consciousness to another, more general (as well as ancient and probably insoluble) metaphysical problem. We may not know what it is for matter to really and mind-independently take on a certain form, but it is hardly an implausible metaphysics that says that this happens. It is arguably this type of metaphysical view that would best explain the success of applied mathematics, engineering, and the sciences: they are successful because the world really does have (or approximate) the relevant mathematical structures—these are *in re* structural universals. This seems to be a commitment of scientific realism. But perhaps we will never get beyond a rather crude operationalism when we empirically investigate such matters; perhaps the metaphysical nature of property instantiation will forever remain obscure to us. That should not, however, discourage us from carrying on such empirical investigations in the case of consciousness. Even if there will be

⁴⁵ For discussion, see Chalmers (1996) and Buechner (2008, ch. 3).

a residual metaphysical mystery, it is a general one, not one specific to consciousness.

The main point here, and the concluding one, is that consciousness could be self-acquainted, where this is not a matter of external relations, and still some form of relatively non-mysterious (hylomorphic) physicalism could be true. One might balk at the idea that this would not be a matter of external relations, especially if we go the computational functionalist route. But think of it like this: If we are realists about the implementation of computational structures, then even though the structures involve parts and elements, there is still a unity to the pattern as implemented. It is, in a certain sense, an indivisible whole that is not just the mereological sum of its parts. Analogously, the circle has its own structure and characteristic properties even though it is made of points. What we really need, and may never have (but who knows?) is a theory that tells us when we have a real, concrete unified whole, (where this is *not* simply a functional or conventional characterization but is a matter of more basic physical relations) and when we have unities and wholes (and instantiations of structures and properties) that are only conventionally real.

Suppose then that we adopt a sort of realism about computational (or otherwise structural) wholes, which we have some independent reason to do. Circles have remarkable properties, *qua* circles, even if they are made up of points. Concrete circular things approximate these. Simultaneous cycles have certain number-theoretic properties just *qua* cycles regardless of *what* they are cycles of (e.g., reproducing cicadas and cicada predators, see [Baker 2005](#)). Likewise, for the concrete implementation of consciousness, it is surely the case that certain elements must be put into a certain arrangement, realizing a certain structure and dynamics. This would not mean, however, that consciousness *as such* is to be identified with either those elements or the arrangement abstractly conceived. Rather it is the *concretely implemented* organization of those elements *qua* whole. In virtue of being an instance of that form or structure, it has

certain properties. One of these could be the property of being self-manifesting. That property could itself be a complex relational property having a certain unity. The account sketched here presupposes a certain realism about the instantiations of mathematical and computational structures—that there are determinate, mind-independent facts of the matter about this. We cannot go further into this rather large and complicated metaphysical hornet’s nest. Suffice it to say that a real, unified, concretely instantiated structure could, in a certain sense, be relational and have components even if it is, in another sense, an intrinsic property.

7 Conclusion

I have argued that the best way to characterize subjective character is in terms of self-acquaintance and not, for various reasons, in terms of Higher-Order, Same-Order, or Privileged-Object representation. I argued that every episode or stream of consciousness is acquainted with itself, and not with a self in some other sense—a homunculus, substance, or haecceity. This is, I maintain, the best way to make sense of the intuition of subject-object polarity and the Humean intuition that we do not find a self-entity. Moreover, one’s sense of being an individual is a consequence of self-acquaintance and concrete existence and not to be conflated with subjective character as such. Such conflation leads to potentially misleading descriptions of subjective character (as “mineness”) and, if taken literally, to metaphysically and epistemologically undesirable consequences. We are individuated and self-acquainted, and that is enough to allow us to derive the sense of self or “mineness”; but self-acquaintance is not itself what individuates us, nor does it necessarily make us aware of what does.

Nevertheless, I conceded to Henrich, Frank, Henry, and Zahavi (among others) that consciousness must have some intrinsic (or internal relational) property in virtue of which it is self-acquainted. But I argued that this does not nullify the appropriateness of de-

scribing subjective character as being a matter of a very complex relation, though it does not seem to be so complex.

Finally, I argued that the position advanced here is not incompatible with a form of (hylomorphic) physicalism. Sensory hyle, the acquaintance relation itself, the self-manifesting episodes, could all be brain processes and properties. On the phenomenological side, this gains plausibility once we take to heart the incompleteness of introspection (and of pre-reflective self-awareness as well): not seeming complex and relational does not entail not being complex and relational. On the ontological side, I argued that even some form of computational functionalism could be true. But, generally, the important thing to remember is that consciousness is the marriage of form and matter. It cannot be simply equated with either. This opens up space for multiple realizability, but it might also mean that not just any old substrate will do. It's an open question. The metaphysical commitment behind this position is just some form of realism about structural universals and their mind-independent instantiation conditions, which is arguably a commitment of scientific realism in any case. Absent dualism, panpsychism, or idealism, that is what we will have to accept, I believe. (Eliminativism is, of course, a non-starter.)

We do not need a theory of the Methexis, however, in order to attempt to find the neural correlates (correlation conceived of as indicating identity here) of consciousness by building mathematical models of the phenomenology and figuring out how the brain might implement the structures so modeled. In fact, just such an approach is quite in line with scientific practice generally: We know that the world we investigate with our relatively crude means is, in multiple ways, a play of matter and form even if we do not really know what the Matter ultimately is, what Forms are, and how the latter come to live in the former.

Acknowledgements

Different parts of this material were presented at many places over several years. I would like

to thank audiences at the Johannes Gutenberg-Universität Mainz (seventeenth meeting of the MIND Group), the Berlin School of Mind and Brain, the Institut Jean Nicod, ZiF, SMU, the SSPP, TCU, and Tucson TSC for relevant discussions. I would like to thank these institutions and the symposia organizers (and in particular, Thomas Metzinger and Jennifer Windt; Manfred Frank, Marc Borner, Andreas Heinz and Anna Strasser; Brad Thompson and Philippe Chuard; Pete Mandik, Rik Hine, and Blake Hestir; and David Chalmers). Thanks to the College of Liberal Arts and the Department of Philosophy and Humanities at the University of Texas-Arlington for research and travel funding in this connection. I should thank (in alphabetical order) Katalin Balog, Daniel Bennequin, Jacob Berger, Alexandre Billon, Marc Borner, Philippe Chuard, Christian Coseru, Justin Fisher, Manfred Frank, Brie Gertler, Robert Howell, Tomis Kapitan, Bob Kentridge, Chad Kidd, Alex Kiefer, Uriah Kriegel, Greg Landini, Stefan Lang, Pete Mandik, Thomas Metzinger, Charles Nussbaum, David Papineau, Gerhard Preyer, Harry Reeder, David Rosenthal, Amber Ross, David Rudrauf, Susan Schneider, Miguel Sebastian, Charles Siewert, Anna Strasser, Brad Thompson, Keith Turausky, Michael Tye, Josh Weisberg, and Dan Zahavi for discussions, questions, criticisms, suggestions, etc., that were in one way or another of help to me in relation to the material presented here. In the same regard, I should thank two anonymous reviewers from the MIND Group for helpful feedback on an earlier version of this article; their feedback helped me to see some of my less-than-admirable tendencies as a writer of philosophy, even if it did not enable me to correct all their manifestations. Special thanks to Ying-Tung Lin of the MIND Group for her help. Special thanks to Trish Mann, Swathi Prabhu, Emma Nwokonko, and Anya Williford for help with the references. And very special thanks, once again, to Thomas Metzinger and Jennifer Windt for launching and managing this unique and ambitious project and to the Barbara-Wengeler-Stiftung for its support.

Explaining Subjective Character: Representation, Reflexivity, or Integration?

A Commentary on Kenneth Williford

Tobias Schlicht

While Williford puts forward a self-reflexive account of subjective character, which identifies the subject of experience with episodes (or the stream) of consciousness, an alternative account is defended here that identifies the subject of experience with the whole organism. On this latter approach, a mental representation is conscious if its neural substrate is integrated into the overall neuronal state underlying the conscious state of the organism at that time. This approach avoids an important problem arising for Williford's theory, namely the individuation of episodes. This problem is elaborated in greater detail.

1 Introduction

The starting point for this commentary on Williford's article is the *commitment* to subjective character as a defining feature of consciousness. Subjective character is what *makes* a conscious experience conscious, i.e., what *all* conscious experiences have in common in virtue of which we call them conscious. Kriegel (2009, p. 1) has offered a distinction between the *qualitative character* and the *subjective character* as two

important aspects of any conscious experience. If you have a phenomenally conscious sensation of red, then there is something that it is like for you to have it. On the one hand, having this experience feels like *this* (where *this* quality distinguishes it from feeling a sensation of pain, say). On the other hand, it feels like something *for you* (i.e., it is subjective *in the same sense* that all of your other conscious experiences are sub-

jective). Qualitative character is the *distinguishing* mark of conscious experiences with regard to each other; subjective character is the *common mark* of all my conscious experiences. This latter aspect has also often been referred to as the me-ishness, ipseity or mine-ness of consciousness (Block 1995; Zahavi 1999).

Williford recognizes that, sadly, not all philosophers theorizing about consciousness share this commitment to subjective character, and that some formulations of it in terms of mine-ness are misleading in giving rise to objectionable implications about essential entities (Metzinger 2011). But for the purposes of this commentary we can leave aside such controversies and instead start with a shared commitment to this feature, on which this commentary will exclusively focus.¹ As a constraint on a theory of subjective character, Williford maintains that it has to respect (1) the relational structure of consciousness, and (2) the Humean intuition that one of the relata, the subject, remains somewhat invisible and is at least not constituted by a special (additional) entity. His solution, in short, is to peacefully combine these two intuitions by *identifying* the subject with (an episode of or) the stream of consciousness, which is itself reflexively self-aware. A further claim is that this account is supposedly “compatible with physicalism” (Williford this collection, p. 1). I do not address this aspect of Williford’s rich paper in this commentary, mostly for reasons of space but also because I think that the putative truth of physicalism should not put any a priori constraints on a theory of consciousness.

¹ One might argue that this move is already problematic since it looks like a *petitio principii*. But I simply take it as an analysis of Nagel’s phrase that *there is something it is like for the organism* to experience something red, say. As a characterization of phenomenal consciousness this is almost unanimously accepted in the field. What it picks out according to the present analysis is a variant aspect that differs in different experiences (qualitative character), and an invariant aspect that remains identical across different experiences (subjective character). I do not have enough space here to argue in detail for this analysis. A further reason for distinguishing both aspects, subjective and qualitative character, is the phenomenal observation that we can become *conscious of ourselves as the identical subject* in contrast to the constantly changing stream (or ensemble) of conscious representations. Here, the qualitative differences of the multiple representations we have at a time do not matter. What matters here is that they are related to myself such that I can call them and experience them as mine (cf. Schlicht 2011).

My commentary is thus structured as follows. In the [second](#) section, I will recapitulate Williford’s take on subjective character and point to problems with his identification of the subject with the stream (or episodes) of consciousness. In the [third](#) and [fourth](#) sections, I will present an alternative way of conceptualizing the subject in the context of a theory of consciousness that also satisfies the constraints mentioned above. On this alternative view, a mental representation is conscious (i.e., it exhibits subjective character) if it is integrated in the right way into the overall conscious state of the organism. This overall state includes representations of the state of the organism. By way of integration, all *conscious* representations are something *for* the organism that is identified as the subject of experience. This alternative, which is an instance of an integration-theory, has the advantage both of bypassing the problems that seem to beset Williford’s account and of being not only compatible with but also supported by the best empirical hypotheses about consciousness currently available. I will sketch an argument for this view and attempt to answer possible objections to the premises of this argument.

2 Williford on subjective character

Williford’s aim is to characterize the subjective character of consciousness in a way that accounts “for both the Humean intuition that the subject-relatum is, in some sense, invisible and that, nevertheless, consciousness has a subject-object relational structure that is phenomenally manifest and non-inferentially knowable” ([this collection](#), pp. 10-11). There are three constraints on an account of subjective character, according to Williford: (a) conscious experiences are relational in having both a subject- and an object-pole; (b) the subject-pole is not constituted by some additional, irreducible, or otherwise special entity; (c) the subject-pole must be something that is nevertheless manifest in consciousness, not hidden from it.

Note that it is not an option for someone taking subjective character seriously to agree that phenomenal consciousness is relational, in-

volving a subject-pole, but at the same time holding that this pole is forever “*hidden*” (p. 11). This does not work because such an account could not explain subjective character. After all, we consider subjective character as real *only* because it supposedly shows up phenomenally: I experience my conscious states as *mine*.²

Williford’s commitment to a subject (subject-pole) rules out the possibility that experiences may be free-floating entities, not being enjoyed by *anyone*. Phenomenal consciousness is supposed to be relational through-and-through, directed *at* some object and existing *for* some subject: “anything that phenomenally appears, appears to someone or something” (p. 9).³ In general, Williford attempts to capture both the intentionality and the subjectivity of consciousness in the slogan that every experience involves the “appearance of something to something” (p. 9), where the latter refers to subjectivity. He leaves the notion of “*appearing* or of *phenomenally manifesting* undefined” (p. 10), but in order for what he says to make sense we have to take it to be just another way of saying that something is *phenomenally conscious*: it is “just the appearance to/in consciousness of something” (p. 10).

In order to meet the constraints he set for himself, Williford identifies the subject with the stream of consciousness or with (some complex or rich) episode of consciousness (p. 10). This identity claim then leads to the situation that the subject-pole of the consciousness-relation *appearing* (or being manifest) in the conscious episode is the episode itself. The subject-pole is thereby manifest, i.e., consciously experienced, but not separable as an entity from the conscious episode in question, and thus it is—in a sense—invisible. But it is only invisible in the sense that there is no additional entity that ac-

counts for the subject-pole. In order to meet the constraints mentioned above, Williford therefore defends “the view that consciousness is self-manifesting” (p. 10), i.e., an episode or stream of consciousness *appears to itself* no matter what else is manifest to consciousness (some perceived object, say).

Partly because Williford subscribes to the Humean intuition that we do not find a self, or a “self-entity, me-haecceity, me-ish quale, or subject-relatum” (p. 10) if we turn to our stream of conscious experiences, he is led to the identification of the subject-relatum with the stream of consciousness itself. Although the conscious episode appears itself *in* the episode, consciousness is self-reflexive, yet not self-representing. The relevant difference between an unconscious and a conscious episode is not due to some form of representation. Rather, the conscious episode contains an internal relational (intrinsic) property that is responsible for the episode’s being *acquainted with itself*.⁴ Subjective character is thus supposedly “the self-acquaintance of every instance of consciousness” (p. 1), which these instances exhibit in virtue of “some internal relational property” (p. 1). The subject of experience, being *identical* to the episode of consciousness, is self-acquainted. But although consciousness is self-reflexive, the claim is not that a mental episode becomes conscious through an act of reflection directed at it (p. 10). This is an impossible path when it comes to explaining subjective character, since an act of reflection presupposes that what it reflects upon is already *mine* in the relevant sense to be explained (Frank 2007; Zahavi 1999). Reflection can discover but not bring into being a self-referential conscious state.

Now, the stream (or episode) of consciousness exhibits subjective character in the sense that the stream itself is manifest within the stream so that the relationality constraint is met, although no additional entity need be introduced in order to play the subject-role. Therefore, the Humean invisibility-constraint is met as well. This is more or less the positive

² One way to put this with respect to sensations like hunger is to say that, since they are related to me in such an unmediated sense, it is impossible to be mistaken about the subject undergoing such sensations (Shoemaker 1968).

³ This claim is defended especially in opposition to what Williford calls F-theories, or varieties of first-order representationalism such as Tye’s (1995) PANIC-theory, which arguably neither accepts nor explains subjectivity so understood. Higher-order and same-order accounts at least accept this feature of consciousness, which they—mistakenly—attempt to explain in terms of representation.

⁴ Thus, the property of being conscious (and thus subjective) is not bestowed upon the episode by some external property, like a higher-order thought directed at (or representing) it (Rosenthal 2005).

story as far as I have understood it. The main philosophical problem for Williford's account is to formulate criteria as to how to individuate an episode. This problem leads to a dilemma for his account that is spelled out in more detail below.

If we follow Williford and identify the subject with complex conscious episodes (or even *the whole* stream of consciousness), then subjective character only seems to arise for complex episodes, and not for any of the episode's parts or elements: "[t]he episode is a unified whole, the differentiated qualities and objects appearing in/to it are like its parts [...]" (pp. 10-11). Since he emphasizes that all episodes have parts (*ibid.*), I take it that a single sensation of red, say, consequently does *not* count as an episode, because it can hardly be separated into parts; then it can instead always appear only as an element of an episode which is in turn a "unified whole". On the other hand, Williford also emphasizes that, trivially, everything always also is an improper part of itself. On this reading, a single sensation of red *could* be an episode. This gives rise to the following options regarding the individuation of episodes that can be put in terms of a dilemma:

1. *If a single sensation of red is too simple to count as an episode*, then all that Williford's theory can explain is why the complex episode as an emergent whole (having single experiences as its parts or elements) is conscious. It *cannot* explain what makes an individual element of this whole episode (or stream), a sensation of red say, conscious. But the varieties of representationalism (which he criticizes) aim to explain exactly this feature of consciousness. A problem with this first horn of the dilemma is thus that we need to answer the question whether or not such single sensations can be conscious independently of being an element of a larger episode.
 - a) *If individual sensations can be conscious independently*, then the question arises as to whether they can be conscious *without* thereby exhibiting subjective character (given subjective character only arises on

the level of whole episodes). This is not what Williford should accept since he takes subjective character to be a defining feature of consciousness; there is no consciousness without subjective character. So if an individual sensation of red could be conscious then it could be so only by exhibiting subjective character. This seems to lead us to Zeki's theory of "micro-consciousness" (Zeki & Bartels 1998; Zeki 2007) according to which every individual node of a perceptual system (visual, auditory etc.) can generate an "atom" of consciousness independently. This is an extreme version of what Bayne (2010) calls an "atomistic" approach to consciousness, standing in contrast to more "holistic" approaches:

"Theorists that adopt an atomistic orientation assume that the phenomenal field is composed of 'atoms of consciousness'—states that are independently conscious. Holists, by contrast, hold that the components of the phenomenal field are conscious only as the components of that field. Holists deny that there are any independent conscious states that need to be bound together to form a phenomenal field. Holists can allow that the phenomenal field can be formally decomposed into discrete experiences, but they will deny that these elements are independent atoms or units of consciousness." (Bayne 2010, pp. 225-226)

The problem with such atomistic approaches is really the phenomenon of the unity of consciousness, i.e., that such individually conscious units would need to be bound together to a much larger all-encompassing unified "phenomenal field", as Bayne puts it, in order to account for what we actually experience. But then we should expect there to be a *mechanism* responsible for such phenomenal binding, a mechanism that we also should expect to break down occasionally under certain circumstances; but there is no evidence for

such a mechanism. The phenomenal unity of consciousness seems to be a deep feature of consciousness just like subjective character, in the sense that it cannot break down and that phenomenal consciousness cannot occur without it. I agree with Bayne's point here (cf. [Schlicht 2007](#)), and I think that Williford would not be prepared to take Zeki's route either. At least there is no indication in the text that would support this reading. Alas, Williford also sets aside the important issue of the unity of consciousness, which arises given the unresolved problem of providing criteria for the individuation of episodes.

- b) So we are left with the alternative that *individual sensations cannot be conscious independently*. For an individual element to become conscious (and to exhibit subjective character) it must then be *integrated* into a larger (cumulative) episode. What's needed then is a theory (and a mechanism) explaining how such integration into an episode takes place. However, then we are left with an alternative view regarding the question of what is responsible for a representation's being conscious, namely some kind of integration-theory. In fact, that is the path I will recommend (and elaborate in more detail) below in section 3. The general idea is that phenomenally-conscious representations are those that are adequately integrated into a global state (we may call it an episode). My worry with regard to Williford's account is simply that once we have such an integration-account, there is no need for his additional story in terms of self-reflexivity in order to explain subjective character. Since subjective character is (taken to be) a defining feature of conscious experience, an account that informs us about how individual sensations become conscious will also inform us about how they acquire subjective character: through integration.

2. But that's not the end of the story. Williford simply could say that a sensation of red may

be a conscious episode. So far, we have discussed the problem of individuating episodes on the assumption that a single sensation of red cannot count as an episode. Now we have to discuss the consequences of the assumption that *a single sensation of red may count as an episode*. This leads to two further possibilities.

- a) One could accept such minimal episodes despite the fact that this concession gives rise to a multiplicity of (streams and consequently) conscious subjects. Although it's metaphysically (somewhat) extravagant, this is a perfectly coherent position to take. Indeed, it seems to be akin to Strawson's theory of the self, according to which a self lasts only as long as an individual state (or episode) of consciousness ([Strawson 1997](#)). But this view flies in the face of experience. For one thing, it is inadequate to explain an important aspect of consciousness, namely what we may call, following Kant, the *(empirical) consciousness of the identity of oneself as subject*: "I am [...] conscious of the identical self in regard to the manifold of the representations that are given to me in an intuition because I call them all together *my* representations, which constitute *one*" ([B134](#)). What he means is that, at least in non-pathological cases, I can become conscious of myself *as* the single, (synchronically as well as diachronically) identical subject vis-à-vis my diverse experiences. I *never* identify myself with one or many of my conscious representations (or episodes for that matter). Rather, I distinguish myself from them *as the subject* who has them when I self-ascribe them. And this empirical consciousness of an identical subject is possible, according to Kant, *because* all my *conscious* experiences are already self-related. I can already call them *mine* because they exhibit subjective character simply by being phenomenally conscious. Kant, famously and notoriously, tried to account for this consciousness of self by simply postulating a *transcendental unity* of apperception in which this is sup-

posed to originate. If Strawson's view were correct, then Kant would presumably reply by pointing to a natural, yet implausible consequence: "I would have as multicoloured, diverse a self as I have representations of which I am conscious" (CpR B134). Accepting this horn of the dilemma therefore has the consequence that we would now need a story that helps us make sense of how the subject of the sensation of red is related to the subject that is identified with an auditory sensation of a loud sound, etc. In effect, this would lead to a binding problem for the multitudinous "subjects" of experience, since in my view, we cannot be content with a multiplicity of conscious subjects. I also think that Williford might not be satisfied with such an outcome, since he never entertains the possibility of multiple subjects in his essay.

- b) Therefore—again, on the hypothesis that a single sensation of red counts as an episode—one could argue that *the multiplicity of conscious episodes has to be overcome in favor of one (unified) stream of consciousness*. This calls, again, for an integration mechanism that produces such a unity. Though I can understand why one would now identify this resulting integrated single stream of consciousness with the subject of experience, I don't see any motivation to identify the episode "single sensation of red" with a subject of experience, if a more complex combination of episodes is needed anyway.

I conclude that the problem of individuating episodes either leads to the acceptance of implausible views like Zeki or Strawson's theories of consciousness and self or to the need for an integration account that explains how individual elements are combined into the one global conscious experience. The claim I would like to put forward is that once we have such an integration account, Williford's proposal becomes superfluous, because what it is intended to explain is then already explained by the integration account.

3 Integration vs. representation

When the aim is to provide an account of the difference between a representation's being phenomenally conscious and it's being unconscious many philosophers are drawn to some form of *representationalism*. This is motivated in part by the prospect of reducing the problem of consciousness to the problem of intentionality or *representation* (Tye 1995; Dretske 1995; Rosenthal 2005; Lycan 1996; Metzinger 2003; Kriegel 2009; Kriegel & Williford 2006). But many of those who are dissatisfied with a representational criterion argue that the difference is due to some sort of *integration* (Dehaene 2014; Van Gulick 2004; Edelman & Tononi 2000; Damasio 2010; Metzinger 1995; Kant 1999; Schlicht 2011). Such integration may eventually result in a higher-order or more complex representational state. In that sense, the two accounts do not mutually exclude each other. But they give different answers to the question of what is responsible for the representation exhibiting the feature of being conscious. To put forward both a representational condition and an integration mechanism would amount to wearing a belt as well as suspenders. Williford's paper demonstrates that other theories are also possible. He favors self-reflexivity as the core feature a representation must exhibit in order for it to be conscious.

In the first part of his paper, Williford scrutinizes all dominant varieties of representationalism, especially with respect to their explanatory power regarding the subjective character of conscious experiences. His case against first-order, higher-order, and same-order or self-representationalism is solid, and I have nothing to add in this regard (cf. also Schlicht 2008b; Vosgerau et al. 2008).⁵

The basis for answering the question as to which conditions have to be met by a single sensation of red in order for it to be conscious and subjectively experienced is the observation

⁵ I disagree with respect to what Williford calls P-Theories, according to which a "privileged object" is represented which makes all the difference between conscious and unconscious representations. Williford interprets Damasio's theory in this way, but although various representations (of the body especially) play an important role in Damasio's theory (as in most other theories), this is not the whole story (see fn. 7).

that the organism in question is already conscious in the creature-sense. This general consciousness (or state of vigilance) admits of degrees (from deep coma to wakefulness) and is one of the conditions for being able to enjoy a sensation of red at all (Dehaene et al. 2006). Empirical evidence points to the assumption that the neural structures in the brain supporting this state contain the relevant structures monitoring and regulating the homeostatic balance of the whole organism. Damasio (1999, 2010) calls these structures “proto-self”-structures, the biological forerunner of that which we eventually experience as a sense of self. He assumes that the brain can only perform these functions of monitoring and regulating if the overall state of the whole organism is represented in the brain.

In addition to representations of the organism, the brain is assumed to produce representations of (objects in) the external world. Given the limited capacity of conscious perception and memory systems, such representations stand in competition (Koch 2004). The basic idea of integration-theories is that some of these competing representations, like a sensation of red, are conscious because they are integrated into a more global state that also contains the structures responsible for creature-consciousness. Van Gulick (2004) has sketched such an integration-theory, based on ideas already to be found in Metzinger (1995):

The basic idea is that lower-order object states become conscious by being incorporated as components into the higher-order global states (HOGS) that are the neural and functional substrates of conscious self-awareness. The transformation from unconscious to conscious state is not a matter of merely directing a separate and distinct meta-state onto the lower-order state but of “recruiting” it into the globally integrated state that is the momentary realization of the agent’s shifting transient conscious awareness. (Van Gulick 2004, pp. 76-77)

In other words, a single sensation of red is consciously experienced if the neural activation

pattern supporting this sensation is integrated in the right way into the neural basis representing the overall state of the organism, the “dynamic core” in Edelman’s words (Edelman & Tononi 2000).⁶

Importantly, the integration mechanism (which is what has to be determined empirically in this framework)—synchronous oscillations, say—is not only responsible for producing a coherent single experiential state of the organism; it also thereby conveys subjective character to the integrated individual representations. If this idea is combined with Damasio’s (1999) notion of proto-self-structures, then integration facilitates a strong connection between the substrate of an individual sensation (of red, say) and the biological structure representing the organism in the brain.⁷ Of course, just like on all other theories, the hard problem is not addressed head-on, i.e., it is not explained *why* activation of these structures feels like something at all. All that can be provided (at this stage anyway) is a coherent story of how all these aspects hang together. But one advantage of the present integration-account is that by establishing a connection between the organism (as represented in the brain) and its object-representations we can make sense of the important fact that all conscious representations feel like something *for the organism*. The organism provides, as Damasio puts it, a “haven of stability and invariance” (1999, p. 142, p. 153; see also Metzinger 2003, p. 161), i.e., just what we need in order to account for subjective character. For remember that subjective

6 Another way to think of this is along the lines of the “Global Neuronal Workspace Model” in which attentional mechanisms determine which of the neural coalitions are integrated (Dehaene et al. 2006). But means other than attention are possible.

7 Williford discusses Damasio’s theory under the label of a P-Theory as a variety of representationalism and finds it wanting. Of course, representations of various sorts, especially of the organism, play an important role in Damasio’s theory (as in many other theories). But I do not share Williford’s interpretation that it is these (special) representations as such that are responsible for consciousness. Various representations (or maps, as Damasio also calls them) have to be integrated in the right kind of way in order for there to be something it is like for the organism. Therefore, I do not consider Damasio’s theory a version of representationalism since there, the mechanism responsible for consciousness is not representation but integration of body representations with object representations via recurrent activations in so-called “convergence zones” (Damasio 1994, p. 95-96, 162).

character is the feature that remains stable across different representations, while qualitative character is the feature that distinguishes different representations from each other. So in order to get an account of subjective character started, we have to look for the point of “*maximal invariance of content*” in the conscious model of reality”, as Metzinger (2003, p. 134) puts it. Metzinger agrees that this invariance is most likely due to the organism and its bodily structures represented in the brain, since it is invariance (or maintenance of homeostatic balance) that keeps the organism alive. Another advantage of this view is that it does so without introducing a questionable new entity and by avoiding Williford’s phenomenologically counterintuitive claim that the stream of consciousness should be identified with the subject of experience. In this commentary, I cannot argue in detail for this positive alternative but hope that these sketchy comments give the reader a general idea of what it aims at. Since I am dissatisfied with Williford’s identification of the subject of experience with the stream or an episode of consciousness, let me now finally turn to an argument for a different conceptualization of the subject.

4 The subject as organism

My alternative claim is that we should simply identify the subject with the organism. This section is an attempt to support this bold claim. The premises of the argument focus on analyses of the structures of phenomenal consciousness and intentionality:

Premise 1 (phenomenal consciousness):

Phenomenal consciousness is characterized by there being something that it is like *for a subject* to be in that state. In this minimal sense, consciousness is relational and requires the assumption of a *subject-pole* of experience.

Premise 2 (intentionality):

The structure of intentionality is such that a *subject* is directed (via some psychological act or attitude like believing, desiring, perceiving etc.) at a content, object, or state of affairs. Inten-

tionality is quasi-relational since at least the *subject* must exist, although the intentional object need not exist.⁸

Premise 3 (subject identity):

The subject that is intentionally directed is *identical* to the subject for whom there is something that it is like to be in a given mental state.

Premise 4 (embodied cognition):

Many intentional attitudes (like perceiving, grasping, emoting) are *embodied* and can be ascribed only to an embodied agent, i.e., to the whole organism.

Conclusion:

The *subject* for which there is something it is like to be in a given mental state and the *subject* that is intentionally directed at a content or object is the *organism*.

4.1 Elaboration of the premises

Premise 1: Phenomenal consciousness

First of all, it is interesting to note that Nagel’s initial characterization of consciousness in terms of *there being something that it is like* is already concerned with *the organism* as the entity *for which* there is something that it is like: After having noted the diversity of beings capable of conscious experience which may lead to very different kinds of conscious experience, Nagel argues that “no matter how the form may vary, the fact that an organism has conscious experience *at all* means, basically, that there is something it is like to *be* that organism, [...] something it is like *for* the organism” (1974, p. 436). So, given that the philosophical community seems to have agreed to refer to Nagel’s slogan in order to characterize phenomenal consciousness in the first place, they should seriously consider Nagel’s talk of the organism as the subject of experience. But apart from this ob-

⁸ A reviewer pointed out that different thinkers had different opinions about *what* is intentionally directed: the mental state, the psychological act, or the thinker etc. As will become clear below, I do not share the view that a mental state is itself directed, but favor the view that a creature of some sort is directed at something *via* an act or attitude. A great advantage of this view is that such attitudes are not limited to mental states like beliefs and desires (as traditionally held), but it also allows also for motor intentional attitudes like grasping or holding etc., i.e., essentially bodily ways of being directed (premise 4). For details see Schlicht (2008a).

servation, all that is stressed in the first premise is the relational character of phenomenal consciousness, much in the sense of one of the commitments defended in Williford's paper. The reasons for holding this are mainly phenomenological: it simply appears that way. And we are all aiming at a theory of why this is so. Williford's elaboration of the relational structure of consciousness in terms of the genitive and dative of manifestation captures the intuition expressed in this premise very well. Thus, there is not much room for disagreement here.⁹

Premise 2: Intentionality

In his canonical elaboration of the structure of intentionality, Subject—Intentional Mode—Content, [Tim Crane \(2001, p. 31\)](#) admits that he does not provide an account of the first relatum, "because the nature of the subject is not something that is within the scope of this book (strange as that may seem)". Yet, as far as intentional states are concerned, the assumption that attitudes are not free-floating entities but come along with a thinker, perceiver, or believer is rather uncontroversial. What's controversial is how we should characterize the subject and what kind of commitment is implied in the "acceptance" of a thinker, perceiver, or believer.¹⁰

Premise 3: Subject identity

In a way, this premise is at the same time trivial and important. First of all, if one accepts premises [1](#) and [2](#), then it is natural to accept premise [3](#), if only because the alternative would lead to a multiplicity of subjects, giving rise to questions regarding the relations between them. I discussed this option above in section [2](#). There are many debates about the relation between consciousness and intentionality, but there is hardly any debate about the relation between the subjects of each. So in a way, this premise simply states the obvious, given premises [1](#) and [2](#). But it is plausible to accept it even independently of these premises as the default position. One important reason for this is that there are many conscious experiences that are both phenomenal and intentional—perceptual experi-

ences, for example. If I am looking at a red tomato, then my conscious experience presents me with an object in the external world at which I am thereby visually directed. But there is also something that it is like for me to see the tomato if I am phenomenally conscious of it. Since it would be odd to claim that there are two subjects involved here—one being intentionally directed and one being conscious of the tomato—the default position is that it is one the same subject that is intentionally directed and phenomenally conscious. Second, despite the discussion among analytic philosophers in the last fifty years, it is not clear that phenomenal consciousness and intentionality can be separated from each other so easily anyway. In fact, proponents of phenomenal intentionality (or cognitive phenomenology, see [Bayne & Montague 2011](#)) like [Searle \(1992\)](#), [Strawson \(2004\)](#), [Pitt \(2004\)](#), [Horgan & Tienson \(2002\)](#), [Kriegel \(2013\)](#) and others argue to the contrary. Again, then the premise simply states the obvious.

But this premise also is important because once we commit to it, we can follow either premise [1](#) or [2](#) in our investigation to see whether we can formulate constraints on the nature of the subject based on either consciousness or intentionality. This is the job of premise [4](#), which accepts lessons from recent investigations into ways of being intentionally directed.

Premise 4: Embodied Cognition

Cognitive Science has recently been dominated by discussions on the so-called 4Es, i.e., embodied, embedded, enactive, and extended cognition. These notions characterize four important ways in which our current theorizing about cognition departs from classical cognitive science. They are more or less independent of each other and can be accepted and rejected in isolation.¹¹ This is not the place to elaborate in detail all four of them, especially because for the purposes of this argument only the feature of embodiment is important. Many of our psychological acts, like *perceiving*, being *emotionally* directed at or affected by something or other, performing *intentional actions*, etc., are embodied

⁹ I support this premise in more detail in [Schlicht \(forthcoming\)](#). For the purposes of this commentary it is sufficient to note the agreement on the intuition that phenomenal consciousness is relational.

¹⁰ Again, I argue for this premise in [Schlicht \(forthcoming\)](#).

¹¹ An exception may be the intricate connection between cognition being embodied and (therefore) being embedded.

in the sense that features of an organism's non-neural body contribute importantly—be it causally or even constitutively—to the execution of these cognitive acts (Wilson & Foglia 2011).

A plausible claim defended by enactivists is that even a basic cognitive act like perceiving involves many bodily movements like eye-, head- and whole-body movements when looking at or focusing on an object, or when jointly attending to an object with someone else (Noë 2004). This can be accepted independently of more radical claims regarding the usefulness of representations typically put forward by enactivists (Hutto & Myin 2013). What's more, a bulk of empirical evidence has accumulated that supports the important role of the body and bodily actions for psychological acts:

- a) Facial expressions and bodily postures are arguably constitutive elements of feelings and their expression. Many theories of emotion such as multifactorial models (e.g., Scherer 2009; Welpinghus 2013) usually include as one component a bodily feature. Moreover, eye- and head-movements count among the constitutive and content-determining elements of visual perception (Noë 2004).
- b) Research on mirror neurons has demonstrated the intricate relation between perceiving and acting in the sense that the same neural structures are employed for the execution and observation or recognition of intentional acts and emotional expressions (Rizzolatti & Sinigaglia 2008; Keysers 2013). Controversial debates about the role of mirror neurons for social cognition notwithstanding, it is fair to say that from a neural perspective, perception and action have to be considered as constituting one single complex system. We develop motor programs for the performance of certain actions and *reuse* these programs in our observation of others when they perform such actions. These motor programs contain goal-directed representations with a bodily format (Goldman & de Vignemont 2009) that are crucially different from the propositional format of a belief, say.
- c) What's more, lessons from studies of pathological conditions like visual form agnosia (Mil-

ner & Goodale 1995) suggest that we can be directed at an object in a purely motor-intentional way, thereby demonstrating a “bodily understanding” (Kelly 2002) of an object that is not based on concepts and cannot be put into appropriate words.

Generalizing these (and many other) points (see e.g., Gallagher 2005) leads to a paradigm shift with regard to our understanding of the subject of intentionality: intentionality is not restricted to propositional attitudes; an embodied agent, i.e., an organism,¹² has many sensorimotor, affective, and cognitive means to be directed at objects and states of affairs. This way of understanding the structure of intentionality allows us to capture many more phenomena that clearly fall under the name of intentionality as directedness, e.g., reaching for and grasping an object.

All the premises taken together yield the conclusion that there is one subject capable of intentionality and consciousness that can be identified with the organism (not with the stream of consciousness), characterized by a variety of cognitive capacities allowing for a range of intentional attitudes—some of which are affective,¹³ others sensorimotor,¹⁴ and still others are of sophisticated cognitive¹⁵ varieties. The overall state of the subject, being the whole organism, is represented in the brain. This representation contains information about its body, its interior milieu, etc., such that all representations having to do with the organism's interaction with objects can be coupled to or integrated with the representations monitoring and regulating the state of the organism in the

¹² Talk about embodied agents is broader than talk about organisms. The biological constraints on full-blown cognitive and conscious agents are currently unknown. Whether artificial cognitive systems are possible depends on the limits set by such constraints. In this paper, I cannot address this point.

¹³ One of Brentano's examples in his famous passage on intentionality being the mark of the mental is love, in which someone is loved. This example cannot be adequately captured by restricting intentionality to propositional attitudes which can be formulated using “that-clauses”.

¹⁴ Many forms of being intentionally directed are sensorimotor, e.g., all that has to do with perception and action, this being the biologically primary form of intentionality (Searle 1983, p. 36).

¹⁵ Most cognitive varieties of intentionality are sophisticated and propositional, like beliefs and desires, which can be put into sentences containing “that-clauses”, e.g., Ken believes that physicalism is true.

brain. On the basis of such couplings, it is in principle possible to make sense of the idea that object-representations become subjective in the sense of being something *for* the organism.

A caveat: this does not amount to an explanation of how consciousness arises in the first place, or of *why* integrated representations are experienced at all. But hardly any theory of consciousness has properly addressed this hard problem so far (Chalmers 1996). The limited claim of this commentary is that we can at best make sense of the subjective character of phenomenal consciousness if we adopt an integration-theory as outlined above and regard the subject for which there is *something that it is like* as the whole organism. As I concluded in the first part, depending on how he is going to individuate episodes—a problem which he has not yet solved—, Williford seems to be in need of such an integration-account anyway. Therefore, this sketch of an alternative should be appealing for someone taking subjective character seriously.¹⁶

Acknowledgements

I would like to thank Jennifer Windt, Thomas Metzinger, and two anonymous reviewers for very helpful comments on an earlier draft of this paper. I am also grateful to Kenneth Williford, who provided such a stimulating and challenging paper and once again to Jennifer Windt and Thomas Metzinger for the chance to contribute this commentary.

Individuation, Integration, and the Phenomenological Subject

A Reply to Tobias Schlicht

Kenneth Williford

Tobias Schlicht argues that subjective character derives from the integration of mental states into a complex of representations of the organism and that therefore there is no need try to account for subjective character in terms of “reflexivity” or self-acquaintance, as I do. He further argues that the proper subject of consciousness is the whole organism and not the episode or stream of consciousness, as I maintain. He maintains that his account solves problems about the individuation and synchronic unity of conscious mental states that mine does not. While I agree that we need an account of the individuation of episodes of consciousness and an account of the synchronic and diachronic unities of consciousness (something I bracketed in my paper), I disagree that making the organism into the phenomenological subject of consciousness helps with these problems. However, I am willing to concede that the organism is the subject of consciousness in some non-phenomenological sense.

1 Introduction

In his insightful commentary on my contribution to *Open MIND*, Tobias Schlicht argues for the following claims: (1) The subject of conscious episodes should be identified with the organism whose episodes they are ([Schlicht this collection](#), pp. 2, 8-9). (2) Once we understand how non-conscious mental states (perceptions, thoughts, etc.) become conscious by being integrated into the underlying organismal creature-consciousness, we will have understood all that is important about how a

conscious state is endowed with subjective character ([Schlicht this collection](#), pp. 5-6). And, (3), such an account would obviate an account like mine, since there would be no need to imagine that individual episodes of consciousness have a sort of self-contained subjective character (which I construe in terms of “reflexivity” or self-acquaintance)—instead, their subjective character would just derive from their integration into the underlying creature-consciousness, which *ipso facto*

makes the organism to be the subject-pole of the episode ([Schlicht this collection](#), pp. 5-8).

Part of claim (3), as stated, (the part that begins with “since”) is my interpretation of Schlicht, since he does not spell out the claim in great detail, given limitations of space. So my arguments directed at that interpretation may not target exactly what Schlicht had in mind. But claims (1) and (2) are stated very clearly ([Schlicht this collection](#), pp. 5-6, 8-9). In this reply, I will take issue with these three claims and discuss some of Schlicht’s other claims in relation to them.

2 The phenomenological subject and the organism

I readily admit (and did so in the contribution) that the claim that the subject of consciousness is the episode (or stream) of consciousness itself is rather counterintuitive.¹ However, part of this counterintuitiveness can be ameliorated easily enough. To begin with, I should have made clearer that I was talking about what I like to call the “phenomenological subject” of consciousness. I did use the phrase, but I did not explain it and should have done so. The phenomenological subject is just *that to which* the objects of phenomenal consciousness *seem* to appear. In other words, granted that consciousness seems to have a subject-object, relational structure, the phenomenological subject is just the subject-pole of conscious experience in so far as it is given (reflectively as well as pre-reflectively).

Now, suppose we interpreted the Humean “no-self” intuition in the strongest possible way. In that case, we would conclude that there is no phenomenological subject at all. As I argued in the paper, I think the Humean intuition is not to be dismissed. However, I do think that the subject-object polarity of consciousness is a datum and not projected or inferred. If one is already sympathetic with the idea that consciousness is always aware of itself (is its own “secondary object”, as Brentano put it (see

[Brentano 1995](#), pp. 128ff.), or is always non-positionally conscious of itself, as Sartre put it (see [Sartre 2004](#), p. 8)), then it is not much of a stretch to identify this feature of “reflexivity” with subjective character and, if we must reify, make the episode or stream into the phenomenological subject. As long as one understands that by “subject” here, I just mean the subject-pole of conscious experience, a pole that one is phenomenally conscious of, then one will get my meaning. Given a commitment both to some version of the Humean intuition and to the intuition that one is phenomenally aware that consciousness has a subject-object polarity, one will need to resolve the tension between these in some way. Self-representationalism and self-acquaintance theories can do this in a very elegant way, I argued, a way that neither first-order nor higher-order representationalisms can. All of this is compatible with the evident fact that we normally experience ourselves as having a body in space that bears various relations to objects in space; but the phenomenological subject of consciousness should not, in my view, be identified with the body or with a representation of the body.

One might, of course, use “subject of consciousness” in different ways. One might, for example, mean “that organism or system to which we attribute consciousness” or “that which is the substrate of consciousness in an organism”. We might then speak of the “metaphysical subject” or “ontological subject” of consciousness, rather than the “phenomenological subject”. The metaphysical subject of consciousness need not appear to or be represented in consciousness. I have nothing against the idea that the organism (or a set of sub-processes of it) is the metaphysical subject of consciousness. I grant, moreover, that we normally speak in such a way that the grammatical subject of attributions of consciousness (or conscious mental states) is a noun that refers to an organism. We say things like “Skipper, my dog, sees his food coming” or “The bird saw me walking toward it and became frightened”. Indeed, insofar as consciousness is a property of or process going on in the brain of organism, there is nothing erroneous about such attributions. However, given the

¹ Indeed, after hearing me present a version of the target paper (at TCU in 2014), Michael Tye told me that even on a charitable reading, the claim lacks a truth value. At least, that’s what I understood him to mean.

falsity of animism and the commitment to what I like to call encephalism (the view that consciousness resides in the brain), the ontology of consciousness cannot just be read off of the grammar of such attributions, not that Schlicht is suggesting that it could.

It would, however, be more accurate to say in the Skipper case that there is a process of phenomenal visual consciousness having such-and-such representational content and being connected in such-and-such a way with Skipper's volitional, appetitive, and motor systems (all, of course, related to Skipper's organismic homeostatic systems) going on in Skipper's brain when, in normal conditions, the food is presented to him. Of course, I just referred to Skipper *qua* organism multiple times in reformulating this apparently simple attribution, but that just has the effect of roughly localizing the conscious process and, of course, connecting it to Skipper's behaviors and functions as an organism. No one should deny that consciousness, as it has arisen in organisms with an evolutionary origin, has a biological function, though it is highly debatable that consciousness should be defined or analyzed in terms of such functions. It may well be that it serves these organismic functions but could exist in substrates that do not have them or need them. In fact, I would put my money on the claim that artificial consciousness is possible in systems whose homeostatic functions can be carried out in a way that its consciousness does not contribute to *at all*. But that is a debate for another time.²

The counterintuitiveness of claiming that the phenomenological subject of consciousness is the episode or stream of consciousness might derive in part from the oddness such a view would seem to introduce into our quotidian attributions of conscious mental states, if we were to try to make our ways of speaking match this theory. It would be rather odd indeed to say, "Skipper's current episode of consciousness sees the food coming". But the view I defend does not really legitimate such locutions. Those attributions run together the phenomenological and

metaphysical notions of "the subject". The sense of counterintuitiveness that comes from saying "the episode sees..." (etc.) stems from the fact that the episode is *not* the metaphysical subject.

When we make normal attributions of conscious mental states to a creature, we encode information about the location or individuation of the conscious episode (and this gets construed as "ownership"—it's Skipper's seeing), information about the representational content and modality or attitude the episode involves (food and seeing, respectively, in this case), and a sort of folk theory about the relational structure of consciousness. That folk theory puts whole organisms or agents, as it were, "behind" the conscious mental state, as the point of view or subject pole from which the experience emanates or, to use another metaphor famously attacked by Dennett (see 1991, ch. 5), as the spectator in the "Cartesian Theater". That folk theory is hopelessly homuncular, it seems to me. It offers no analysis of what a subject is and gives no hint as to what the real conditions of unity are for either organisms or subjects. (By contrast, self-representational and self-acquaintance theories try to preserve what is right about the Cartesian Theater intuition while avoiding a commitment to homuncularism.)

When we say "Skipper sees" we do not really mean that Skipper is, as it were, behind some sort of internal telescope looking out of his eyes or at some internal screen, though the first theory of seeing that some kids come up with is indeed the homuncular and regressive one according to which there is a little person in our heads looking at just such an internal screen. It seems that what is encoded in the folk theory implicit in our normal conscious mental state attributions is something like a homuncular projection of our third-person experience of other conscious organisms onto the organism's first-person experience. In other words, we see Skipper with his excited behavior and the food out there in front of him, some distance from his body; we then imagine that this relationship that we see "sideways on" (to borrow a phrase from John McDowell, see e.g., McDowell 1994, pp. 34-36) is, so to speak, rotated 90 degrees

² It is also possible that something other than consciousness could carry out most (but not all) of the functions consciousness performs in us and other organisms; this is also a debate for another time.

and moved inside Skipper's head—with Skipper as an irreducible agent assuming the position behind the eyepiece of his internal periscope.

That may be a bit too fanciful an exercise in the conceptual archaeology of folk-psychological mental state ascriptions, but the main point is just that our normal attributions of conscious mentality seem to run together generally accurate information about individuation or location ("ownership"), content, and attitude with a naïve and homuncular picture of subjective character. So, yes, it is true, I would say, that the organism is the subject of consciousness in the sense that conscious episodes (so far anyway) take place in organisms (actually in their brains) and causally depend upon organismic metabolic and homeostatic processes for their existence. In this sense, the organism is the *metaphysical* subject of consciousness, and this is properly reflected in our usual mental state attributions. However, I would emphatically (perhaps even hysterically) deny that the whole organism could be the *phenomenological* subject of consciousness. This is something also reflected in our usual attributions, but this is because the metaphysical and phenomenological subjects are simply conflated by folk psychology. The whole organism could not be the phenomenological subject for two reasons.

First, if one agrees with me, as Schlicht seems to, that subjective character and the subject-object polarity are phenomenally manifest even in pre-reflective consciousness, but one adds to this the claim that the phenomenological subject is the organism, then it would seem to follow that we are always aware of ourselves *qua* organism when we are consciously aware of anything—since, again, all consciousness by hypothesis has subjective character. Now, this could mean either that we represent ourselves *qua* organism or that we are acquainted with ourselves (and we are, in fact, organisms). Surely we do not, at the level of consciousness, represent ourselves *qua* organisms all the time, unless all one means by that is that consciousness has a biological function of some sort (that is, in, say, the teleofunctional sense, consciousness is "about" the organism and its ongoing relationship to the world). The latter is

undoubtedly true, but that is not a phenomenological characterization of subjective character; rather it is a thesis about the function of consciousness and its relation to organismal homeostasis. Of course, one could make an identity claim according to which subjective character (as experienced) really just is the suitably integrated representation of the organism, but this then would mean that one is embracing some form of P-theory (a theory according to which conscious representational states are distinct from non-conscious ones in part because they target some privileged object, e.g., the organism, a substantial self). If the claim is taken to mean that the organism is self-acquainted, then I might be willing to agree depending on the spin one puts on that claim.

One might just mean that there is some sub-process of the organism that is self-acquainted (that is self-manifesting or directly phenomenally self-representing, if one prefers). If that is all that is meant by the claim, then I can agree. Something like this is exactly the position I defend in the paper. After all, the central claim was just that consciousness is self-acquainted. And it was an unstated assumption of the paper that consciousness is a sub-process of the brain, and the brain a part of the organism. If, on the other hand, one means that the *whole* organism is directly acquainted with itself, this seems to me to be either an unexamined endorsement of commonsense, homuncular ways of making conscious mental state attributions (criticized above) or the claim that consciousness *necessarily* involves the entire organism.

The latter disjunct seems as false to me as the former. Yes, the prolonged existence of consciousness depends on the prolonged operation of the essential metabolic and homeostatic functions. And, indeed, almost certainly the metabolic functions that support synaptic transmission and some other basic neuronal processes are *sine qua non* for consciousness as it happens to be implemented in human and animal brains. But none of the specific means whereby our bodies support these functions have to be in place, it seems to me.

We can have artificial hearts and artificial respiration. In principle, we could offload all the

metabolic processes outside those internal to the nervous system to non-natural machines. And we could even, in principle, replace the natural generation of essential neurotransmitters with their artificial synthesis and, possibly, artificial projections for distributing them in the brain properly. Homeostasis could be maintained artificially and, in principle, without the relevant brainstem nuclei needing to do anything anymore (unless, of course, some of their activities just *happen*, for totally contingent evolutionary reasons, to be constitutively necessary for the occurrence of consciousness in brains like ours).

In short, it is certainly physically possible (though technologically beyond our current means) to keep a brain alive and operating in a “vat”! As long as we maintain those processes that are the neural correlates of (are identical to, in my view) consciousness, there would be consciousness in that brain in that vat. I am sorry, but all the evidence indicates that encephalism is true. And it seems to me to be a sort of externalist fetishism to think that consciousness literally extends beyond the brain (save by intentionality and causal interfacing). As Dan Lloyd says, we *already are* brains in vats! The cranium is the vat! (See [Lloyd 2004](#) pp. 244-245.)

Haven’t we learned from dreams, hallucinations, ALS, direct brain stimulation, and locked-in syndrome that consciousness does not need anything but the relevant brain functions to exist? Of course, the functioning brain depends upon a properly functioning body, but this does not mean that consciousness should be identified with those (other) bodily functions in some way. If we go this route, adding bodily correlates to neural correlates, when the latter causally and distally depend on the former, what is stop us from adding everything the body depends upon to our list of correlates (the gravitational constant, the bonding properties of molecules, the stability of the proton, etc.)?

True, at a certain level of analysis, it is hard to say precisely where the nervous system ends and the rest of the body begins. But then the same can be said for the body and the rest of the world (especially given that we routinely

appropriate, by breathing and eating, parts of that world). The boundaries are fuzzy at a certain scale, but this does not mean we should say there are no boundaries at all. Moreover, causal dependencies and interdependencies are myriad, but the causal relation is not the parthood relation—we cannot infer from “X causally depends on Y” that Y is a part of X. Human consciousness, as it is currently implemented, causally depends on respiration, but this does not mean that respiration is part of consciousness or that the physiological correlates of respiration are also correlates of consciousness.

If it is true that consciousness resides in the brain and depends on our specific homeostatic and metabolic processes only contingently (and I mean physically contingently, not merely logically contingently), then saying that consciousness requires an organism as a subject-pole starts to look a little fishier. This brings me to the second main reason why I would reject the claim that the whole organism is the phenomenological subject of consciousness.

What, after all, is an organism? It is clearly not just a collection of parts. We can agree with the Aristotelian tradition that it is a functional unity. We can agree that it is a system that, in virtue of its form or organization, is able to give rise to temporal successors (and I don’t necessarily mean offspring) that maintain that form or organization (at least for a while and at least within the range of conditions it evolved to live in). The matter always changes, but the form remains, from cradle to grave.

The organism takes matter from its environment to keep its processes going. And relative to its function of maintaining homeostasis (thereby giving rise to temporal successors that have the same organization it does) and to the scale at which those functions are, so to say, visible, we can truly say that the organism behaves like a goal-directed *whole* with interdependent parts and processes (and organs—the heart needs the lungs; the lungs need the heart; the kidneys need the stomach, etc.). This is all fine and dandy. But it is clear that organs are not to be identified with the whole organism. Skipper is not Skipper’s heart, though without it (or some suitable artificial replacement) little

Skippy would soon cease to be an organism at all and eventually become soil (or parts of other organisms).

More to point here, the brain is not the organism. Consciousness resides in the brain. We could, in principle, preserve consciousness simply by preserving the functioning brain. If this is true, then you do not need an organism for there to be consciousness, you just need a suitable *organ*—the brain.

I would never deny, of course, that we normally represent ourselves as having a body and relating to a world through that body. No doubt about it. Moreover, I believe it is metaphysically necessary that any consciousness be embodied in some substrate and that this embodiment configures consciousness in a way that is phenomenologically accessible to a certain extent. And, of course, we are organisms with a certain natural history. All of this “facticity” does indeed configure our consciousness to one degree or another. If all the organismal claim comes down to is that conscious beings are necessarily acquainted with their own contingent embodiment in a certain manner, then I will wholeheartedly agree. If it means that, contingently, consciousness evolved out of and is still connected to basic homeostatic functions (in some way), I will regard the claim as a not implausible hypothesis to be investigated.

This last claim is not, it seems to me, exactly what Damasio (see [Damasio 2010](#), ch. 2) and philosophers who follow him on this point, like [Charles Nussbaum \(2003\)](#) and apparently Schlicht himself, mean. They want to say something stronger. Like Francisco Varela (who possibly influenced Damasio on this point, see [Damasio 1999](#), p. 347; cf. [Varela 1979](#); [Maturana & Varela 1980](#)), they seem to want to connect consciousness essentially in the constitutive sense to the kinds of processes that are involved in homeostasis and the very emergence of an internal organism/non-organism distinction. It may well be that the subject/object distinction apparent in consciousness is, in evolutionary terms, some sort of extrapolation of this more basic distinction. It is clear, however, that, whatever the exact relation, the organism/non-organism distinction in, say, the immune sys-

tem, cannot just be identified with the subject/object distinction in consciousness. On Damasio’s view (as I understand it anyway) consciousness arises out of multiple, integrated layers of representation of the organism/non-organism distinction, where this representation itself has a certain regulatory function.

I certainly agree with [Schlicht \(this collection, p. 7\)](#) that, for Damasio, organismal and objectual representations have to be integrated in the right way for there to be something it is like for the organism, and I did not mean to suggest otherwise. This does not, however, make Damasio’s theory a non-representationalist theory (no more than the poise requirement makes Tye’s theory non-representationalist (see [Tye 1995](#), p. 138, [2000](#), p. 62)). As long as representation is considered a necessary condition for consciousness, the theory is representationalist, by my lights. And since the relevant representations, in Damasio’s theory, include, centrally, representations of the organism, it still qualifies as a P-theory in my sense—the organism is a privileged object. The representations that, when integrated, constitute consciousness, must include representations of the organism, according to the theory. Whatever else is represented in conscious mental states, on this sort of view, the organism certainly is. And the organism (ultimately in its guise as the “core self”) could thus serve as the phenomenological subject of consciousness.

I do understand how such a theory attempts to capture subjective character. In effect, it bundles it up into an object of a special sort that is always represented (one way or another) in any conscious mental state. For various reasons (e.g., the Fichte-Shoemaker Regress, see [Henrich 1982](#); [Frank 2004](#); [Frank 2007](#), pp. 157ff.; [Shoemaker 1968](#)), I do not think that such a theory can do the trick. Briefly, it is not enough simply to represent some object that you just happen to be. That is not sufficient to ground the manifest indexicality (the “I am this, here, now” aspect) of our conscious experience. Also, it is somewhat puzzling to require that consciousness representations have to have some specific type of content. Consciousness seems to be so flexible in this regard, that is

odd to think that there is such a “magic” object of representation. By contrast, I view subjective character (“reflexivity”) as a formal or structural feature of consciousness and not as a matter of representing some object or other (whether consciously or unconsciously)—including “the organism”. In fact, I believe such views, while on the right track relative to views that disregard subjective character, get the cart before the horse. *The representation of oneself as a self or an particular organism depends upon reflexivity, and not the other way around.*

For an organism (call it O) to benefit from representing an organism interacting with the world and with other organisms, there must be some way that it encodes that *it* is O (and not anything else). In effect, it needs a “you are here” (or rather “I am here”) dot on its map, a kind of “fixed-point” (see [Ismael 2007](#)). The mapper needs to know where *it* is on the map it has made. On pain of regress, it cannot derive a representation like “I must be here and not there, this organism on the map and not that one” without having some antecedent, unmediated self-reference or primitive self-knowledge (again, see [Shoemaker 1968](#)). Without this direct self-reference, the best we could hope for is a system that just happens to control itself by representing something that resembles itself in the relevant ways. Such a system might as well be controlling an exact duplicate in a duplicate room next door. We do not get manifest indexicality, self-location, or subjective character out of this. A system built up around reflexivity or direct self-reference (or primitive self-knowledge, if you prefer), would have all the control functions of a system that lacks it as well as these other features of subjectivity. Following a suggestion by Metzinger (personal communication), though with a certain modification, I would be happy to call this kind of reflexivity “prepersonal”. As such, it is the basis for one’s conscious representation of oneself as a person, organism, or anything else for that matter; but it is not essentially the representation of a person or an organism. Rather, it is the reflexivity of a process that happens to be housed in an organism (and in an organ within that organism) and that allows that organism to self-locate in a

multiplicity of spaces (physical, social, semantic, etc.).

I would add that that reflexivity could not itself be purely representational, as I argued in the paper. It very well could be, however, that reflexivity was first achieved in the evolution of organismic control systems and that these control systems have everything to do with the maintenance of homeostasis, though this is a contingency. *That* does not seem implausible to me at all. But that is a hypothesis about the evolutionary origin of self-acquaintance, not an account of what self-acquaintance is or how it is routinely generated and supported in the brain.

3 Unity, individuation, and integration

This brings me to Schlicht’s second and third claims. [Schlicht](#) is absolutely right, of course, to press me on the need for an account of the synchronic and diachronic unities of consciousness and for an account of the individuation of episodes and streams of consciousness ([this collection](#), p. 5). I bracketed such worries because I have not worked out any such accounts to my own satisfaction. I do, however, disagree with [Schlicht](#) on the idea that regarding the organism as the subject of consciousness can help with individuation ([this collection](#), p. 6). It is, in my view, not much easier to specify the metaphysical individuation conditions for an organism than it is to do so for an episode of consciousness. And it is problematic to assume that the brain has, so to speak, figured out what these conditions are for us. It is true that the brain must regulate a certain set of functions and processes in order to facilitate the maintenance of homeostasis; and I can even grant that doing so involves “representation” in a teleosemantic or functional-role sense. But this is orthogonal to any issues about the metaphysical individuation of organisms. While it may be easier to say what sort of processes an organism must involve (see above) and to roughly localize those processes than it is to say when one episode of consciousness begins and another ends, it is no easier to provide the *ultimate* metaphysical individuation conditions that ground the identities of the more basic physical processes that

both organisms and consciousness depend upon. At the end of the day we are always left turning our spades with the thought that there just exists a plurality of things in the cosmos—this proton (or bare particular or property or location) is not that one—end of story!

In the case of consciousness there is no *special* problem of metaphysical individuation, if what we are talking about is the fact that these episodes over here are in “my” head (in this brain), and those over there are in “your” head (in that brain). From a purely epistemic point of view, it does indeed seem to be the case that we individuate episodes of consciousness by reference to individuated organisms. But so what? This is a mere contingency. If, say, we saw conscious processes (or their correlates) first, and only with great effort could we locate the organism to which the processes were attached, we would individuate organisms by referring to the streams of consciousness that “own” those organisms. There is what we might call the “epistemic relativity of individuation”. This does not mean that there are no mind-independent facts about what ultimately individuates things. It just means that, since we have no access to what the ultimate individuator is, no particular way we individuate something should be regarded as privileged. We are guided by practical and interest-relative considerations. We might as well talk about the acorns’ squirrel rather than the squirrel’s acorns, but squirrels are more entertaining to us.

In any case, for any physical process, once you drink the metaphysical individuation Kool-Aid, you won’t come back to normal. At some point you’ll just find yourself saying “this is not that”. And anything you scratch (from universes, to stars and planets, to organisms, to molecules and particles) will fall apart in this connection. I believe there are real unities in nature and that conscious mental states are such real unities (it follows that I think certain brain processes are too), but from the epistemic and conceptual point of view Nagarjuna and the Madhyamikas seem to be right—we cannot pinpoint the basic individuator anywhere, they just seem to dissolve upon analysis one way or another (see e.g., Westerhoff 2009). I believe

such individuator exist but that they are inaccessible to us. And, as I argued in the paper, it is a serious confusion to think that in being self-acquainted you *ipso facto* have access to what it is that ultimately individuates you. You are aware of the unity and individuality of your episodes of consciousness, but those features, in turn, could depend on other unities and individuation conditions that you have no access to (cf. Williford 2011, pp. 202-203).

I am as happy as the next bloke to claim that conscious mental episodes arise and eventually give way to the next conscious mental episodes. Perhaps they overlap somehow to form a stream. Or perhaps they are punctate and we could empirically determine their temporal boundaries; I do not know. It is, however, clear that my conscious episode of reading H.P. Lovecraft for nostalgia’s sake before bed is not the conscious episode of eating yogurt for breakfast that I began the day with. But is it the same *organism* that eats in the morning and reads in the evening? It is indeed, given our normal (possibly partly pragmatic) individuation criteria for organisms. One would not have to be Heraclitus, however, to notice that the being that started the day is *quite different* from the one that unwisely decided to read Lovecraft before bed. And at a certain very fine-grained level of analysis, it is a *radically* different being.

We say things like “I ate yogurt this morning” and “I read Lovecraft at the age of 14” and “I am reading Lovecraft right before bed tonight”. We take this “I” to refer to the same organism and to the same “autobiographical self” to use Damasio’s term or same “ego” in Sartre’s sense of the word. But as Sartre pointed out (2004, pp. 7-9), no such temporally extended and dubitable entity could be entirely present in consciousness (so as to serve as its subjective character). Instead we have only a set of processes that remain more or less constant (and of course a causal-historical chain that is not broken). But the whole causal-historical chain does not exist at the present moment. It cannot be packed into a single conscious episode (though it could, of course, be represented in one). Nor can it, as a real pole of identity, exist

throughout all conscious episodes. There is no transcendental ego. Nor is there any transcendental organism. An appeal to the organism does not, just by itself, help us with the diachronic unity problem or the individuation problem. And though the brain may somehow unconsciously always “represent” us as organisms (in perhaps the teleosemantic sense of “represent”), it is evident that we are not always conscious of ourselves as organisms (whatever exactly that is supposed to mean). Yet subjective character is there whenever consciousness is.

Thus, I do not see how the organismal theory helps with either the individuation problem for conscious episodes and streams or the related diachronic unity problem. But it is also not obvious to me how the organismal theory could help us with the synchronic unity issue either—the issue of how different phenomenal and representational contents get integrated into whole, unified conscious mental states or episodes. I fully agree with Schlicht that a brain process (e.g., an “unconscious perception” of something) can be integrated into consciousness, making a new whole, and then possibly slip out again. And I too like Edelman’s and Tononi’s “Dynamic Core” idea (see [Edelman & Tononi 2000](#), Part IV) as a way of conceptualizing this integration and dis-integration. And I would emphatically reject the “micro-consciousness” idea of Zeki (see [Zeki 2007](#)). It does not seem to help to imagine many consciousnesses in the brain that somehow meld together to make a bigger one. (At least I hope it is not like that!)

In connection with this, I, like most people, believe that normally there is only one stream of consciousness existing in a given brain (with split-brain cases perhaps being an exception). I prefer the idea that consciousness is a type of process that has certain generic, essential structural features (temporality, subjective character, phenomenal character, representational character) and certain variable features (this comes down to variability of phenomenal and representational characters at different times). Due to some constantly fluctuating integration process, the phenomenal and representational characters of consciousness are al-

ways in flux, while temporality and subjective character remain invariant. Moreover, phenomenal and representational characters are such that they can, so to speak, expand and contract.

I can be hearing Bach’s *Musikalisches Opfer* while staring at a Jackson Pollock painting. I can then close my eyes so that only the beauty remains in my consciousness. If I open them again, then the visual horror will be reintegrated into it. When I closed my eyes there was “contraction”; when I opened them again, “expansion” back to the “size” the experience was before I closed them. There must indeed be something that accounts for this integration process and the resulting synchronic, differentiated unity of consciousness.

I completely agree with Schlicht that we need a theory that allows us to understand how something enters consciousness and how it gets integrated into a whole with other things that have already entered consciousness, but I do not know what that theory. Moreover, I do not know if it is possible to have a conscious experience of but one sensory quality in one modality (say, the auditory consciousness of a pure C tone) without any other thoughts, imaginings, perceptions, or anything else. I would say, though, that if one could, that episode of consciousness would still have subjective character (and temporality).

Though I agree that we all need an integration story, it is quite unclear to me that that story alone will give us a story about subjective character, unless, like [Van Gulick](#) (see e.g., [2004](#); cf. [Metzinger 1995](#)), one thinks that subjective character as a kind of reflexivity emerges out of integration. That may be, though I have never understood how, exactly, that is supposed to happen on Van Gulick’s view (though I do have some sense of what he means). It is not clear to me how this is supposed to happen on [Schlicht’s](#) view either (see [this collection](#), p. 11). But I would be quite pleased if an account like this could be made to work, since deriving reflexivity from integration would, it seems to me, be a theoretical advance.

In any case, for me, subjective character as reflexivity is a phenomenological given. It is

part of the data set from which I begin. It is my “Phenomenological Muse”. I could be wrong about its importance, of course, but until I am shown that, I will explore the model space that is appropriate to that intuition and leave it to empirical testing to determine whether or not the Muse was lying to me. (I will add, in a purely psychologistic vein, that many philosophers are allergic to reflexivity for purely irrational reasons. They just find it odd or too complicated or too puzzling. So they see it as an advantage if they can offer an account that gets around the need for it. For me this is like taking Marlon Brando out of *Apocalypse Now* or preferring decaf coffee to the real deal.)

As I see it, subjective character is like a universal or form. It is just the “reflexive” structure of consciousness. It is not to be reified into an entity (or refried like a bean, for that matter). If we think of it as an entity, we will find ourselves puzzling over questions about momentary subjects and how all these different subjects relate to each other over time and at a time. This is a confusion in my view. Yes, our normal use of language and the naïve ontology it encodes demand entities and substances to correspond to our nouns! But consciousness is not an entity or substance. It is a process; it is more like a wave than the medium the wave requires. It has a certain structure and a certain dynamical profile. Subjective character is, like temporality, an ever-replicated form that, in my view, is necessary for all consciousness. There is no subject *entity* strictly speaking. When there is an episode of looking back down the tunnel of previous conscious episodes that are connected in the normal way to that very episode of conscious looking, individuated subjective character is always seen. Just in terms of subjective character, all the episodes are qualitatively identical. This helps reinforce the illusion of a stable, continuous subject entity.³ Again, there is no such entity. There is just a common form or structure living in the many different tokens. After Parfit (1984) and the Buddhists, we might say that this at once helps dissolve the thing we

once thought so substantial and important and draws us closer to other tokens, no matter what stream they happen to be in.

Finally, it seems to me that Schlicht (this collection, p. 7) must take “creature-consciousness” to be more fundamental than “state-consciousness” (or “episode-consciousness”), whereas I would adhere to the usual idea that phenomenally conscious creatures are just those that host episodes (or states) of consciousness. I don’t see how reversing this order helps.

4 Conclusion

To recapitulate: (1) I do not see what is gained, either in relation to the individuation problem or the unity and integration problems, by regarding the organism as the phenomenological subject of consciousness. (2) I understand how P-theories attempt to do this by making the organism part of the representational content of every episode of consciousness, but I do not find those theories plausible or helpful, even if we stress the integration aspect of the theories (which does not make them cease to be P-theories). (3) I was less clear on how Schlicht thinks that an integration theory could account for subjective character if it deviates from the Damasio-style theory or from Van Gulick’s HOGS model, which latter I have also always found a little hard to understand, though I am in sympathy with it. (4) I would emphatically deny the existence of Zeki-style micro-consciousnesses; rather, I believe there is (normally) only one stream of consciousness per brain—and that stream can “expand and contract” as more or less gets integrated into it. (5) We do need an account of how unconscious processes get integrated into consciousness and of both diachronic and synchronic unity; but I am not prepared to offer such an account at present. (6) Regardless of how such an account goes, I take reflexivity (self-acquaintance) to be an essential structural feature of all consciousness; and I take it to be a phenomenological datum. All streams of consciousness are immediately aware of themselves, and that is the foundation of all other forms of self-representation, autobiographical cognition, and so on. (7) This reflexivity is subjective

³ See Hofstadter 2007, ch. 7, “The Epi Phenomenon”, for a nice analogy in this connection: the illusion of a marble in the center of a box of envelopes arises just from the stacking of the envelopes (with their repeated structure).

character (for-me-ness), but it is a mistake to turn this structural feature into a kind of entity or homunculus. Thus in saying that the episode is the phenomenological subject, I am offering a non-homuncular account of the subject of consciousness. This ought to reduce a little bit of the weirdness of my claim that the episode is the phenomenological subject. (8) In other senses of “subject”, it is undoubtedly correct to say that the subject of consciousness is the organism, since it is (so far) organisms that have consciousness. However, strictly speaking, consciousness is a sub-process of the organism and lives in one of its organs—the brain. (9) Since we could, in principle, have conscious, functioning brains without the rest of the organism, it seems to follow that the organism is not the phenomenological subject—unless one adopts a P-theory according to which the privileged object we represent is just the organism we happen to be; but see (2) above.

Acknowledgments

I would like to thank Thomas Metzinger and Jennifer Windt and the MIND team, once again, for organizing this volume. Thomas and Jennifer also gave me very valuable feedback on a draft of this reply—thank you both for that! I would also like to thank Tobias Schlicht for writing such a gracious, challenging, and stimulating commentary. I hope he knows that I honestly do not think he is irrationally allergic to reflexivity or that he embraces a fetishistic externalism! Cheers, Tobias!
